METALS HANDBOOK

VOL. 6
WELDING AND BRAZING

8th EDITION

METALS HANDBOOK, eighth edition

- Vol. 1. Properties and Selection of Metals (1961)
- Vol. 2. Heat Treating, Cleaning and Finishing (1964)
- Vol. 3. Machining (1967)
- Vol. 4. Forming (1969)
- Vol. 5. Forging and Casting (1970)
- Vol. 6. Welding and Brazing (1971)
- Vol. 7. Metallography (in preparation)
- Vol. 8. Failure Analysis (in preparation)

Additional volumes are planned.

PRINCIPAL SUBJECTS

Arc Welding Processes and Their Application to Low-Carbon Steel

Arc Welding of:

Electroslag and Electrogas Welding

Resistance Welding

Flash and Friction Welding

Electron Beam Welding

Gas Welding

Brazing

METALS HANDBOOK

8th Edition

VOL. 6

Welding and Brazing

prepared under the direction of the

ASM HANDBOOK COMMITTEE

MANAGING DIRECTOR: ALLAN RAY PUTNAM

MEMBERS OF ASM APPLICATIONS COMMITTEES ON WELDING AND BRAZING*

Applications Committee 1

P. H. BROTZMAN, Chief Metallurgist, Firestone Tire & Rubber Co.; GASPER KOVACS, Manufacturing Engineer, Luxaire, Inc.; GEORGE M. MUCHA, Applications Laboratory Supervisor, Tocco Div., Park-Ohio Industries, Inc.; KENT R. SHISLER, Caterpillar Belgium SA (formerly, Manager of Quality Control, Towmotor Corp.); LOUIS STASUN, Manager of Product Design, Elwell-Parker Electric Co.; D. C. WILLIAMS, Chief Metallurgist, Addressograph-Multigraph Corp.; D. S. ZAMBORSKY, Corporate Metallurgist, Warner & Swasey Co.

Applications Committee 2

JACK E. DALY, Production Engineer, Lorain Products Corp.; STEVE KISH, Manager, Engineering Materials, Weatherhead Co.; W. E. MUMFORD, Corporate Welding Engineer, Manufacturing-Engineering, Motor Wheel Corp.; RICHARD A. PETERSON, Superintendent, McDowell-Wellman Engineering Co.; ARTHUR G. PORTZ, Metallurgy and Joining Engineering, Cleveland Pneumatic Tool Co.

Applications Committee 3

RICHARD R. GRANT, Superintendent of Fabrication, Jaeger Machine Co.; JOHN G. HENRY, Supervisor, Metallurgy Dept., Goodyear Atomic Corp., Goodyear Tire & Rubber Co.; WALTER V. HOBBS, Chief Methods Engineer, Ranco Controls Div., Ranco Inc.; JOHN E. HOUGLAND, Ohio Div., McNally Pittsburgh Manufacturing Corp.; ROBERT KOESTER, Diamond Power Specialty Corp.

VEARL M. LOADER, Metallurgical Engineer, Rupp Industries, Inc. (formerly, Manager of Product Development, Lennox Industries, Inc.); R. F. MACLAINE, Welding Engineer, Power Systems Div., McGraw Edison Co.; W. A. MOLVIE, Chief Engineer, Pipe Fabrication Dept., Dravo Corp.; E. A. PIGAN, Headquarters Manufacturing Laboratory, Westinghouse Research and Development Center, Westinghouse Electric Corp.; W. E. RHODES, Special Products Manager, Acro Div., Robertshaw Controls Co.

Applications Committee 4

ARDEN A. ALBAUGH, Manager, Research and Development Engineering, Trailmobile Div., Pullman Inc.; G. J. BALLMAN, Assistant Superintendent, Process Engineering, Delco Moraine Div., General Motors Corp.; RAYMOND M. BURBEE, Manufacturing Engineer, Steelcraft Manufacturing Co., American-Standard Co.; PAUL CORTLAND, Welding Engineer, Flight Propulsion Div., General Electric Co.; F. E. DONATHAN, Manager, Manufacturing Engineering, Superior Coach Corp.; JOHN M. FAULKNER, Metals Joining Engineer, Aerospace Electric Div., Westinghouse Electric Corp.

JOHN C. KING, Supervisor, Manufacturing Service Engineering, B. F. Goodrich Aerospace and Defense Products, B. F. Goodrich Co.; JAMES H. PEACOCK, Manager, Materials Engineering, Duriron Co., Inc.; RAYMOND RUHE, General Foreman, F. H. Lawson Co.; RONALD TAIT, Airtemp Div., Chrysler Corp.; ROBERT F. WILLIAMS, Chief Engineer – Machine Design, National Automatic Tool Co., Inc.; HARRY WURSTER, Research Metallurgist, Mosler Safe Co.

Applications Committee 5

HARVEY AINSWORTH, Welding Engineer, General Railway Signal Co., General Signal Corp.; RALPH A. ALLENSON, Superintendent, Jamestown Metal Div., AVM Corp.; WILLIAM J. BEULER, Manager of Engineering, Graham Manufacturing Co., Inc.; FRANK J. LAUTA, Supervisor, Metals Laboratory, Gleason Works.

GAIL E. SAUR, Engineering Manager, Welding Consumables Dept., Westinghouse Electric Corp.; JOHN M. SAYBAN, Welding Engineer, Erie City Energy Div., Zurn Industries, Inc.; JAMES E. TWYMAN, Manager of Quality Control and Materials Evaluation, Air Preheater Co., Inc.; S. A. WRIGHT, Chief Metallurgist, Motor Components Div., Bendix Corp.

Applications Committee 6

ROBERT BRUSCATO, Research Metallurgist, Chicago Bridge & Iron Co.; WIRT C. GILLIAM, JR., Supervisor of Materials Engineering, Micro Switch Div., Honeywell Inc.; ROBERT HARRIS, Plant Engineer, DuKane Corp.; ERIC HOLBY, Chief Welding Engineer, Pioneer Service & Engineering Co. (formerly with DK Aerospace Div., MSL Industries, Inc.); GARY J. MORRIS, Senior Metallurgical Technician, Kleinschmidt Div., SCM Corp.

Applications Committee 7

ROBERT D. BAGGULEY, Mechanical Engineer, G&W Electric Specialty Co.; HENRY A. BOTT, Research Engineer, Cenco Instruments Corp.; JOHN D. EYESTONE, Senior Staff Engineer, Hawthorne Works, Western Electric Co., Inc.; E. R. FREEMAN, Senior Metallurgist, Quality Assurance Laboratory, Teledyne-Continental Aviation and Engineering; GEORGE E. KEITH, Technical Services Manager, Westclox Div., General Time Corp.; SUNG CHUL KIM, Senior Product Engineer, ITT Bell & Gossett Div., International Telephone and Telegraph Corp.

EUGENE R. KUCH, Chief Metallurgist, Gardner-Denver Co.; PAT LAMM, Welding Engineer, Barber-Colman Co.; C. D. LOYD, Project Metallurgist, Research Dept., Caterpillar Tractor Co.; DANIEL H. STIEHR, Manager of Engineering, Diebel Manufacturing Co.; CARY D. WHITE, Assistant to the President, Paul Mueller Co.; DAVID WINTER, Mattison Machine Works.

Applications Committee 8

ROBERT BLAIR, Welding Engineer, Industrial Control Div., Square D Co.; MELVIN L. BOTH, Advance Process Engineer – Welding, Components Div., J. I. Case Co.; DAVID E. BROWN, Metallurgist, Manufacturing Research, Cutler-Hammer; EDWARD L. FOSTER, Welding Engineer, Geuder, Paeschke & Frey Co.; F. E. GARRIOTT, Welding Consultant, Ampco Metal Div., Ampco-Pittsburgh Corp.; J. C. HIPP, Technical Specialist, Electronic De-

*In addition to 18 author committees, rosters of which are presented or referred to on the first pages of articles in this volume to which they contributed information, 13 applications committees provided more than 300 examples of welding and brazing practice, which appear in pertinent articles throughout the book. The members of these applications committees on welding and brazing are listed above and on the following page.

vice/Ceramic Engineering, Centralab Electronics Div., Globe-Union Inc.; ROY E. HOLMGREN, Chief Engineer, Anchor Coupling Co. Inc.

RALPH KEIDEL, Manager of Welding Engineering, Koehring Co.; C. J. KING, Assistant Chief Engineer – Development, Perfex Corp.; TED LAIK, Welding Supervisor, Heil Co.; JOSEPH F. POTOCHNIK, Manager of Materials and Processes, Allis-Chalmers Manufacturing Co.; FRED L. SCHULTZ, Welding Engineer, Bucyrus-Erie Co.; AUGUST J. VASHOLZ, Harley-Davidson Motor Co.

Applications Committee 9

J. R. CHAMBERS, Chief Engineer, National Annealing Box Co.; ANTHONY COOPER, Supervisor Manufacturing Engineering, Power Systems, Westinghouse Electric Corp.; S. A. COUGHLIN, Group Leader, Metals Joining, Research & Development Center, Tubular Products Div., Babcock & Wilcox Co.; RALPH H. FLORY, Senior Mechanical Designer, Frick Co.; JOHN FORBES, Manager, Engineering Processes, New Stanton Div., Robertshaw Controls Co.; THOMAS R. FROLO, Chief Inspector, Power Piping Co.

JOHN R. LANDER, Welding Engineer, Pittsburgh Bridge & Iron; ALEX J. MELEG, Manager, Quality Control, Diebold, Inc.; HERBERT W. OTTO, Welding Engineer, National Roll Div., General Steel Industries, Inc.; STUART ST. DENIS, Welding Superintendent, United Engineering and Foundry Co.; ERWIN J. SEEL, Welding Engineer, Mesta Machine Co.; KENNETH L. WALKER, General Fireproofing Co.

Applications Committee 10

JOHN E. AHEARN, Senior Engineer, Reading Plant, Western Electric Co., Inc.; JAMES A. BARD, Metallurgist, Matthey Bishop, Inc.; FRANK BRAUTIGAM, Chief Metallurgist, Equipment Div., Pennsalt Chemicals Corp.; J. D. CAMERON, Senior Materials Engineer, Industrial Div., Honeywell Inc.; ROBERT L. HARRIS, Materials Engineer, Tennessee Valley Authority (formerly, Manager, Welding Engineering Dept., Badenhausen Corp.); FRANK D. HENDRICKSON, Welding Engineers, Inc.; BARRY D. LAWRENCE, Welding Engineer, Sun Shipbuilding & Dry Dock Co. (formerly with Birdsboro Corp.); JOHN LEBER, Schick Electric Inc.

GUY A. LECLAIR, Manager, Welding Laboratory, Mountaintop Plant, Foster Wheeler Corp.; B. L. SHARON, Director of Metallurgy, Avco Lycoming Div., Avco Corp.; DONALD L. THOMPSON, Welding Engineer, York Div., Borg-Warner Corp.; J. G. TOUGH, Manager, Quality Control, Dorr-Oliver Inc.; JAMES WALIZER, General Foreman, Welding Dept., Piper Aircraft Corp.; A. K. WILSON, Chief Metallurgist, Darling Valve & Manufacturing Co.; WALTER H. WOODING, Chief Welding Engineer, Industrial Equipment Div., Baldwin-Lima-Hamilton Corp.

Applications Committee 11

STUART D. BRESNICK, Materials Technology Dept., United Nuclear Corp.; DAVID E. CALKINS, Administrative Assistant, Pall Trinity Micro Corp.; FLOYD C. CHITTY, Manufacturing Engineer, Consolidated Diesel Electric Co.; BAROUYR Z. HAIRABEDIAN, Advanced Manufacturing Engineering, International Business Machines Corp., Kingston, N. Y.; C. W. JORDAN, Manager, Materials Development and Analysis, International Business Machines Corp., Owego, N. Y.

ATSUMU MATSUOKA, Engineering Dept., REF Dynamics Div., UPO Transportation Equipment Group, Universal Oil Products Co.; WALTER E. MOULTON, Chief Metallurgist, Oneida Ltd.; WARREN NELSON, Supervisor, Manufacturing Engineering, ARMA Div., AMBAC Industries; CLARENCE E. PARKER, Metallurgist, Bossert Manufacturing Corp.; RAYMOND WARD, Consultant – Materials, Aerospace Electronics Dept., General Electric Co.

Applications Committee 12

WALTER E. ARING, Manager of Engineering and Manufacture, Champion Spark Plug Co.; F. K. FOWLER, Supervisor, Methods Development Dept., Holley Carburetor Co.; JAMES C. GOULD, Research Metallurgist, Ann Arbor Div., Conductron Corp.; JESSE HEADY, JR., Welding Supervisor, Ex-Cell-O Corp.; J. A. HUDSON, Chief Engineer, Toledo Commutator Co. Div., Walter Kidde & Co., Inc.; OSIE E. JACKSON, Product Engineer, Associated Spring Corp.; JOHN M. OHNO, Metallurgical Products Dept., General Electric Co. (formerly, Head, Materials Technology, Aerospace Systems Div., Bendix Corp.).

ADRIAN R. OLREE, Product Engineer, Steelcase Inc.; NICHOLAS P. SARLE, Staff Metallurgist, Alloy Products Div., Brush Beryllium Co.; M. L. SEVERSON, Professor of Metallurgy, South Australian Institute of Technology (formerly, Chief Materials Engineer, Research and Development Dept., Kelsey-Hayes Co.); W. C. WEBSTER, Section Engineer, Welding Processes and Instrumentation, Manufacturing Development, General Motors Corp.; HERBERT H. WILHELM, Supervisor, Materials Laboratory, ARO Corp.

Applications Committee 13

FRED BLANKENHORN, Senior Metallurgist, Research and Development Dept., South Wind Div., Stewart-Warner Corp.; JON CHANDONIA, Metallurgist, Penn Products Div., Penn Controls, Inc.; JULIUS G. CHISZAR, Foreman, Roach Appleton Manufacturing Co. Div., All-Steel Equipment Inc.; P. J. DILLON, Director, National Technological Center, Simmons Co.; CHESTER DUNN, Department Head, Union City Body Co., Inc.; LLOYD W. EBERT, Welding Engineer, Tillage Div., White Farm Equipment Co.; ALVIN H. JACOBS, Manager, Welding Services, Buehler Corp.; J. G. MCARDLE, Senior Welding Engineer, Graver Tank & Mfg. Co. Div., Envirogenics.

R. E. METCALF, Supervisor, Materials Engineering, Chrysler Corp.; CHARLES M. MILLER, Director of Engineering, Adams & Westlake Co., Allied Products Corp.; R. H. POTTER, Chief Engineer, Tool and Manufacturing Dept., Auto Specialties Manufacturing Co.; W. E. THRELKELD, Metallurgist, American Bearing Corp.; S. C. WARREN, Vice President of Development Engineering, George Koch Sons, Inc.

FOREWORD

THE PUBLICATION of Volume 6, "Welding and Brazing", marks the crossing of the midpoint in the preparation of the ten-volume 8th Edition of METALS HANDBOOK, and the completion of the five volumes devoted to metalworking processes.

One of the continuing aims of industry is to increase the index of productivity from year to year. Volume 6, together with its companion volumes on other metalworking processes, can serve as a dependable guide to the adaptation of the most efficient and productive methods of fabricating metals. These books provide industry with reliable information on modern techniques for converting metals economically into useful products, and they can thus be helpful toward contributing to improvements in the index of productivity.

Volume 6 required the dedicated efforts of authors and author committees comprising more than 400 experts with broad experience and specialized knowledge in the fields of welding and brazing, and in the application of these joining processes to all commonly used metals and alloys. These experts were selected for this task by the Handbook Committee — a group of engineers and industrial managers who guide the planning of technical content and monitor the over-all editorial policy. The diligent and competent editorial staff coordinated and edited the information supplied by the authors into the well-organized and readily usable form in which it is presented in this book. To all these people — and to the many other contributors from industrial, academic, research and government organizations — the members of ASM, and all other users of this valuable reference book, owe sincere gratitude and appreciation.

The American Society for Metals takes pride in making available to the metalworking community Volume 6 of the 8th Edition of METALS HANDBOOK, and is confident that the information presented in these pages will be of great benefit to those concerned with modern technology and its application.

THOMAS E. LEONTIS
President – American Society for Metals

ALLAN RAY PUTNAM
Managing Director

PREFACE

THIS IS THE SIXTH in a series of volumes that will supersede the single-volume 7th edition of METALS HANDBOOK and greatly enlarge its scope. In preparing this new volume, the aim of the ASM Handbook Committee and the authors has been to provide the reader with practical information that will help him select and control welding and brazing processes and that will clarify many of the relations between product design and the control of welding and brazing processes.

The welding and brazing processes and the base metals discussed here are those most frequently used in the metalworking industry. Slightly more than half the book deals with arc welding; approximately two-thirds of the examples of practice that appear throughout the book are concerned with steel as the metal being welded or brazed.

The table below compares in detail the subject coverage in this sixth volume of the 8th edition with the coverage of corresponding subject matter in the 7th edition.

The principal new contribution made in this volume is the multiplicity of examples that describe welding and brazing practices. Numbered consecutively from 1 through 661 from the front to the back of the book, these examples deal with the methods and procedures used, and with improvements made or problems solved, in specific applications; and they emphasize the results obtained in joining a great variety of assemblies and structures. Many cross references are given in the text, and in tables at the ends of some articles, to direct the reader to related examples presented elsewhere in the book. To make it easy to find any of the 661 examples, the span of example numbers presented on each pair of facing pages is indicated at the tops of those pages, near the inside margins.

As it was for the first five volumes of this 8th edition, principal reliance for authorship has again been placed on committees of engineers and production managers from industry, in order to arrive at a balanced presentation of divergent viewpoints and to achieve realism in relation to practice. Of the 31 committees participating in this volume, 18 contributed on specific assigned subjects. Rosters of the members of these 18 author committees are presented or referred to on the first pages of the articles to which they contributed. The remaining 13 committees were concerned with welding and brazing applications without restriction as to proc-

Coverage of Welding and Brazing in Volume 6 of the 8th Edition Compared With That in the 7th Edition

Section (page reference, 8th edition)	Illustrations 8th ed	Illustrations 7th ed	Tables 8th ed	Tables 7th ed	Examples 8th ed	Examples 7th ed	Contributors 8th ed	Contributors 7th ed	Pages 8th ed	Pages 7th ed
Welding										
Arc welding processes and their application to low-carbon steel (1 to 186)	1058	3	239	2	180	0	162	7	186	13
Arc welding of metals other than low-carbon steel (187 to 382)	1019	4	305	8	180	0	184	16	196	12
Electroslag and electrogas welding (383 to 400)	74	0	9	0	9	0	5	0	18	0
Resistance welding (401 to 484)	335	12	89	2	60	0	94	3	84	3
Flash and friction welding (485 to 518)	177	0	40	0	34	0	22	0	34	0
Electron beam welding (519 to 564)	261	0	59	0	42	0	21	0	46	0
Gas welding (565 to 592)	147	4	34	3	38	0	41	3	28	4
Total for welding	3071	23	775	15	543	0	529	29	592	32
Brazing										
Brazing processes and their application to carbon and low-alloy steels (593 to 660)	373	2	40	3	68	0	26	3	68	4
Brazing of metals other than carbon and low-alloy steels (660 to 702)	197	0	44	3	50	0	58	4	42	3
Total for brazing	570	2	84	6	118	0	84	7	110	7
Total for welding and brazing	3641	25	859	21	661	0	613	36	702	39

Each member of an applications committee (see pages v and vi) is included in all sections to which he contributed. Members of author committees that contributed to more than one section are included in each. Eliminating duplications from these sources reduces the total number of contributors from 613 to approximately 400.

Distribution of Subject Matter on Metalworking Processes in Volumes 2 Through 6 of the 8th Edition

Metalworking process	Illustrations No.	Illustrations %	Tables No.	Tables %	Examples No.	Examples %	Contributors No.	Contributors %	Pages No.	Pages %
Welding (Volume 6)	3,071	22.8	775	20.3	543	15.4	529	23.6	592	21.0

Total	13,477	100.0	3812	100.0	3522	100.0	2240	100.0	2826	100.0

ess or metal; they contributed a total of more than 300 examples of practice, which are distributed in the pertinent articles throughout the book. Rosters of the members of these 13 applications committees appear on pages v and vi in this volume.

Simon A. Greenberg, welding consultant, San Francisco, was retained as a manuscript reviewer and technical editor for this volume. He reviewed the manuscripts and proofs of the entire book, and has been responsible for many improvements in technical content, editorial presentation, and general clarity. Because of the importance of his contribution to this volume, Mr. Greenberg is listed on the title page as engineering editor.

Other individuals, not named on the title page, made significant contributions in reviewing manuscripts and galley proofs: Jay Bland, M. L. Both, E. B. LaVelle and N. H. Mason each reviewed approximately half the book; from five to ten articles each were reviewed by D. E. Brown, J. D. Eyestone, R. L. Harris, A. N. Kugler, B. D. Lawrence and J. G. McArdle; D. C. Dilley reviewed the nine articles on brazing, in manuscript and proof; others, too numerous to list, have participated in the review of several articles each. We are grateful to all the reviewers; their work has increased the accuracy and clarity of the volume, and has provided greater unity and consistency among disparate contributions than would have been possible under a review procedure in which each article was read only by the author committee that was responsible for its preparation. In addition to their other contributions, the reviewers have helped to bring the technical terminology in this book into closer agreement with AWS A3.0-69 (Terms and Definitions, American Welding Society, 1969).

PUBLICATION of this book completes the five volumes of the 8th edition that are concerned with metalworking processes. In the order presented, these processes are: heat treating, cleaning, finishing, machining, forming, forging, casting, welding and brazing. A decade has been required for compiling and publishing these volumes. The table above summarizes numerically the results of this work, listing the processes by decreasing number of pages the subjects occupy in the five volumes. Preparation of the 2826 pages involved the participation of more than two thousand contributors. Upon the collective experience and high competence of these contributors rest the accuracy and authority of the information in those pages.

Shielded Metal-Arc Welding

*By the ASM Committee on Shielded Metal-Arc Welding of Steel**

SHIELDED METAL-ARC WELDING is a manual arc welding process in which the heat for welding is generated by an arc established between a flux-covered consumable electrode and the work. The electrode tip, weld puddle, arc, and adjacent areas of the workpiece are protected from atmospheric contamination by a gaseous shield obtained from combustion and decomposition of the flux covering. Additional shielding is provided for the molten metal in the weld puddle by a covering of molten flux (slag). Filler metal is supplied by the core of the consumable electrode and, with certain electrodes, from metal powder mixed with the electrode covering. Shielded metal-arc welding is often referred to as arc welding with stick electrodes, and as manual arc welding.

Process Capabilities

Shielded metal-arc welding is the most widely used welding process for joining metal parts, mainly because of its versatility. Also, equipment is less complex, more portable and less costly than for other arc welding processes.

Versatility. Shielded metal-arc welding can be done indoors or outdoors. Joints in virtually any position that can be reached with an electrode (for example, joints directly overhead and vertical joints) can be welded. By the use of bent electrodes, even joints in blind areas can be welded — for example, the back sides of pipes in restricted areas, which are inaccessible locations for most welding processes.

Joints in almost any location can be welded, because the power-supply leads can be extended for relatively long distances and no hoses are required for shielding gas or water cooling. Some locations where shielded metal-arc welding has been used in the field are storage tanks, ship structures, and bridges. Machinery or other equipment in manufacturing plants and in remote areas such as oil fields can be repaired by use of the process, because the welding equipment is light and portable.

Shielded metal-arc welding is generally more useful than other welding processes for joining the components of complex structural assemblies, because it is better adapted to multiposition welding and difficult locations. In the assembly of pipe and coupling connections, joints that have been prepared for automatic or semiautomatic equipment may not fit when the assembly is fitted to a machine. When this occurs, it is a simple and quick procedure to gas cut the assembly apart, adjust it in place to fit properly, tack weld it, and then weld the complete assembly by the shielded metal-arc process. For this type of work, other welding processes may require more extensive dismantling of the structure.

Welded joints can be cut apart on location and rebuilt with added structural members — a practice that is often necessary, particularly in operations such as well drilling, quarrying and mining.

Joint Quality and Strength. The quality and strength of shielded metal-arc welded joints can be controlled as easily as the quality and strength of joints welded by other manual methods that employ consumable electrodes. Shielded metal-arc welding electrode materials are available for matching the properties of most base metals. Thus, the properties of a joint can match those of the metals joined.

Metals welded most easily by the shielded metal-arc process are carbon and low-alloy steels, stainless steels and heat-resisting alloys.

Cast iron, and the high-strength and hardenable types of steel, can also be

Some of the examples presented in this article were contributed by members of other Metals Handbook welding committees. A total of 70 examples of shielded metal-arc welding appear in other articles in this volume, as recorded in Table 16, on page 23.

Table 1. Output Ratings of Power Supplies Used in Shielded Metal-Arc Welding

Output current, amp, at load, volts — Rated (60% duty cycle)(a)	Maximum (35% duty cycle)(b)
Constant-Current Motor-Generators (DC)	
300 at 32	375 at 35
400 at 36	500 at 40
500 at 40	625 at 44
600 at 44	750 at 44
Transformer-Rectifiers (DC)	
400 at 36	500 at 40
500 at 40	625 at 44
600 at 44	750 at 44
800 at 44	1000 at 44
Transformers (AC)	
400 at 36	500 at 40
500 at 40	625 at 44
600 at 44	750 at 44
(One-hour duty rating)(c)	(35% duty cycle)(b)
750 at 44	925 at 44
1000 at 44	1250 at 44
1500 at 44	1875 at 44

(a) Rated current can be delivered continuously for 6 min out of every 10 min. (b) Maximum current can be delivered continuously for 3½ min out of every 10 min. (c) Rated current can be delivered continuously for 1 hr, then for 45 min of every hour for the next 3 hr.

shielded metal-arc welded, but procedures that include preheating or postheating, or both, may be needed. Electrode selection and care are more critical for welding hardenable steels.

Copper alloys and nickel alloys are often welded by the shielded metal-arc process, although gas metal-arc welding and gas tungsten-arc welding are usually preferred and are more widely used for joining these metals.

The softer metals such as zinc, lead and tin, which have low melting and boiling temperatures, are not amenable to shielded metal-arc welding.

The use of shielded metal-arc welding for joining of metals other than low-carbon steel is discussed elsewhere in this volume, in articles that deal with the welding of specific metals.

Limitations of shielded metal-arc welding compared with other arc welding processes, such as gas metal-arc and submerged-arc welding, are related mainly to metal-deposition rate and deposition efficiency. Electrodes used in shielded metal-arc welding have fixed lengths (usually 18 in. or less), and therefore welding must be stopped after each electrode is consumed. With the arc welding processes that use continuously fed electrode wires or no filler metal, welding can be done much longer without interruption.

Another limitation of shielded metal-arc welding is that deslagging is required after each pass, to remove the slag covering that forms on the weld. In gas metal-arc welding, multiple passes can be made without stopping for slag removal, since no flux is used.

Principles of Operation

An adequate power supply is the first requirement for shielded metal-arc welding. To prepare for welding, suitable cables are used to attach one terminal of the power supply to the electrode holder, and the other terminal to a ground clamp, as shown in Fig. 1.

To start welding, an arc is "struck" by touching the workpiece with the tip of the electrode — much like striking a match. The welder guides the electrode by hand in welding a joint, and controls its direction and travel speed. The welder maintains arc voltage by controlling arc length — the distance between the end of the electrode and the work surface. In many applications in which electrodes with heavy coverings are used, the welder actually drags the electrode in the joint or on the work and uses the electrode angle to control arc length. Electrodes are discarded at a length of about 2 in.

Electrically, the process is simple in concept; a power supply with a drooping volt-ampere characteristic is required. With it the current decreases as the arc becomes longer, and increases as the arc becomes shorter.

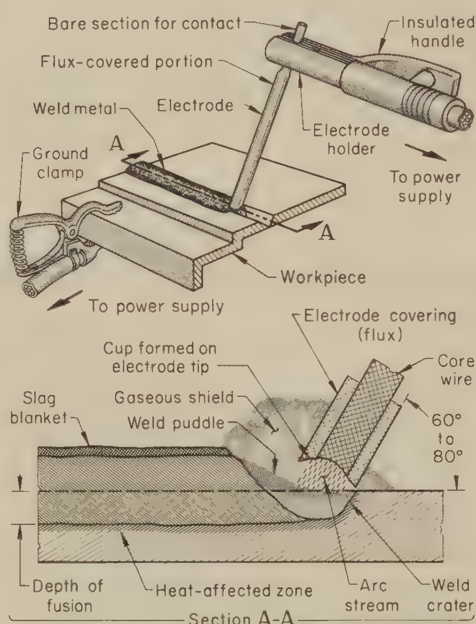

Fig. 1. Typical setup and fundamentals of operation for shielded metal-arc welding

Table 2. Space Requirements, Output Ranges, and Costs of AC and DC Power Supplies for Shielded Metal-Arc Welding

Typical floor space required, in.	Typical output range, amp	Typical cost
Light-Duty Transformers (AC)		
14 by 14	30 to 180	$ 125
	35 to 295	230
Heavy-Duty Transformers (AC)		
22 by 29	50 to 375	$ 280
	50 to 625	320
28 by 45	100 to 1300	2139
Light-Duty Motor-Generators (DC)		
18 by 26	40 to 260	$ 439
Heavy-Duty Motor-Generators (DC)		
19 by 36	30 to 450	$ 685
19 by 39	40 to 600	815
19 by 42	50 to 800	1029
Transformer-Rectifiers (DC)		
21 by 39	25 to 425	$ 567
24 by 44	25 to 525	630
Heavy-Duty Transformer-Rectifiers (DC)		
22 by 39	40 to 375	$ 505
	50 to 625	635
Gasoline-Engine Generators (DC)		
31 by 75 (52 hp)	30 to 450	$1640
(69 hp)	30 to 600	1730
(85 hp)	40 to 800	1995

However, the basically simple concept is complicated by the effect of transfer of metal across the arc, which can short-circuit the power supply. As a result, the dynamic characteristics of the power supply are all-important; the reactance of the circuit that controls the speed of current response to short circuits affects the drop size and stability of the arc.

Electrode Coverings. The chemical and metallurgical properties of a weld depend mostly on the type of electrode to be used and its type of covering.

Oxygen and nitrogen in the atmosphere can cause excessive porosity and poor ductility in the welded joint if they are not excluded from the weld puddle. In shielded metal-arc welding, combustion and decomposition of the electrode covering from the heat of the welding arc produce a gaseous shield that excludes the atmosphere from the weld area. The molten metal is further protected by materials in the electrode covering that form a molten slag, which acts like a protective blanket until the metal has solidified (Fig. 1). Most electrode coverings also contain deoxidizers and nitrogen absorbers.

The electrode covering also provides materials such as sodium and potassium that are readily ionized when heated by the arc. These help to keep the gap between the end of the electrode and the workpiece conductive and to stabilize the arc.

The electrode covering also may be used to introduce alloying additions into the weld. Most electrodes used for welding low-carbon steel have a plain carbon steel core, but alloying elements are sometimes added from the covering. Some coverings contain iron powder, which increases metal-deposition rates.

The electrode covering provides a cuplike shape at the end of the electrode (see section A-A in Fig. 1). This cup acts like a nozzle, increasing thermal efficiency and providing arc-stream direction, which helps the welder to direct the transfer of metal from the electrode into the weld puddle.

The usability characteristics of an electrode, such as speed of deposition, variety of possible welding positions, shapes of weld beads, ease of slag removal, and properties of the weld, are controlled by the design and chemical formulation of the electrode covering.

Welding Positions. The usual welding positions are flat, horizontal, vertical and overhead, as shown for groove and fillet welds in Fig. 2. In some welding, the positions of the hours on a clock are used as reference locations.

The flat position is the easiest for welding. In this position, welding benefits from the force of gravity, and maximum deposition rates are obtained. Next in ease of welding is the horizontal fillet position, in which the force of gravity helps to some extent. For welding in these positions, the joint should be level, or nearly so, when possible (see also "Positioning", page 11).

Welding in positions other than flat (frequently referred to as out-of-position welding) requires the use of manipulative techniques and electrodes that result in faster freezing of the molten metal and slag, to counteract the effect of gravity.

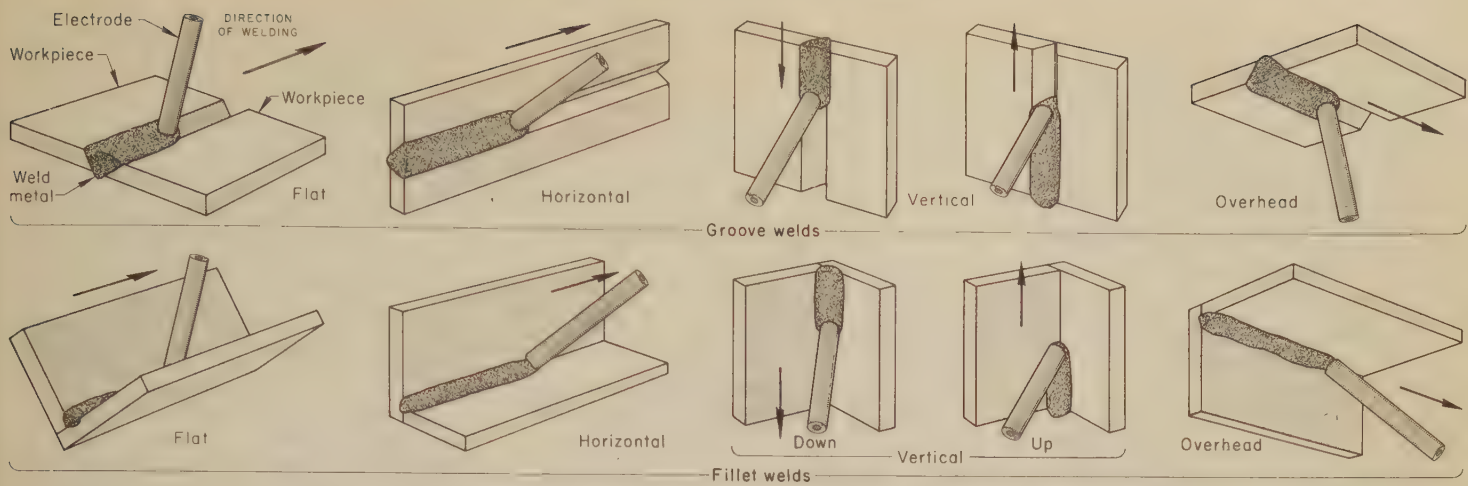

Fig. 2. Usual welding positions, for making groove welds (top row) *and fillet welds* (bottom row)

Power Supplies

Many types and sizes of power supply are used for shielded metal-arc welding. When alternating current is used, high-voltage power is transformed or stepped down through a welding-type transformer to a voltage low enough for safe use. When direct current is used, a generator or a transformer-rectifier unit is used. A transformer-rectifier consists of a step-down-voltage transformer with means to rectify alternating current to direct current.

Either alternating current or direct current can produce acceptable results in welding low-carbon steel. Although each has distinct advantages, the choice usually depends on availability of equipment and the type of electrode to be used. The sections on Direct Current, on page 5, and Alternating Current, on pages 5 and 6, deal with the characteristics, advantages and disadvantages of these currents.

Combination ac/dc power supplies are widely used and are versatile for general-purpose applications. They consist of a transformer and a rectifier in combination and are capable of supplying either alternating current or direct current. When direct current is used, either straight or reverse polarity is available. Output ratings for various power supplies are given in Table 1.

Constant-Current Output. In general, power supplies with constant-current output and a means of controlling current output are required for shielded metal-arc welding. Constant-current output is obtained with a drooping volt-ampere characteristic; that is, voltage within a specified range is reduced as current increases. Figure 3 shows a typical curve for voltage versus current output. Constant-current output is preferred because small variations in voltage caused by variations in arc length do not significantly affect the current output and deposition rate. For instance, the dashed lines in Fig. 3 show that a 3-volt drop in voltage results in only about a 10-amp increase in current output.

Selection Factors. Factors that influence the selection of power supply include available power, available floor space, initial costs, location of the operation (in a plant or in the field), personnel available for maintenance, versatility, required output, duty cycle, efficiency and type of electrodes to be used. Table 2 gives typical space requirements, outputs and initial costs for power supplies. Efficiency of power supplies in terms of power costs and melting and deposition rates is discussed on page 4.

The deposition rate desired determines, to a great extent, the output required from a power supply. The deposition rate obtained, however, is related to the duty cycle, capacity and efficiency of a power supply. (See "Efficiency of Power Supplies", page 4.)

The duty cycle of a power supply is the percentage of time, calculated on several successive 10-min periods, during which it can operate at full capacity without exceeding recommended maximum operating temperature. If a power supply is operated at its rated capacity but beyond its rated duty cycle, overheating will occur, possibly resulting either in no welding at all or, if the power supply is of the rectifier type, in burning-out of the plates. Overheating will occur also if a power supply is operated beyond its capacity, unless the duty cycle is reduced. However, short periods of overloading are not usually harmful to constant-current power supplies; for example, a duty cycle of 76% can be permitted for short periods on a power supply rated at 60%. Table 1 gives dc and ac output ratings for duty cycles of 60% and 35%, and ac output ratings for 1-hr duty.

Transformers for shielded metal-arc welding with alternating current generally have constant-current (drooping) volt-ampere characteristics (Fig. 3). Although heavy-duty transformers

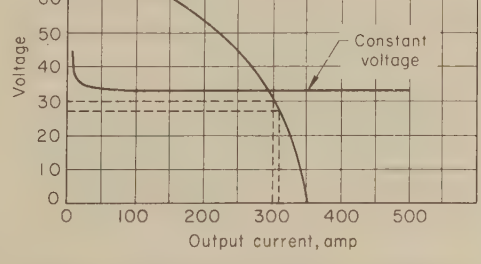

Fig. 3. Volt-ampere curves for constant-current and constant-voltage power supplies

Table 3. Effect of Duty Cycle and Power Factor on Power Cost for a 300-Amp Transformer (a)

Duty cycle(b)	Power cost, $, at a power factor of: 60%	70%	80%	90%
20%	$2.33	$1.40	$1.40	$1.40
40%	4.66	2.80	2.80	2.80
60%	7.00	5.65	4.20	4.20
80%	9.32	7.56	6.20	5.60

(a) Costs are monthly demand charges calculated at 50¢ per kva for a 300-amp transformer that is operating at rated load. (b) Percentage of time transformer is in operation.

with outputs up to 1500 amp are available, transformers with ratings of 200 to 500 amp are most often used in industrial welding applications. Transformers with ratings of less than 200 amp are used extensively in farm and job-shop applications, because they can be operated with 220-volt power and usually have sufficient capacity.

Transformers have lower initial costs than direct-current power supplies (Table 2). Also, they are more economical in terms of cost of power (see "Efficiency of Power Supplies", on page 4), and arc blow is minimized (see "Arc Blow", on page 10).

Poor power factor is inherent in the use of transformers of the constant-current type. Welding characteristics are not affected by a poor power factor, but power cost is increased (as shown in Table 3). For this reason, correcting capacitors can be used to reduce operating costs.

Some plants have, in addition to transformers, electric motors such as large synchronous motors that operate air compressors and other equipment. These motors have a favorable influence on power factor and therefore help to keep the plant power factor within acceptable limits. Under these conditions, welding transformers without power-factor correction are satisfactory. However, in plants where a major portion of the total consumption of electricity is by welding transformers, or where the reserve capacity is inadequate, transformers with power-factor correction should be chosen.

Table 3 shows the effect of power factor and duty cycle on power cost for a 300-amp transformer. The costs are calculated at a utility rate of 50¢ per kva of demand per month, but actual costs vary according to local rates. As shown in Table 3, power cost

is generally proportional to duty cycle and, especially at high duty cycle, decreases as the power factor increases.

Motor-generators and transformer-rectifiers are power supplies for welding with direct current. Most of these dc machines have constant-current (drooping) volt-ampere characteristics. A constant-voltage power supply—that is, one that has nearly constant voltage output with increasing current output (see Fig. 3)—is not well suited to shielded metal-arc welding, because the volt-ampere curve does not have sufficient droop to compensate for variations in arc voltage.

The motor-generators most widely used in industry for shielded metal-arc welding have outputs of 200 to 600 amp. However, units having much larger capacities are available.

Engine-driven generators can be used in the shop or field where no line power supply is available.

Maintenance costs for motor-generators are higher than for transformer-rectifiers. All motor-generators have some moving parts that require periodic repair or replacement. Engine-driven generators have more moving parts and high initial cost (Table 2).

Other factors being equal, direct-current power supplies that have outputs with the same percentages of ripple (superimposed alternating current) will have the same performance. A relatively pure direct-current output is desirable, but all direct current except that from a battery has some ripple. The current from a motor-generator has a ripple content of up to 6%, which is created as the brushes collect the current from the commutator. Transformer-rectifiers also produce current containing alternating-current ripple. With conventional three-phase transformer-rectifiers, ripple content of 20 to 30% has been observed, although it is more often nearer 6%.

A transformer-rectifier does not produce a uniform direct current and can give ammeter readings different from those obtained with a motor-generator of the same rated capacity. When high-amperage current is used, a transformer-rectifier may require adjustments so as to give melting or deposition rates equal to those obtained with motor-generators. Melting and deposition rates obtained by the use of motor-generators and transformer-rectifiers are compared in the next section, "Efficiency of Power Supplies".

Most motor-generators and transformer-rectifiers have switches that permit current to be supplied with either straight polarity (electrode negative) or reverse polarity (electrode positive), without the need for disconnecting and reconnecting cables. This facility is advantageous in applications that involve a wide range of work metals and electrode types. (See the section on Direct Current, page 5.)

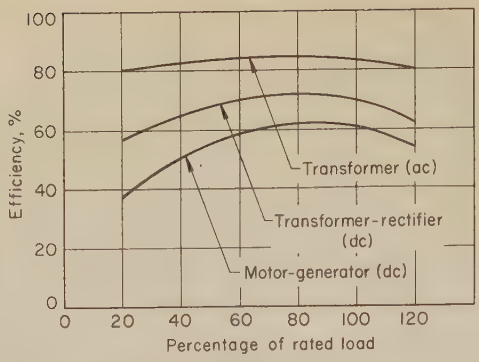

Fig. 4. Effect of operating load (as a percentage of rated load) on efficiency of three types of power supplies

Efficiency of Power Supplies

Efficiencies of power supplies can be compared in terms of (*a*) cost of power for current output, (*b*) melting rate, and (*c*) deposition rate.

Cost of electric power is significant in welding, but usually is a relatively small fraction of the total direct cost.

A motor-generator is the least efficient power supply in terms of cost of power for current output, because a large mass is continually rotated, even when welding power is not being used. Transformer-rectifiers and transformers operate at higher efficiencies, because they have no moving parts except cooling fans, and their no-load power loss is negligible. Their higher efficiency is especially significant when duty cycles are low. Even at high duty cycles, however, the efficiency of motor-generators does not match that of transformer-rectifiers or transformers.

Table 4. Power Costs for Three Types of Power Supply Operated at 300-Amp Output for Various Duty Cycles(a)

Power supply	Power cost for duty cycle of: 20%	40%	60%	80%
Motor-generator(b)	$0.80	$1.25	$1.71	$2.19
Transformer-rectifier	0.47	0.87	1.28	1.70
Transformer	0.38	0.71	1.05	1.37

(a) Power cost per unit, calculated at 1½¢ per kwhr for a 9-hr shift. (b) Electrically driven.

Efficiencies are always measured at rated load with arc or resistance loads and therefore represent actual operating conditions. Figure 4 compares efficiencies of a transformer, a transformer-rectifier, and a motor-generator, operating at 20 to 120% of rated load. The curves show that the motor-generator is least efficient, the transformer-rectifier is next, and the transformer is most efficient. Similar conclusions can be drawn from Table 4, which compares power costs for a motor-generator, a transformer-rectifier, and a transformer, each operated at 300-amp output for various duty cycles over a 9-hr shift.

Although direct-current power supplies are less efficient, in terms of power cost, than alternating-current supplies, direct current is usually the better choice when power is needed for many different base metals and electrodes (see the sections on Direct Current, page 5, and Alternating Current, pages 5 and 6).

Melting rate, or burnoff rate, is the rate at which an electrode of a specific type and size is melted by a specific welding current. It is usually expressed in inches per minute. Figure 5(a) compares melting rates for five different sizes of E6012 electrodes at five levels of current supplied by a transformer, a transformer-rectifier, and a motor-generator. Average melting rate with the motor generator was 7.7% higher than that with the transformer-rectifier, and 12.4% higher than that with the transformer.

For a given power supply, the melting rate of an electrode increases as current is increased. Figure 6 shows the effect of current supplied by a transformer and by a transformer-rectifier on the melting rate of five sizes of E6012 electrodes. The melting rate increases rapidly as the current is increased, especially for smaller-diameter electrodes. When welding current is too high, however, electrode deposition efficiency decreases rapidly because of arc blow, weld spatter and excessive heating of the electrode.

Deposition rate, expressed in pounds per hour or minute, is a direct measure of the amount of weld metal produced under a given set of conditions. Deposition rates for five sizes of E6012 electrodes used with a transformer, a transformer-rectifier, and a motor-generator are given in Fig. 5(b). Here, the deposition rates for the three power sources are essentially in the same order as the melting rates in Fig. 5(a), with the deposition rate for the motor-generator being highest. Calculations from the data in Fig. 5 show average deposition rate with the motor-generator to be 8.8% greater than with the transformer-rectifier, and 15.1% greater than with the transformer.

Deposition rate of an electrode is always less than melting rate because of losses by spatter and fume. The ratio of deposited weight to melted weight times 100 is the electrode efficiency.

Arc blow sometimes offsets the efficient operation of motor-generators at high welding currents. To overcome arc blow, the current must sometimes be decreased, as discussed in the section on Arc Blow (see page 10).

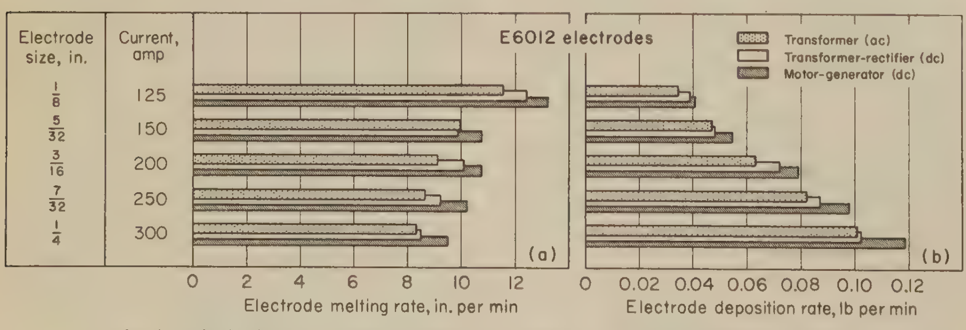

Fig. 5. Effect of type of power supply on melting rate and deposition rate of various sizes of E6012 electrodes at five levels of welding current

Variations in performance among different power supplies of the same general type must be considered when efficiencies are evaluated. For example, performance tests have shown that deposition rates at given currents for transformer-rectifiers from five different manufacturers varied 11% and that melting rates for the same equipment varied 9%.

Variations in electrode melting and deposition rates among different types of power supplies are a result of differences in electrical characteristics and types of electrodes.

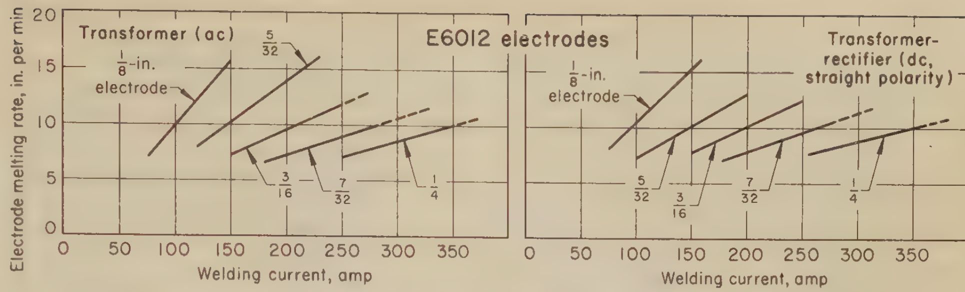

Fig. 6. Effect of level of welding current and type of power supply on melting rate of five sizes of E6012 electrodes

Direct Current

Direct current flows continuously in one direction through the welding circuit. Whether the current is uniform or fluctuating will not affect its direction, for any given welding setup. Because the current flow is continuous, the welding arc is relatively steady and smooth. The principal characteristics of direct current, and some important aspects of its use in shielded metal-arc welding, are discussed in the paragraphs that follow.

Voltage Drop in Cables. Welding cables should be as short as possible. Cable length is more critical for direct current than for alternating current. The voltage drop in long cables, added to that at the arc, can either overload the power supply, or prevent it from producing enough voltage for a proper welding arc.

Low Currents. Direct current surpasses alternating current for use at low amperages with small-diameter electrodes.

Electrodes. All classes of covered electrodes are satisfactory for use with direct current.

Arc starting is generally easier with direct current than with alternating current, particularly with small-diameter electrodes.

Maintaining a short arc, when the arc must be crowded into the molten puddle, is easier with direct current than with alternating current.

Arc Blow. Direct current is highly susceptible to arc blow, particularly when welding is being done near the ends of joints, in corners, or on small, complex structures composed of a number of pieces. Welding on massive structures with high currents, or where fit-up is poor, also encourages arc blow. Arc blow causes excessive weld spatter (see the section on Arc Blow, page 10).

Welding Positions. Direct current is somewhat easier to use for out-of-position welding on thicker sections than alternating current, because lower currents can be used. Experienced welders usually can produce the same results with both types of current.

Welding of Sheet Metal. Because of the steady, easily started arc, direct current is preferable to alternating current for welding of sheet metal.

Polarity (direction of current flow) is important when direct current is used for welding. Most dc power supplies have switching arrangements for reversing the polarity of the welding current whenever required. Current flow for straight polarity (electrode negative) and reverse polarity (electrode positive) is illustrated in Fig. 7.

Type of electrode, metal being welded, and required penetration are important factors in the choice of polarity. Some electrodes are specially made for deep penetration and work best with reverse polarity. Other electrodes are designed for shallower penetration and work better with straight polarity. (See the section on Electrodes, page 6.)

Straight polarity can be used for shielded metal-arc welding of all steels (except when using low-hydrogen electrodes), but not for most nonferrous metals. Melting and deposition rates are higher than with reverse polarity, and penetration is shallower and narrower (see Fig. 8). The contractional stresses are less severe, and restraint cracking is less likely. Also, because more of the heat is concentrated on the electrode, welding is more rapid with straight polarity and the workpiece is less susceptible to distortion. In addition, higher welding speed is usually possible with straight polarity.

Straight polarity is preferred for welding sheet metal, because the shallow penetration minimizes melt-through in thin sections. It is also preferred over reverse polarity for welding joints with excessively wide gaps or root openings, and for buildup.

Reverse polarity produces maximum penetration for a given set of welding conditions. Although the welding current is the main determinant of the extent of penetration, electrodes operating on reverse polarity provide deeper penetration than those operating on either straight polarity or alternating current (Fig. 8). This characteristic makes reverse polarity the better choice for root passes in groove welds made with the use of backing bars or strips, and for out-of-position welding.

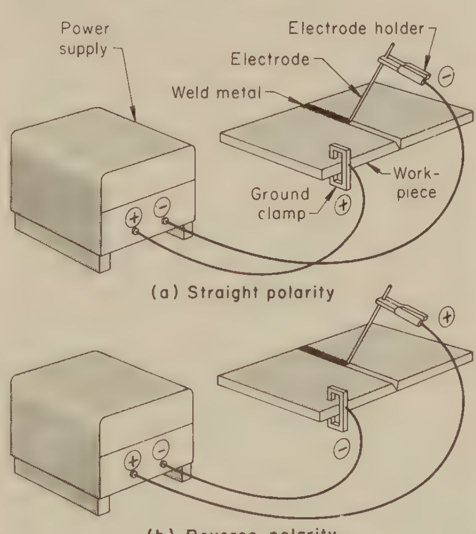

Fig. 7. Current flow for straight polarity (electrode negative) and reverse polarity (electrode positive)

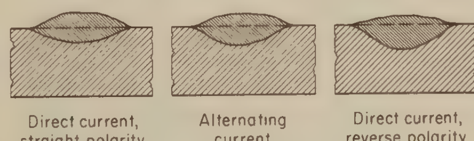

Fig. 8. Typical relative depths of penetration for different current characteristics

Alternating Current

Alternating current combines both reverse and straight polarity alternately in regular cycles. In each cycle, the current starts at zero, builds up to its maximum value in one direction, decays to zero, builds up to its maximum value in the opposite direction and decays to zero again. Cycles are repeated continuously while the welding arc is maintained. For the 60-cycle alternating current normally used in the United States, the direction of flow, and hence the polarity, changes 120 times each second. These changes produce a very rapidly pulsating arc that is somewhat harsh and less stable, compared with a direct-current arc.

Deposition rates and depth of penetration obtained with alternating current are intermediate between those obtained with reverse-polarity and straight-polarity direct current, when welding at the same current rating (see comparison of depths of penetration in Fig. 8). All electrodes that operate well on alternating current will operate on direct current with either reverse or straight polarity, although one polarity is usually recommended or preferred.

Some specific characteristics of alternating current, and aspects of its use in shielded metal-arc welding, are discussed in the paragraphs that follow.

Voltage Drop in Cables. Alternating current is preferred to direct current for welding that must be done at considerable distances from the power supply, because voltage drop is less than for direct current in long cables. Long cables should not, however, be coiled excessively, either on the floor or over hooks, because the inductance set up by the coils will reduce the output of the power supply, and may overload the transformer. Cables should never be longer than required for the job.

Low Currents. Alternating current is less suited than direct current for use at low amperages with small-diameter electrodes.

Electrodes. Only ac/dc electrodes with coverings specifically formulated for use with alternating current should be used. Because of the reversing nature of the current, coverings must contain arc stabilizers to re-establish the arc immediately after the current decays to zero during each cycle.

Arc starting with small-diameter electrodes is more difficult with alternating current than with direct current. When the arc is struck by the use of low current, electrodes may stick or freeze unless designed specifically for alternating-current welding with low open-circuit voltages.

Maintaining a short arc (arc crowding) is more difficult with alternating current than with direct current except when iron-powder electrodes are used.

Arc blow is rarely a problem with alternating current. The reversing nature of the

current causes the magnetic field in the work to build up and decay alternately in opposite directions, and thus neutralizes the magnetic field. (See the section on Arc Blow, on page 10.)

Weld Spatter. Somewhat more weld spatter is produced than with direct current, partly because of the pulsating nature of alternating current.

Welding Positions. With the use of suitable electrodes, satisfactory welds can be made in all positions.

Welding of Sheet Metal. Alternating current, because of the difficulty in arc starting, is generally less desirable than direct current for the welding of sheet metal (see "Arc starting", column 3, page 5).

Welding of Thick Sections. Alternating current is well suited for welding of thick sections by the use of large-diameter electrodes and maximum currents, because arc blow is seldom serious. In flat-position welding of heavy plate, maximum deposition rates can be obtained if suitable electrodes are used.

Electrodes

Electrodes used in shielded metal-arc welding have many different compositions of core wire and a wide variety of types and weights of flux covering.

This section deals mainly with electrodes for shielded metal-arc welding of low-carbon steel; electrodes for welding of other metals are dealt with in articles on welding of specific metals in this volume.

Standard electrode diameters (diameters of the core wire) range from 1⁄16 to 5⁄16 in. Length is usually 9 to 18 in., although electrodes up to 36 in. long have been made for special applications. A bare (uncoated) end of the electrode, standardized at a length of ¾ to 1½ in., is provided for making electrical contact through the electrode holder (see Fig. 1).

Classification of mild steel covered electrodes according to the system devised by the American Welding Society is generally used throughout industry. In this system, designations consist of the letter E (for "electrode") and four digits. The first two digits indicate minimum tensile strength, in 1000 psi, of deposited weld metal in the as-welded condition. The third digit indicates welding positions for which the electrode can be successfully used: E*xx*1*x* indicates all positions; E*xx*2*x*, flat welds and horizontal fillet welds only. The fourth digit indicates the type of covering and suitable current characteristics, as shown in Table 5. For example, E6011 is an electrode that deposits weld metal with a minimum tensile strength of 60,000 psi (first two digits); can be used for welds in all positions (third digit); has a high-cellulose, potassium covering and can be used either with alternating current or with reverse-polarity direct current (fourth digit).

Table 5. Coverings and Suitable Currents Indicated by Fourth Digit in AWS Classifications of Mild Steel Covered Arc Welding Electrodes

Fourth digit	Covering	Current(a)
0	High-cellulose, sodium(b)	Dcrp(b)
	High iron oxide(c)	Ac or dc(c) (d)
1	High-cellulose, potassium	Ac or dcrp
2	High-titania, sodium	Ac or dcsp
3	High-titania, potassium	Ac or dc(e)
4	Iron powder, titania	Ac or dc(e)
5	Low-hydrogen, sodium	Dcrp
6	Low-hydrogen, potassium	Ac or dcrp
7	Iron powder, iron oxide	Ac or dc(d)
8	Iron powder, low-hydrogen	Ac or dcrp

(a) Ac = alternating current; dc = direct current; dcrp = direct current, reverse polarity; dcsp = direct current, straight polarity. (b) When third digit is 1. (c) When third digit is 2. (d) Either polarity for flat welds; dcsp for horizontal fillet welds. (e) Either polarity.

Electrode Coverings. The composition of the electrode covering largely determines the performance of an electrode and the soundness of the weld. Table 6 lists 18 materials that are used in making electrode coverings, although there are more than 18 that can be used; 12 or more may be included in a specific covering. Each material is used for at least one, and often more than one, purpose. Table 6 gives typical compositions of electrode coverings for classes of electrodes used in welding low-carbon steel, and lists the primary and secondary functions of the constituents of the coverings.

The thickness of the covering varies from 10 to 55% of the total diameter of a covered electrode, depending mainly on the type of covering. Coverings are usually applied by extrusion of the flux onto the core wire.

Characteristics of Electrode Classes

E6010 and E6011 electrodes give a deep-penetrating, forceful, spray-type arc and are usable in all welding positions. They develop a low volume of slag that is easily removed. The deposits usually have good mechanical properties and are radiographically acceptable. The main constituent of the covering is cellulose, which decomposes during welding to provide a gas shield. The gases formed from the decomposition of cellulose and the high moisture content (up to 5%) of the electrodes produce the arc characteristics. The covering of E6011 electrodes contains potassium to assist in maintaining the arc when alternating current is used.

E6012 and E6013 electrodes provide a medium-penetrating arc. They yield a semiglobular to globular viscous slag that permits welding of joints with poor fit-up. The contour of horizontal fillet welds obtained by use of these electrodes varies from convex with E6012 electrodes to nearly flat with E6013 electrodes. Both types can be used for out-of-position welding, and most E6013 electrodes operate successfully in the vertical-down position.

The E6012 electrodes can be used at relatively high welding current, because the coverings contain only a small proportion of cellulose and a large proportion of refractory material.

Coverings of E6013 electrodes generally contain more potassium than those of E6012 electrodes and thus give a quieter arc with less penetration. The high potassium content of the coverings of some E6013 electrodes permits the use of low open-circuit voltage. In small sizes, E6013 electrodes are most often used for welding of sheet metal.

E6020 electrodes provide a spray-type arc that has medium-to-deep penetration. They produce a heavy, honeycombed slag that is easily removed. Coverings for these electrodes consist mainly of the oxides of iron and manganese. Protection is provided by the volume of slag. The molten weld metal from these electrodes is too fluid for welding other than horizontal fillets or joints in the flat position. These electrodes have higher deposition rates than other conventional electrodes of equivalent sizes, and produce welds of equivalent strength and soundness.

Table 6. Typical Functions and Composition Ranges of Constituents of Coverings on Mild Steel Arc Welding Electrodes

Constituent of covering	Function of constituent: Primary	Secondary	Composition range, %, in covering on electrode of class: E6010, E6011	E6012, E6013	E6020	E6027	E7014	E7016	E7018	E7024	E7028

(a) Effect of relative humidity on moisture absorption of E7016 electrodes. (b) Redrying characteristics of E7016 electrodes. These values are typical; they will vary among different brands.

Fig. 9. Effects of humidity and redrying temperature on moisture in electrode coverings

Iron-Powder Electrodes. As shown in Table 6, the coverings on E6027, E7014, E7018, E7024 and E7028 electrodes contain iron powder in addition to the constituents present in coverings on several classes of conventional electrodes. Except for the iron powder, the constituents of E7014 and E7024 coverings resemble those of E6012 and E6013, and the constituents of E7018 and E7028 resemble those of E7016. In general, covering thickness increases as the content of iron powder increases. The iron powder and additional covering thickness permit higher welding currents and higher deposition rates than are possible with electrodes having coverings containing similar constituents but without iron powder. Thicker coverings also provide a deeper shield and permit the use of the drag technique in the flat position. In addition, the weld bead deposited in a horizontal fillet generally has a flatter contour when iron-powder electrodes are used.

When the covering of an electrode contains more than 40% iron powder, it is too thick to permit use of the electrode for vertical and overhead welding and for horizontal groove welds. Thus, the E6027, E7024 and E7028 electrodes, with 40 to 55% iron powder in the covering (Table 6), can be used only for flat-position welding and for horizontal fillet welds. (E6027 electrodes are also restricted as to welding position by the fluidity of the covering.)

E7016 electrodes have low-hydrogen coverings containing little or no hydrogen-bearing materials, such as cellulose, clays and asbestos. These electrodes are baked at a relatively high temperature (500 to 600 F) to minimize the retention of water from the silicate binder. Because of the low hydrogen content of the covering, the weld metal deposited is also low in hydrogen and is free of porosity. The carbon dioxide from the calcium carbonate, and the silicon fluoride (SiF_4) formed from the fluorspar in reaction with silicon dioxide, provide the shielding gas. The high proportions of titanium dioxide and of potassium silicate in the covering permit the use of E7016 electrodes with alternating current as well as reverse-polarity direct current.

E7015 electrodes are low-hydrogen electrodes used with reverse-polarity direct current. Although included in AWS A5.1-69, the E7015 electrodes are no longer generally manufactured.

Effect of Moisture in Electrode Coverings

It is often mistakenly considered that moisture is harmful in the coverings of all mild steel electrodes. Precautions are usually taken by fabricators to store electrodes in dry places, and this practice should be encouraged. However, redrying, which is often done after prolonged storage, can impair both quality and operation of electrodes with cellulose-type coverings, especially E6010 and E6011 electrodes.

Table 7 shows recommended moisture contents of coverings, and storage and redrying conditions for different classes of electrodes. Some brands of E6010 and E6011 electrodes will operate satisfactorily and produce satisfactory weld-metal deposits when the moisture content of the covering is above the recommended range. All other types of electrodes usually operate best when the moisture content is lowest.

Redrying temperature depends on the composition and thickness of the covering. Coverings containing organic material are usually redried at temperatures below the charring point (250 F), whereas inorganic coverings, such as the low-hydrogen types, are redried at temperatures up to 700 F. It is important that the drying procedure prescribed by the manufacturer be followed precisely for specific electrodes; otherwise, the electrodes may become unusable. Holding-oven temperatures shown in Table 7 should be maintained after redrying. Electrodes should not be removed from holding ovens for more than 1 or 2 hr before being used. Otherwise, redrying may be required.

Determination of Moisture Content. The moisture content of coverings on all except low-hydrogen electrodes can be determined by weighing an approximately 1-gram sample of the covering before and after redrying for 1 hr in an electric oven at 220 F. The weight loss calculated as percentage of predrying weight is the moisture content.

Moisture content for low-hydrogen electrodes is usually determined at temperatures between 1650 and 1800 F, using a special apparatus and technique as described in AWS A5.5-69.

E6010 and E6011 Electrodes. Manufacturers of E6010 and E6011 electrodes normally control moisture content so that it is between 3% and 5% for E6010 and between 2% and 4% for E6011. Therefore, a redrying practice that lowers the moisture content below the designed range is not recommended. E6010 and E6011 electrodes may perform satisfactorily even when the moisture content in the covering exceeds optimum values, but only if the covering does not blister during welding and does not interfere with operation of the electrode.

Ordinarily, the soundness of welds made with E6010 or E6011 electrodes is not impaired by excess moisture if the operation of the electrode remains satisfactory. When most brands of E6010 and E6011 electrodes are redried to a moisture content much below 2.0%, there is more weld spatter and increased probability of porosity in the weld metal. Arc control may also be impaired. The moisture content of E6010 electrodes can accidentally be decreased to values lower than the recommended level when a container is left open and electrodes are exposed to a hot, dry atmosphere.

Low-Hydrogen Coverings. The moisture content of low-hydrogen coverings (E7015, E7016, E7018 and E7028 electrodes) should be kept below the values in Table 7 (or, preferably, below 0.3%). If moisture content is much above these values, underbead cracking is likely. Low-hydrogen electrodes should not be allowed to remain in open boxes or bins for more than 1 or 2 hr.

A safe practice, followed by many fabricators, is to return all unused low-hydrogen electrodes after either a 2-hr exposure or a working shift to a redrying oven maintained at 250 to 350 F for at least 8 hr before reissuing them.

Figure 9(a) shows amounts of moisture absorbed by the covering on E7016 electrodes exposed for various periods of time to a humid condition (85% relative humidity at 85 F), a medium-

Table 7. Recommended Moisture Content of Coverings, and Storage and Redrying Conditions, for Mild Steel Covered Arc Welding Electrodes

Electrode class	Recommended moisture content of covering, %	Relative humidity, %, for storage at normal temperature of 80 ± 20 F	Temperature of holding oven, F	Redrying temperature, F (1 hr at temperature)
E6010	3.0 to 5.0	20 to 60	(Follow manufacturer's recommendation)	
E6011	2.0 to 4.0	20 to 60		
E6012, E6013, E6020	Less than 1	60 max	100 to 120	275 ± 25
E6027, E7014, E7024	Less than 0.5	60 max	100 to 120	275 ± 25
E7015, E7016	Less than 0.4	50 max	130 to 330	550 ± 50
E7018, E7028	Less than 0.6	50 max	130 to 330	650 ± 50

humid condition (67% relative humidity at 85 F), and a relatively dry condition (52% relative humidity at 85 F). Figure 9(b) shows the total percentages of moisture contained in coverings on E7016 electrodes after redrying the electrodes at about 250 to 850 F in a well-ventilated oven. Values shown in Fig. 9 are typical; they will vary considerably among different brands.

Times and temperatures required for restoring E7016 electrodes to their original usability after the coverings have absorbed the amount of moisture that causes underbead cracking differ for electrodes from different manufacturers. A procedure for one typical commercial brand of E7016 electrodes is as follows: Redry for approximately 1 hr in a well-ventilated oven by slowly increasing the temperature to 550 ± 50 F. Prolonged drying periods (weeks or months) at either lower or higher temperatures can cause the covering of some brands of E7016 electrodes to become brittle and crack.

Selection of Electrode Class

An all-purpose electrode for shielded metal-arc welding does not exist, although many types of covered electrodes overlap in adaptability to specific applications. To some degree, the class of electrode selected depends on whether alternating current or direct current is available for welding (see Table 5). Other factors in the selection of electrodes are:

1 Composition of the base metal
2 Position of welding
3 Fit-up
4 Service requirements of the welded joint
5 Penetration requirements
6 Cost of the welding operation
7 Skill of welding personnel.

Table 8. Penetration Obtained With Eleven Classes of Mild Steel Covered Electrodes

Electrode class	Penetration	Electrode class	Penetration
E6010	Deep	E6027	Medium
E6011	Deep	E7014	Medium
E6012	Medium	E7016	Medium
E6013	Less than E6012	E7018	Shallow
		E7024	Shallow
E6020	Medium(a)	E7028	Shallow

(a) Deep with high current

Composition of the base metal, which also influences the need for preheating and postheating operations, is the primary factor in electrode selection. All low-carbon ferritic steels can be welded with any class of mild steel electrodes, unless ambient temperature is low.

Steels having carbon content greater than about 0.35%, or tensile strength above 60,000 psi, are often welded using electrodes with low-hydrogen coverings or with iron-powder low-hydrogen coverings, to avoid the need for preheating and postheating (see the articles on Arc Welding of Hardenable Carbon Steels, page 187, and on Arc Welding of Alloy Steels, page 200).

Position of Welding. Welding in the vertical and overhead positions restricts the number of suitable classes of electrodes and generally decreases deposition rate. For this reason, most fabricators try to position workpieces so that welding will be in the flat or horizontal position (see "Positioning", on page 11). They can then use all-position electrodes at optimum deposition rate, or the higher-speed electrodes designed specifically for horizontal and flat-position welding.

Fit-up. Good fit-up of individual components of an assembly to be welded enables virtually any class of electrode to be used successfully. If there is a large root opening between components, special techniques or E6012 electrodes should be used.

Service Requirements. Electrodes with low-hydrogen coverings or iron-powder low-hydrogen coverings generally are used for applications in which welds must have high strength, good ductility, and good low-temperature impact strength. For welds that must pass radiographic inspection for soundness, general fabricating classes of electrodes, such as E6012, E6013, E7014 and E7024, are less useful. For best appearance of welds, E6020, E6027 and E7024 electrodes are often used.

Penetration requirements influence the selection of electrode class. The use of the wrong class of electrode can result in welds with penetration insufficient to provide adequate strength.

Table 8 compares the depths of penetration normally obtained with various classes of mild steel covered electrodes.

Cost of the welding operation is affected in two ways by the selection of electrode class. First, this selection influences the deposition rate, which often is the major factor in over-all cost of the welding operation. The second, and usually smaller, effect is the direct cost of the electrodes consumed.

For the electrodes listed in Table 10, deposition rate in ounces per hour is highest for the iron-powder electrode E7024 and the iron-powder low-hydrogen electrode E7028, and is much lower for welding with the remaining electrode classes, comparing equal diameters.

The iron-powder electrodes E6027 and E7024, which are relatively low in cost per pound of electrode and permit high deposition rates, often give the lowest over-all welding cost and provide weld quality adequate for many applications. For additional information on the relation of electrode selection to cost, see pages 21 and 22. Figure 34 compares electrode cost and arc time per inch of weld for E6020, E7018 and E7024 electrodes, and Table 15 and Example 8 give a complete cost breakdown for welding with E6013 and E7024 electrodes.

Welder Skill. Best results cannot be obtained in welding with a particular class of electrodes unless the welder is proficient enough in handling them. Flat-position electrodes, such as E6020, require less welder skill than the all-position electrodes, such as E6010. The low-hydrogen electrodes require greater welder proficiency than other types. Brief practice periods with a new type of electrode are always advisable.

Selection of Electrode Size

For many applications, obtaining the most economical operation depends as much on the selection of electrode size (diameter of the core wire) as on the selection of electrode class.

The principal considerations in selection of electrode size are joint design, thickness of the weld layer, welding position, permissible heat input, and the degree of welder skill. Table 9 shows typical ranges of welding current and welding speed at which several standard sizes of six classes of covered electrodes are used in making fillet and butt welds of various sizes in the flat,

Table 9. Typical Operating Conditions and Speeds for Various Sizes of Electrodes in Shielded Metal-Arc Fillet and Butt Welding in Different Positions

Electrode size, in.	Current, amp	Weld size, in.	Speed, ipm, for welding positions: Flat	Horizontal	Downhill, 30°	Vertical	Overhead

horizontal, 30° downhill, vertical and overhead welding positions.

The dimensions of a joint are established either by specifications or by welding procedures that have been qualified by test. The number of passes required to meet specifications depends largely on joint design, size of the electrode, thickness of the work metal, position of welding, and degree of skill of the welder.

All classes of covered electrodes are designed for multiple-pass welding. Electrode sizes suitable for use in different passes for some types of joints and welding positions are given below:

1 For pipe welds (or other single-welded joints) requiring good fusion at the root, a ⅛-in. or a 5⁄32-in. electrode is recommended for the first pass. For the remaining passes, 5⁄32-in. or 3⁄16-in. electrodes can be used in all welding positions; for welding in the flat position, electrodes that are 3⁄16-in. or larger can be used.
2 For flat-position welding of double-bevel or single-bevel joints that have a backing strip or can be back-gouged, a 3⁄16-in. electrode can be used for the first pass, and a 7⁄32-in. or larger electrode for the remainder.
3 For fillet welds in the flat position, 3⁄16, 7⁄32 or ¼-in. electrodes are satisfactory. Larger electrodes can be used if the work is thick enough to tolerate the additional heat.
4 For out-of-position fillet and butt welding, a 3⁄16-in. electrode is the largest that it is practical to use. Often the first pass is deposited with a 5⁄32-in. electrode.
5 The sizes of low-hydrogen electrodes generally used for vertical and overhead welding are ⅛ and 5⁄32 in.; electrodes for flat and horizontal welding are 3⁄16 in. or larger.

Electrode Deposition Rates and Properties of Welds

Deposition rate is the weight of metal deposited in a unit of arc time, and is generally expressed as pounds (or ounces) per hour. Table 10 shows typical deposition rates obtained in welding with covered electrodes of various sizes and classes. Table 10 also shows deposition efficiency and spatter loss, and lists the mechanical properties of weld metal obtained with some of the classes and sizes of electrodes. Under normal conditions, the data in Table 10 on electrode performance and weld properties can vary as much as ±7% because electrodes are obtained from different suppliers or are from different heats or lots from the same supplier, and because of difference in techniques of various welders.

For any specific class of covered electrode, deposition rates are primarily a function of the current setting at which the electrode is used. The type and size of the welding electrode and the welding position determine which power supply and current range will be used. Manufacturers of welding electrodes have recommended current ranges for each welding position in which their product may be used. (Some typical ranges are given in Table 9.)

Figure 10 shows the influence of current on the deposition rate, deposition efficiency (weight of deposited metal as a percentage of the net weight of electrodes consumed, exclusive of stubs), spatter loss, and weld-metal tensile strength and elongation, for ¼-in. E6011 electrodes. The shapes of the curves in Fig. 10 will vary for E6011 electrodes of sizes other than ¼ in., for different classes of electrodes, and for the same size and class of electrode obtained from different suppliers.

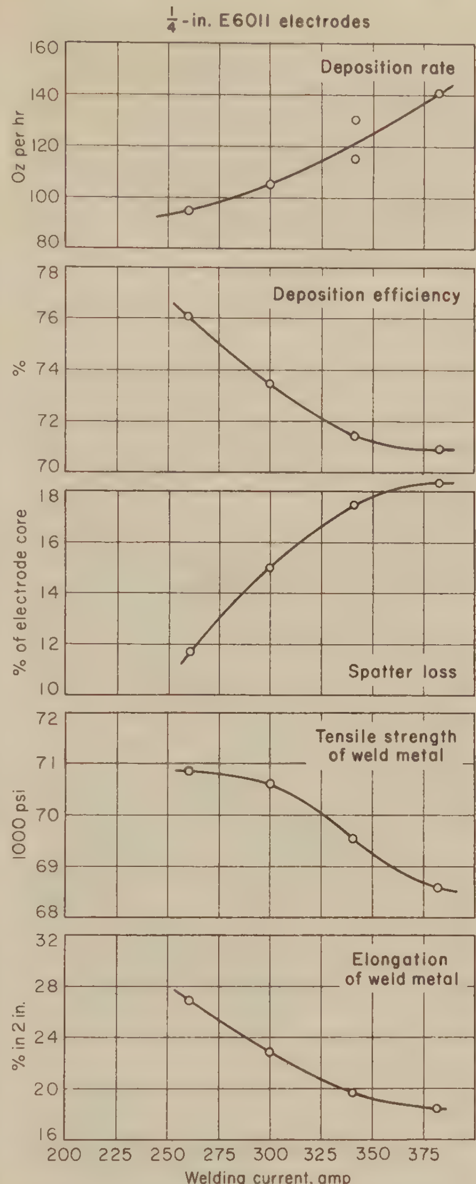

Fig. 10. Effect of current on deposition rate, deposition efficiency, spatter loss, and mechanical properties of weld metal, for ¼-in. E6011 electrodes

Arc Length

The end of an electrode must be close enough to the work to ensure that molten metal from the electrode will be transferred directly and accurately into the weld puddle. Arc length, the distance between the end of the electrode and the weld puddle, is a designed function of the electrode covering, but changes may be necessary under some welding conditions. In general, arc length should not exceed the diameter of the electrode core wire. Welders should deviate from this rule only on the basis of their skill and experience. Arc length is usually shorter for the types of electrodes that have thick coverings. Maintenance of arc length depends mainly on the skill of the welder — which, in turn, depends on his knowledge, visual perception, manual dexterity, and experience.

Arc length largely controls arc voltage and directly affects welding speed and efficiency. Shorter arcs allow an increase in current, which will increase rate of deposition and thus welding speed. When an arc is too long, heat is dissipated to the air, the stream of molten metal from the electrode to the work is scattered in the form of weld spatter, and deposition rate is reduced. In addition, susceptibility to arc blow, and porosity due to loss of shielding, increase as length of arc increases. In welding with direct current, the shortest possible arc is used, to minimize arc blow and contamination by the air.

Control of arc length in vertical and overhead welding demands greater attention from the welder and more skill than in welding in the flat position. In overhead welding, only certain types of electrodes can be used and the welder must adjust the arc length during deposition to retain control of the weld puddle.

For fillet welds, and for root passes in properly prepared butt welded pipe joints, the arc can easily be crowded into the joint for maximum speed and penetration.

The importance of controlling arc length is demonstrated in the example that follows.

Table 10. Typical Electrode Performance and Mechanical Properties of Weld Metal

Electrode class	Electrode size, in.	Current (ac), amp	Deposition rate (100% arc time), oz/hr	Deposition efficiency, %	Spatter loss, % of core wire	Properties of weld metal — Strength, psi — Tensile	Yield	Elongation in 2 in., %
E6011	3⁄16	200 max	88	76	16	70,000	60,000	25
	¼	300 max	112	72	...	...	...	...

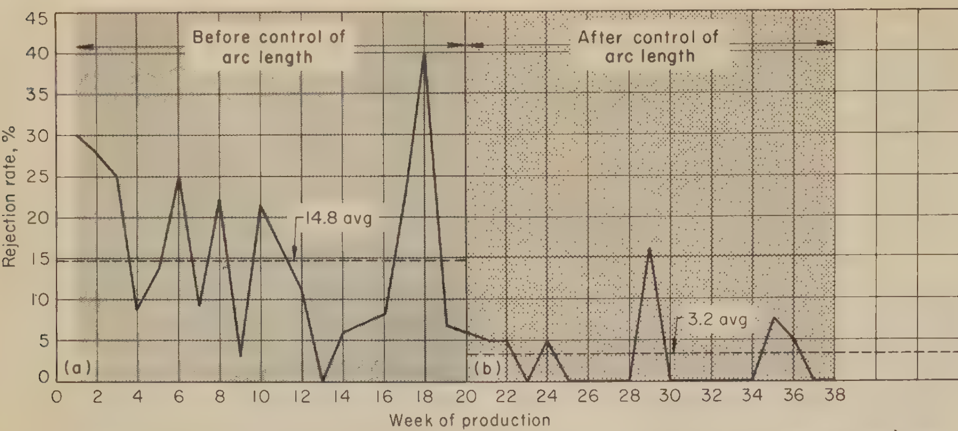

Fig. 11. Comparison of weekly rejection rates for porosity in welded pipe joints before and after control of arc length (Example 1)

Example 1. Control of Arc Length That Reduced Rejections for Porosity (Fig. 11)

Porosity in welded pipe joints was the cause of rejections that averaged 14.8%, with a high of 40%, over a 19-week period, as shown in Fig. 11(a). Investigation showed that the porosity resulted from failure to maintain a short arc length (for low voltage) in welding. When arc length was brought under control, average rejection rate over an 18-week period dropped to 3.2%, with no rejections in 12 of those weeks (Fig. 11b).

Arc Blow

An electric current flowing through the electrode, workpiece and ground cable sets up magnetic fields in a continuous series of circles perpendicular to the current path. When the fields around the workpiece or around the electrode are unbalanced, the arc bends away from the greater concentration of the magnetic field, and this deflection from its intended path is known as arc blow. Arc blow is encountered particularly when using direct current, because the induced magnetic fields are constant in direction. It occurs to only a minor degree with alternating current, because the induced magnetic field that builds up, collapses as soon as the current reverses.

Figure 12(a) shows magnetic fields around the electrode that result in forward blow (deflection in the direction of electrode travel) and backward blow (deflection opposite the direction of electrode travel). Sometimes deflection is to one side (because the concentration of magnetic flux is greater on one side of the arc than on the other), but usually deflection is in the direction of electrode travel or opposite to it.

Backward blow is encountered when welding toward the ground connection, toward the end of the joint, or into a corner. Forward blow is encountered when welding away from the ground connection or at the start of a joint. The conditions may become so severe that a satisfactory weld cannot be made because of incomplete fusion and excessive weld spatter. For instance, with electrode coverings containing large amounts of iron powder (such as 30%) or with other thick coverings, the large blanket of molten slag produced during welding can be troublesome. The difficulty arises because the forward fanning-out of the arc permits the heavy slag deposit in the crater to run under and ahead of the arc.

The forward blow at the start of a weld deposit is only momentary, because the magnetic field soon finds an easy path through the weld metal being deposited behind the arc. Because this following field is in the workpiece and the weld, a slight backward blow is created for the remainder of the weld.

At the finish end, the magnetic field ahead of the electrode is crowded and becomes a problem. As the end approaches, there is a corresponding increase in the backward blow, which may become severe.

The welding current passing through the work also causes the work to act as a conductor surrounded by a magnetic field. The circles of the magnetic field around the current path are in planes perpendicular to the workpiece, and are present between the electrode and the point at which the workpiece is grounded. This condition is most likely to occur in narrow plates.

In welding away from the ground connection, the magnetic field perpendicular to the workpiece is behind the electrode (Fig. 12b) and forward blow results. In welding toward the ground connection (Fig. 12c), the reverse is true and backward blow results.

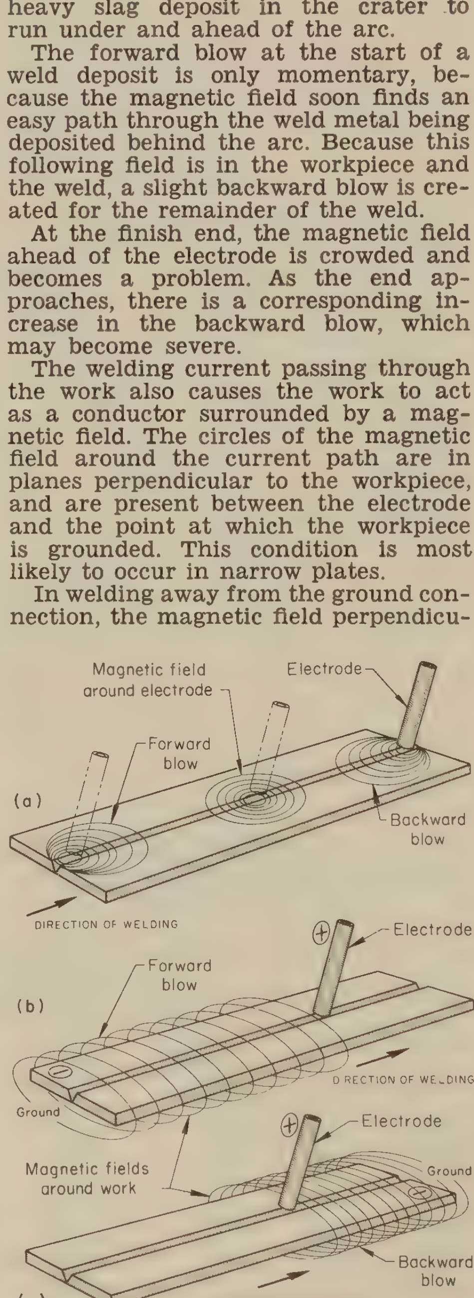

Fig. 12. Magnetic fields that result in forward or backward arc blow (a) *around the electrode;* (b) and (c) *around the work*

Corrective methods for use when severe arc blow is encountered are:

1 Change to alternating current.
2 Reduce welding current and keep arc length at the minimum.
3 Weld toward a heavy tack weld or toward an existing weld.
4 On long welds, use a backstep sequence.
5 Place the ground connection (*a*) as far as possible from the weld, (*b*) at the start of a weld and then weld toward a heavy tack weld, or (*c*) at the end of the weld.
6 Wrap the ground cable around the workpiece so that the current flows in a direction that will establish a magnetic field that will neutralize the magnetic field causing arc blow.

Electrode Holders

An electrode holder is a simple clamping device for holding the electrode, and is provided with an insulated handle for the welder's hand (see Fig. 1). The welding current is conveyed through the electrode holder to the electrode. The clamping device should be designed to hold the electrode securely in position and yet allow quick and easy change of electrodes, and also to provide good electrical contact.

Electrode holders vary from simple types that cost only a few dollars to the large, heavily insulated holders that are sometimes needed for welding with long duty cycles and high current. A typical general-purpose electrode holder is shown in Fig. 1.

It is generally advisable to use the lightest and simplest holder that will do the job; heavy, complex holders reduce the efficiency of the welder. Electrode holders usually are relatively inexpensive, and it is better to use the right holder for each application rather than to stretch the capabilities of another holder. Usually holders are selected according to current rating.

Welding in a confined space may require the use of a short-stub holder. With a short-stub holder, the electrode fits into a socket, and either the handle or the head of the holder is turned to operate the jaws that clamp the end of the electrode. A short holder enables the welder to operate in a confined space and to consume the electrode to a short stub.

The jaws of an electrode holder should be kept in good condition to ensure good electrical contact and to minimize heating in the holder. Poor contact can result in poor performance and low-quality welds. Electrode holders should never be cooled by immersing them in water.

For welding with alternating current, all components of an electrode holder should be nonmagnetic.

Ground Clamps

Ground clamps are devices for connecting the ground cable to the workpiece (see Fig. 1). A ground clamp must furnish a strong, positive connection, yet be quickly and readily movable from one part of the workpiece to another. It should be of rugged design.

Jigs, Fixtures and Positioners

The use of jigs, fixtures and positioners is usually desirable, for at least four reasons: (*a*) to minimize distortion caused by the heat of welding, (b) to permit welding in a more convenient position, (*c*) to increase welding efficiency and (*d*) to minimize fit-up problems.

With a welding jig or fixture, the components of a weldment can be assembled and held securely in proper relationship and with correct fit-up during positioning and during welding. The time required to assemble parts to be welded (setup and fit-up time) often is a large percentage of total fabricating time. If assembly follows a predetermined sequence of controlled fit-up and alignment conditions, welding efficiency will be increased.

For fabricating a single weldment or a few weldments of the same size and shape, temporary tooling can be used. For quantity production, it is economical to design and construct accurate, durable jigs or fixtures. If fixtures can pay for themselves in one year, the investment is generally considered sound. For producing a specific weldment in quantity, the use of duplicate jigs or fixtures makes it possible for a helper to fit together one assembly while the welder is welding another. Production is thus increased by adding only the cost of an extra fixture and a helper. The degree of increased production depends on the proportion of arc time to floor-to-floor time, and varies widely for different weldments.

Use of a specially designed fixture for assembling and tack welding 16 components of a large weldment is described in the example that follows.

Example 2. Benefits Provided by Use of a Fixture for Assembly and Tack Welding (Fig. 13)

The 16 major components of a low-carbon steel weldment were assembled in a specially designed fixture, as shown in Fig. 13. After being tack welded in the fixture, the assembly was removed from the fixture for final welding.

The fixture held each of the 16 components (some of which were welded subassemblies) in a predetermined position, and clamps kept them securely aligned. The sequence of assembly was unimportant, and highly skilled fitters were not required.

Although each component could have been tack welded as it was added to the assembly, it was more economical to complete the assembly in the fixture and then tack weld. Tack welding was done by the shielded metal-arc process, using a 5⁄32-in. E6010 electrode. Each component was tacked at its extreme corners and, wherever possible, with ½-in. tack welds on 7-in. centers. With this amount of tack welding, the assembly had enough strength and rigidity to be removed from the fixture, transported, and positioned for welding. The following benefits were provided by the use of fixtures:

1 The components were fitted and tack welded in 2.25 man-hr; free fitting had required 5.25 man-hr.
2 Less fitting skill was required and the skilled personnel were consequently available to handle more complex fitting.
3 Less time was required to train the fitters.
4 Weldments were more uniform.
5 The completed weldments required less straightening and grinding; less time for final assembly, because fewer tailoring operations were required; and less preparation time for painting, because outside appearance was more uniform.

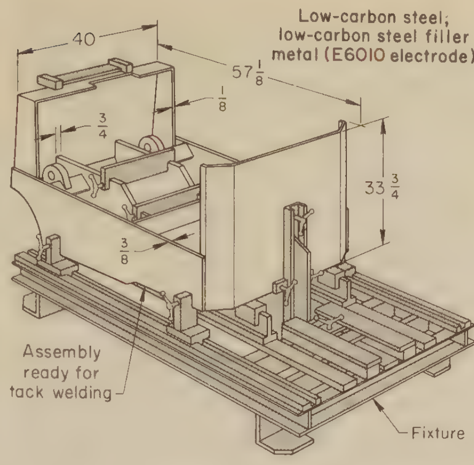

Fig. 13. Sixteen-component assembly mounted in a fixture and ready for tack welding (Example 2)

Desirable features for fixture design include the following:

1 Whenever possible, the fixture should be designed so that all joints in an assembly are convenient for welding without removing the assembly from the fixture. Slots, or other means of access to joints on the reverse side of the weldment, should be provided.
2 The fixture should be strong and light, but rigid enough to ensure accurate alignment.
3 The fixture should permit quick and easy positioning (by one hand, if possible). Thus, balancing of the fixture may be necessary.
4 The use of light alloys for moving parts reduces weight. Air or electric motors should be used for revolving, and air or hydraulic rams or racks for tilting the fixtured assembly.
5 For maximum utility and minimum cost, the accuracy and complexity of a fixture should be no greater than required. Welded steel construction is usually best.
6 The fixture should permit location and clamping of components in position so that assembly, tacking and welding can be done in one fixture.
7 The fixture should permit freedom of movement in one plane, to avoid residual stress in the completed weldment. Design should permit heat distention to release, rather than bind, the assembly being welded.
8 Floating rather than rigid anchoring is recommended.

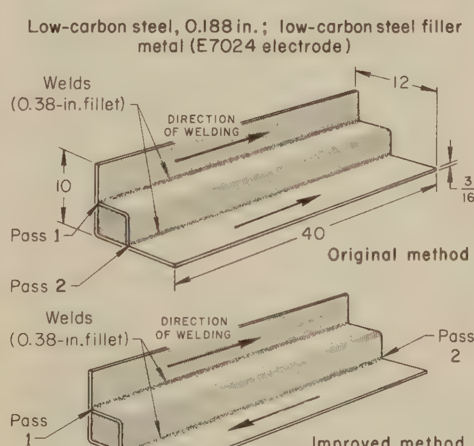

Fig. 14. Weldment for which reversal of pass direction eliminated the need for clamping to keep distortion within acceptable limits (Example 3)

9 Fixtures should be kept cool enough to handle; air, water, fins or insulated handles can be used.
10 To facilitate shop flow, jigs or fixtures can be mounted on wheels, or used in conjunction with floor-mounted or overhead conveyors. Alternatively, they may be located in a production line so that the work can be moved directly to and from them.
11 Indexing arrangements are helpful in providing accurate, quick positioning of work.
12 Clamps must operate quickly. Screws and moving parts should be protected against weld spatter. Fusion to a fixture or to clamps can be avoided by the use of slots or copper backing. If possible, clamps and locating devices should be integral with, and hinged to, the fixture.
13 Use of nuts and bolts, wrenches, C-clamps, wedges and hammers, and hand screws should be minimum. Use of eccentrics and cams, cranks, pinions and racks, air or hydraulic rams, solenoids, or magnetic clamps is preferred.
14 The fixture must be designed to permit quick and easy removal of the weldment.

Technique To Minimize Fixturing. Sometimes the need for fixturing or clamping to prevent excessive distortion can be minimized or eliminated by a change in welding technique. The change in welding technique need not be complicated and may consist merely of a change in welding direction, as in the application described in the example that follows.

Example 3. Change in Pass Direction That Minimized Distortion Without Need for Clamping (Fig. 14)

The 3⁄16-in.-thick low-carbon steel weldment shown in Fig. 14 was initially produced by welding both joints in the same direction (upper view in Fig. 14). With this technique it was necessary to clamp the assembly securely to a table during welding and cooling, to keep distortion within acceptable limits.

When the two joints were welded in opposite directions (lower view in Fig. 14), distortion was within acceptable limits without the need for clamping.

The weldment was made by first tack welding, using a 5⁄32-in. E7014 electrode and 200-amp current, and then depositing the 0.38-in. fillet welds with ¼-in. E7024 electrodes at 405 amp.

Positioning is sometimes essential simply to make joints accessible, because assemblies usually require more than one weld. The main object of positioning, however, is to increase welding speed by putting the joint in a flat (or at least more favorable) position. Such increases in speed are often considerable. Changing from a vertical or overhead position to a flat position can increase welding speed by up to 400%. Flat-position welding also improves weld quality, because it increases the ease of welding.

In flat-position welding, deposition is assisted by gravity. Electrodes with coverings containing iron powder, which have a deposition rate up to 50% greater than that of other types of electrodes having the same core-wire size, can be used at maximum efficiency in welding in the flat position.

Positioners. Devices for positioning can be made readily. Because of the many different types of positioners available, manual positioning in production welding is seldom justified. The headstock-and-tailstock type of

positioner (see Fig. 15) is available in many sizes and is widely used for positioning large, bulky assemblies. This type of positioner is extremely flexible, because the headstock and the tailstock are separate units.

Figure 16 shows a positioner on which a workpiece can be rotated and tilted, by the use of either manual or power drives. It is available in sizes ranging from small bench models to large floor models that have capacities exceeding 100 tons. The general type of positioner shown in Fig. 16 can be modified in various ways as needed. The view at left in Fig. 17 shows a rotary positioner that can be used for welding with either manually or mechanically held electrode holders. In the middle view in Fig. 17 a workpiece is in position on it for welding of one side; in the view at right the workpiece has been inverted on the positioner for welding of the opposite side.

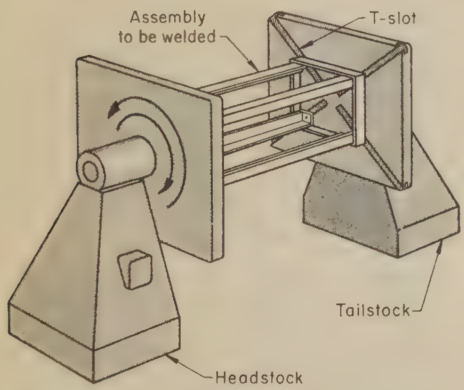

Fig. 15. Headstock-and-tailstock positioner that holds and rotates bulky assemblies

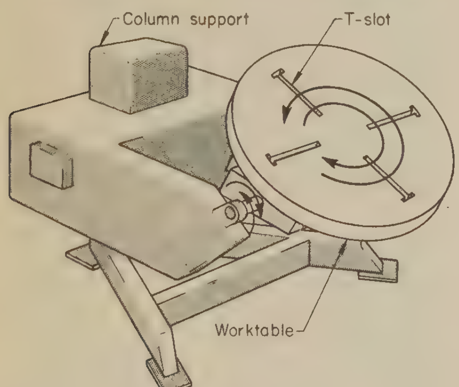

Fig. 16. Positioner that rotates and tilts workpieces

For welding cylindrical workpieces, such as tanks, a roll-type positioner (Fig. 18) is advantageous. The speed of the drive rolls can be regulated as needed, and rotation can be constant or intermittent, and in either direction.

Workpieces often are rotated in a lathe or in a specially designed mechanism that permits welding in the most efficient position. Positioning devices discussed and illustrated in the articles on Gas Metal-Arc Welding and Gas Tungsten-Arc Welding are also applicable to shielded metal-arc welding.

Accessory Equipment

Oxyacetylene torches are often used to bevel edges before welding, and when fitted with special gouging tips (see page 299 in Volume 4 of this Handbook), are used to gouge out defective welds in preparation for repair welding. Gouging may also be done with a carbon-graphite electrode and compressed air (see "Air Carbon-Arc Cutting" on page 301 in Volume 4).

Hammers in assorted sizes and a pry bar are needed in many applications to obtain the desired fit-up.

Heat-sensitive crayons or pastes are used to determine preheat and interpass temperatures.

Deslagging chisels or hammers are needed for cleaning the welds between passes. Wire brushes are normally used for cleaning the surfaces of the joint before welding and for cleaning the layers of welds. Deslagging hammers and wire brushes are either manual or power operated. Rotary grinders are also needed to grind out defects for repair welding.

Striking, Maintaining and Breaking an Arc

An arc is struck by touching the work with the electrode and then quickly withdrawing the electrode to normal arc length (see the section on Arc Length, on page 9). When contact is made, the electrode tends to "freeze", or stick, to the workpiece. Often a lateral scraping or scratching motion similar to that in striking a match is necessary to prevent sticking.

The method of restriking an arc varies with electrode type. Generally, the projecting covering on the electrode tip (shown as "Cup" in section A-A in Fig. 1) becomes conductive during use and assists in restriking and maintaining the arc, particularly when the covering contains iron powder. To permit restriking when electrodes such as E6020, low-hydrogen electrodes, and stainless steel electrodes are used, the projecting covering may have to be broken by tapping the tip to expose the core wire.

The arc is maintained by a uniform movement of the electrode toward the work to compensate progressively for the portion of the electrode that has been melted and deposited in the weld puddle. At the same time, the electrode is also advanced progressively in the direction of welding.

Various procedures are employed to break the arc at the end of a weld. In one procedure, the electrode is drawn to the end of the joint, making a somewhat lighter deposit, the direction of electrode travel is reversed, and then the electrode is withdrawn. In another procedure, the electrode is held stationary long enough to fill the crater and then is withdrawn.

In welding long joints, when electrodes are changed and welding is to be continued from the crater, the arc is shortened, and then is stopped by quickly moving the electrode sideways out of the crater. When the arc is re-established in the crater, it should be struck at the forward, or cold, end of the crater, moved backward over the crater until the weld is reached, and then forward to continue the weld. This procedure is especially beneficial in eliminating "starting porosity". For electrodes that deposit heavy slag, if the slag has cooled below a red heat, it is necessary to remove the slag before restriking the arc. With this procedure, the crater is filled and porosity and trapping of slag are avoided. It is particularly important that this procedure be used in welding with low-hydrogen electrodes.

Electrode Angle and Manipulation

The angular position of the electrode in relation to the weld influences the ease with which filler metal is deposited, uniformity of fusion, and weld contour. Correct positioning of the electrode also ensures freedom from undercutting and slag inclusions.

As shown in the top view in Fig. 19, the lead angle of the electrode is the angle that the electrode makes in advance of a line perpendicular to the weld axis at the point of welding, taken in a longitudinal plane; the work angle is the angle that the electrode makes with a line perpendicular to the weld axis at the point of welding, taken in a transverse plane. Figure 19 shows typical lead and work angles for flat-position welding and for horizontal fillet welding.

Techniques for specific welding positions vary considerably among welders, and much practice is required before a welder can become proficient at making good welds. Regardless of the technique used, the goal is a sound weld. Two fundamental rules are: (*a*) radical motions of the electrode should not be used, because entrapment of slag in the weld must be avoided; and (*b*) the arc must not be broken if the electrode is "hopped" from one side of the puddle to the other.

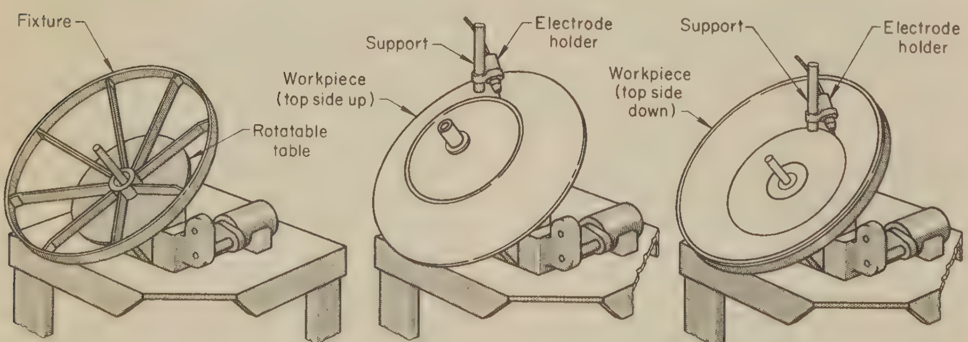

Fig. 17. Rotary positioner that can be used for welding two sides of a workpiece, with either a manually held or (as shown) a mechanically held electrode holder

Slag is usually more fluid than weld metal. Therefore, some electrodes, particularly the electrodes that have heavy coverings and produce a thick slag blanket on the weld, can be used only in the flat position. Obviously a welder cannot cope with slag that runs ahead of the weld or that falls off the weld during out-of-position welding. Even all-position electrodes require specific techniques for out-of-position welding. These techniques, which enable the welder to keep the weld metal where desired, are generally acquired only by training and experience.

It is frequently necessary to change the technique when the type of electrode is changed, even though both electrodes are all-position electrodes. For instance, an E6010 electrode requires a technique different from that for an E7018 electrode.

In welding in the vertical position, different techniques of electrode manipulation may be used for different passes. For a vertical joint with a root opening, the root pass may be made by advancing the electrode with a slight up-and-down motion or a slight inverted-T motion, and the next pass, or passes, may be made with a weaving motion. With the inverted-T technique, the electrode is first raised slightly above the weld puddle (not enough to break the arc), then dropped straight down to (but not touching) the puddle, and then moved from side to side so that metal is tied to both sides of the joint. With the weaving technique, often required in out-of-position welding, the advancing electrode is moved from side to side of the weld puddle and, as each side is alternately reached, is raised slightly and then lowered to impinge on the side of the puddle.

Electrode Clearance. The joint to be welded should provide clearance between the parts joined and the electrode. Figure 20 shows limiting dimensions for clearance that will avoid interference and provide visibility to the bottom or end of the joint.

Techniques for Limited Accessibility. In shielded metal-arc welding, a long, small-diameter electrode can be used to make a weld in spaces too confined to permit the use of an electrode holder of the type required for gas metal-arc or gas tungsten-arc welding. Where weld accessibility is extremely limited, it may be necessary to bend the electrode slightly in order to reach the weld area. When this is done, the electrode covering must remain intact, to provide protection for the arc and the weld puddle. Not all electrodes will bend and still retain an intact covering. Class E6013 electrodes will usually bend satisfactorily without damage to the covering, but because of variations in electrode manufacture, not all electrodes of this class will bend. Correct moisture content is extremely important for satisfactory bending; if a covering is too dry, it will crack and spall when bent. Heating the electrode by shorting it out may help in bending.

Effect of Welding Speed

Welding speed is the rate of travel of the electrode in relation to the workpiece, regardless of which is moving. Optimum speed depends on the melting rate of the electrode, type of current, closeness of fit-up (see the section on Fit-up, on page 14), composition of the metal being welded, type of electrode being used, welding position, and welding technique.

Welding speed must be high enough to permit the arc to lead the puddle slightly. Increasing welding speed while maintaining constant arc voltage (arc length) and constant current will reduce the width of the weld bead and increase penetration, until an optimum speed is reached at which penetration will be maximum. Speeds greater than the optimum may result in decreased penetration, poor appearance, undercutting at the edges of the weld, tight slag, and porosity. The optimum speed is usually the highest speed at which weld quality, slag removal, bead size, and surface appearance of the weld are acceptable. The welding speed has a major influence on extending or restricting the limits of the heat-affected zone. Thus, welding speed affects the structure and hardness of the weld and of the heat-affected zone.

If a smaller weld bead is produced by use of a higher speed, with no other change, heat input per unit of weld seam length will be less. Faster cooling and, consequently, greater hardening will result. If the same size of weld bead is produced by the use of a higher current and a higher speed, heat input per unit of length will be the same but the rate of heat input and the rate of cooling will be higher. Hardening, therefore, will be more pronounced.

Welding Procedures

After a joint design has been selected and the edges of the members have been prepared, the first step in welding is to place the parts in position and to adjust them for optimum fit-up. Tack welds are frequently used to hold the fixed positions. For welds in joints that require more than a single pass, welding is initiated by depositing a narrow bead at the bottom of the joint. Welding then proceeds by depositing consecutive beads over the original bead until the desired dimension of the weld is obtained. The weld should be cleaned (deslagged) following each pass in multiple-pass welding.

Procedures vary considerably, depending on joint design, position of joint, thickness of sections being welded, and variation of thickness among sections being welded. These variables and the procedures that deal with them are discussed in the sections that follow.

Joint Design

Joint design (shape and dimensions) is determined by the design of the workpiece, metallurgical considerations, and established codes or specifications.

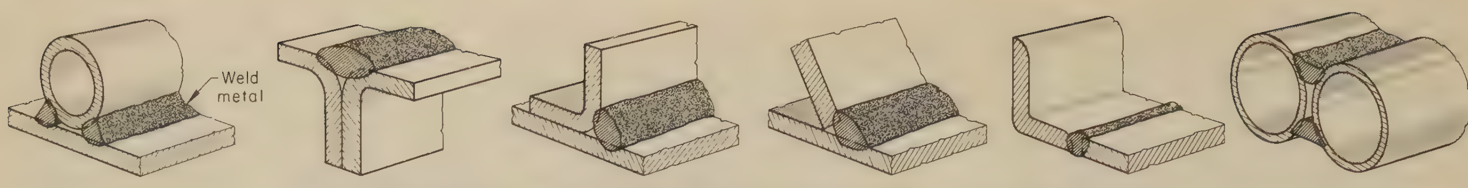

Fig. 21. Joints that have natural grooves and thus need little or no edge preparation

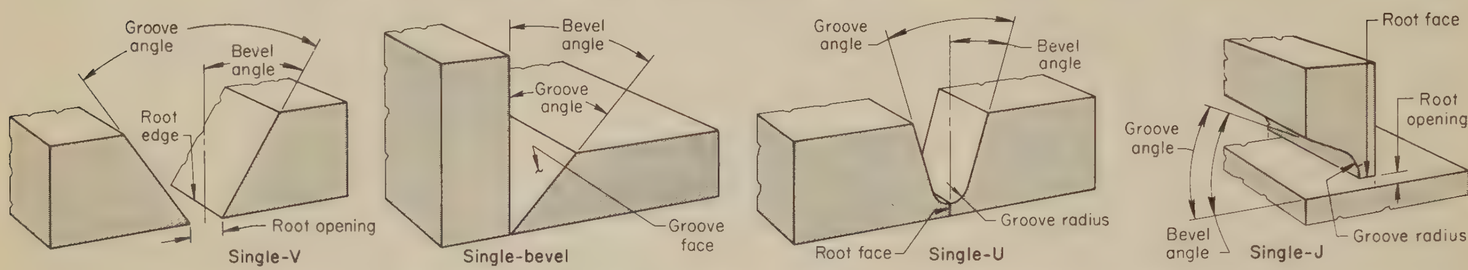

Fig. 22. Nomenclature for four standard types of single-groove joints frequently used in shielded metal-arc welding

Edge Preparation. Joints for square-groove and for fillet welding are prepared by simply squaring off the edge to be welded on each member, if the as-received edge is not suitable. Edge preparation for bevel, V, U, J and combination grooves is more complex.

Methods most often used for edge preparation are machining, chipping, shearing, grinding, gas cutting, gas gouging, and air carbon-arc gouging.

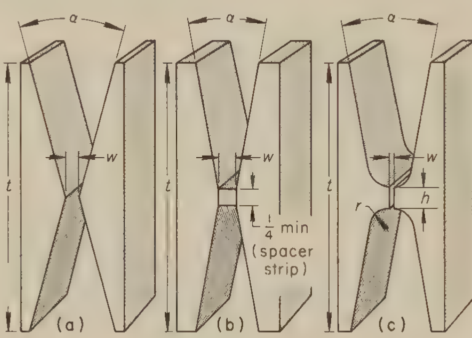
Joints in metal up to 3⁄16 or ¼ in. thick seldom require beveling for complete penetration. Partial-penetration welds can be made in work metal up to ½ in. thick without beveling.

Some joints have natural weld grooves (Fig. 21) and require minimum or no edge preparation.

Standard Groove Types. Nomenclature for angles, faces, radii and root openings in several standard types of groove joints is given in Fig. 22. Recommended proportions and dimensions for standard joints are given in "Recommended Proportions of Grooves for Arc Welding", pages 148 to 150.

Single-bevel grooves and V-grooves are the types most often used, because they are easily prepared by gas cutting. Edges of U-grooves can be prepared by gas cutting, using special tips and techniques, or by machining, which produces more uniform grooves.

U-grooves generally require less weld metal than V-grooves, but the use of spacer strips in V-grooves (see Fig. 23b) sometimes results in the same saving of weld metal, in addition to providing the economy of gas cutting.



Joint	t, in.	α, deg	w, in.	r, in.	h, in.
(a)	4 to 6	30	3⁄16	...	...
(b)	4 to 6	20	¼	...	...
	Over 6	10	½	...	...
(c)	4 to 6	20	0-1⁄16	3⁄16	¼-5⁄16
	Over 6	10	0-1⁄16	5⁄16	¼-5⁄16

Fig. 23. Shapes and dimensions of three joints for groove welding of sections over 4 in. thick

A U-groove, which has a generously rounded bottom, permits the use of larger electrodes for the first pass than can be used with V-grooves, which have a sharp or only slightly rounded bottom. There is, however, little or no difference between the welding speeds obtained for U-grooves and V-grooves up to 1 in. deep.

Single-bevel and -J grooves are well suited for T-joints and corner joints. Single-V, -U and -bevel grooves are the usual edge preparation for butt joints 3⁄16 or ¼ in. to about ¾ in. thick.

For metal ¾ in. thick or more, double-bevel, double-V, double-J and double-U grooves are recommended if welding from both sides is possible. Joints with these grooves produce less distortion of the welded parts and reduce the amount of weld metal required for a given thickness. Three joint designs for groove welding of sections over 4 in. thick are shown in Fig. 23. The joints shown in Fig. 23(b) and (c) are specially designed so that the groove angle can be reduced. A reduction in the groove angle reduces the amount of weld metal required to fill the joint and minimizes cracking in thick sections.

Groove angles of 45° to 60° are used for thinner sections requiring grooves, but are not satisfactory for thick sections because excessive amounts of weld metal are required to fill such large grooves. Large savings can be realized by keeping the amount of filler metal and the arc time to a minimum.

Weld Location

Welds should preferably be located away from points of maximum stress. Figure 24 shows two sets of examples of poorly and properly placed welds for different directions of loading. The poorly placed welds result in stress concentrations in unwelded regions of the joints.

On double-welded lap joints, the overlap should be small enough to prevent buckling or separation.

Fit-up

Poor fit-up increases welding time, and often is the cause of unsound welds. In the welding of sheet steel 0.060 in. thick (the minimum practical thickness for shielded metal-arc welding), good fit-up is mandatory; if fit-up is poor, unsound welds (often because of burn-through) will result. Some desirable and undesirable fit-ups in joints of which the components are 0.060-in.-thick sheet are shown in Fig. 25.

Table 11 shows the arc time required for bridging root openings of 3⁄16 to ½ in., with the use of 3⁄16-in. E7018 elec-

Table 11. Arc Time Required for Bridging Root Openings of Various Sizes in Welding Low-Carbon Steel With 3⁄16-In. E7018 Electrodes and the Stringer-Bead Technique in Three Positions(a)

trodes, in welding low-carbon steel in three different welding positions.

Figure 26 shows the effect of size of root opening on the speed with which butt joints can be welded in low-carbon steel plate of various thicknesses. These data, for welding of square-groove or single-V-groove butt joints from both sides in the flat position, show that for 1/4-in.-thick plate, a joint with a 1/32-in. root opening can be welded nearly three times as fast as the same joint with a 3/16-in. root opening. A 1/32-in. root opening is the minimum shown in Fig. 26, but a further reduction, to 1/64 in., prevents angular distortion and weld cracking in some applications.

Size of root opening has a similar effect on welding time for fillet welds. A 7/16-in. fillet weld in the flat position can be made at 12 in. per minute with a 1/32-in. root opening, but at only 8 in. per minute with an 1/8-in. root opening; and a root opening of 3/16 in. will require multiple-pass welding and a speed of only about 3 in. per minute.

For unusually large root openings, an overlay may be deposited on the joint faces to reduce the root opening.

Fillet Welds

Fillet welds as large as 1 in. require six to eight passes and usually have poor appearance. Where strength greater than a 3/8-in. fillet weld can provide is required, edge preparation such as a 1/4-in. bevel in the joint should be considered before enlarging the fillet size. Welding conditions for various sizes of fillet welds are given in Table 12.

Single-Pass Fillet Welds. The maximum size of sound fillet weld that can be made in a single pass depends on the position of welding, electrode size, electrode type, amperage, and work-metal thickness. Attempts to make fillet welds that are too large for one pass can result in undercutting, unequal legs, lack of penetration, and slag entrapment. The largest size of single-pass fillet weld is 3/8 in. in the flat position, 5/16 in. in the horizontal and overhead positions, and 1/2 in. in the vertical position. Typical sizes of various classes of electrodes for five sizes of single-pass horizontal fillet welds are given in Table 13.

Table 12. Conditions for Fillet Welding in Flat and Horizontal Positions With E7018 Electrodes(a)

Fillet size, in.	Pass No.	Electrode size, in.	Current, amp: Range	Current, amp: Optimum	Melting rate, in./min
Welding in Flat Position					
1/8-5/32	1	1/8	120-160	140	...
1/8-3/16	1	5/32	150-220	170	...

	2	5/16	420-540	460	...
	3,4(b)	5/16	420-540	460	...
Welding in Horizontal Position					
1/8-5/32	1	1/8	120-160	140	...
1/8-3/16	1	5/32	150-220	170	...
5/32-1/4	1	3/16	240-300	260	11.60
3/16-5/16	1	7/32	280-350	300	...
1/4-5/16	1	1/4	320-400	350	9.54
3/8-7/16	1	7/32	280-350	300	...
	1(c)	1/4	320-400	350	9.54
	2	1/4	320-400	350	9.54
1/2-5/8	1	7/32	280-350	300	9.54
	1(c)	1/4	320-400	350	9.54
	2, 3	1/4	320-400	350	9.54
11/16-3/4	1	7/32	280-350	300	...
	1(c)	1/4	320-400	350	9.54
	2-6	1/4	320-400	350	9.54

(a) For welding with alternating current or reverse-polarity direct current, using the stringer-bead technique (except where use of weaving is footnoted to pass number), chipping for multiple-pass welds, and using small-diameter electrodes to tie-in ends and corners of joints. (b) Using weaving technique. (c) Alternative first pass.

Table 13. Classes and Sizes of Electrodes for Single-Pass, Horizontal Fillet Welds

Electrode class	Electrode size, in., for fillet size, in., of: 1/8	3/16	1/4	5/16	3/8(a)
E6012, 6013 ...	5/32	3/16	1/4	1/4	1/4
E7014	1/8	5/32	7/32	1/4	1/4
E7018	1/8	5/32	3/16, 7/32	1/4	1/4
E7024	1/8	5/32	3/16, 7/32	7/32	...

(a) Usually made in two passes; a great deal of operator skill is required for making a 3/8-in. fillet weld in one pass.

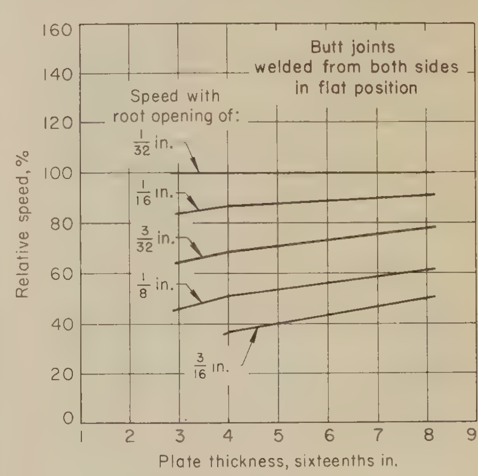

Fig. 26. Effect of size of root opening on speed of flat-position welding of square-groove and single-V-groove butt joints in low-carbon steel plate of various thicknesses

Multiple-Pass Fillet Welds. For larger fillets that require multiple-pass welding, horizontal fillets usually require more passes than flat fillets.

Effect of Work-Metal Thickness. For a given thickness of work metal, a fillet weld should be no larger than is required for adequate strength. Needlessly large welds add to cost by increasing deposition time and wasting metal. Minimum sizes of fillet welds for adequate strength, and for avoiding cracking due to joint stresses during cooling, are:

Thickness of thicker member, in.	Minimum size of fillet weld, in.
Up to ¼	⅛
¼ to ½	3⁄16
½ to ¾	¼
¾ to 1½	5⁄16
1½ to 2¼	⅜
2¼ to 6	½
Over 6	⅝

Intermittent Welds. An intermittent fillet weld, one of broken continuity, is often used when the strength of a continuous fillet weld of minimum size exceeds requirements (unless a continuous weld is required for appearance or because the welded joint must be leakproof or weatherproof). For adequate strength, the minimum length of an intermittent weld should be at least four times the size of the fillet, and not less than 1½ in.

Maximum center-to-center spacing of intermittent welds should not exceed 16 times the thickness of the thinner member of joints that will be loaded in compression, or 32 times the thickness of the thinner member of joints to be subjected to other types of loading. The length of the unwelded spaces between continuous sections of weld should not, however, exceed 12 in.

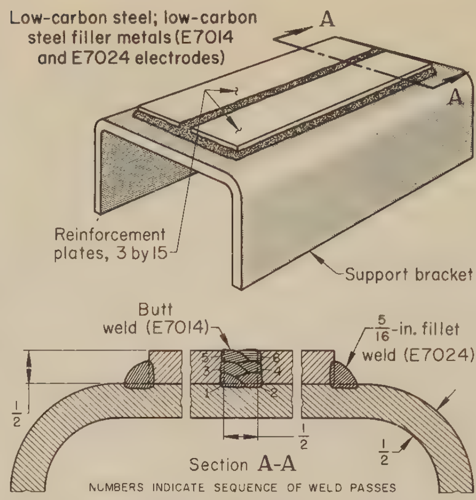

Fig. 27. Support bracket to which reinforcement plates were joined by horizontal fillet welds and then a six-pass square-groove weld (Example 4)

Groove Welds

For making a full-penetration square-groove weld, the electrode must be of a size that permits fusion of the weld root and gives proper arc length.

The amount of penetration obtained varies with the welding technique used. Even a very shallow weld puddle under the arc will form an insulating layer and thus decrease the penetrating power of the arc. When the electrode is raised to keep the tip out of the molten metal, the resulting longer arc dissipates more of its heat into the air, and in flaring out widens the weld bead. The welder should therefore maintain a short arc and the correct electrode angle. This will automatically force the weld puddle away from under the electrode tip, especially when travel speed is high. With heavily covered electrodes, the correct arc length will be obtained when the electrode is dragged along the joint with the covering touching the workpieces.

Smooth square-groove welds are readily produced on thicknesses of 0.060 to 3⁄16 in. (typical procedure for welding of thin sections is discussed on page 17), but for thicknesses of 3⁄16 to ¼ in. roughness is often a problem.

In the next example, a square-groove butt weld was used to fill a relatively wide opening, with little distortion.

Example 4. Use of a Six-Pass Square-Groove Butt Weld With Horizontal Fillet Welds (Fig. 27)

Figure 27 shows a low-carbon steel support bracket to which two ½-in.-thick reinforcement plates were joined — first, with 5⁄16-in. horizontal fillet welds, then with a six-pass square-groove weld in the ½-in. opening between the plates (section A-A).

The fillet welds were single-pass welds made with 7⁄32-in. E7024 electrodes at 325 amp, dcsp. For the square-groove weld, 5⁄32-in. E7014 electrodes were used, at 200 amp, dcsp. Cleaning with an air-operated chipping hammer followed each pass. Total time for each weldment was 12½ min.

The support bracket was designed with two support plates (instead of one larger plate) to minimize distortion in the weldment. The two-plate design eliminated the need for postweld straightening.

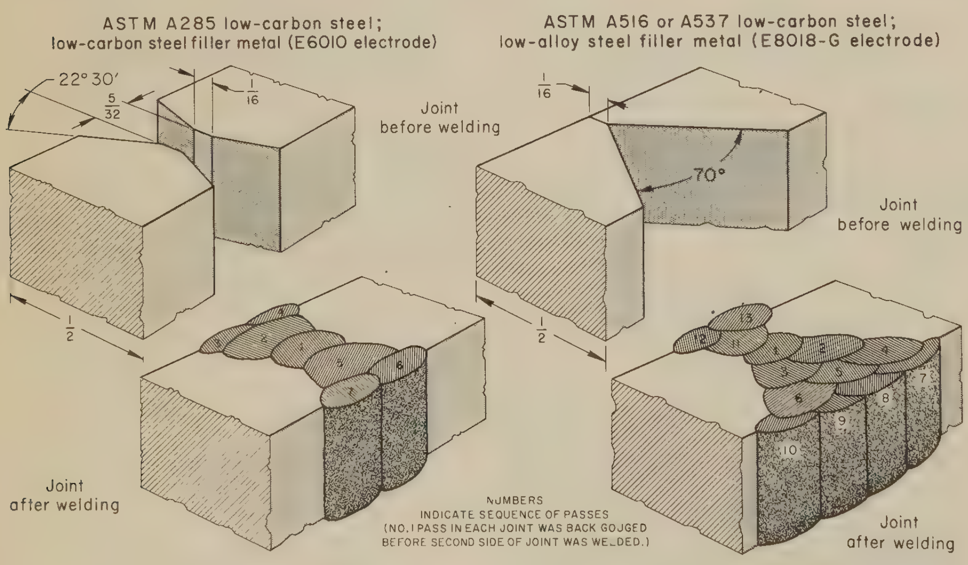
The service requirements of a weldment often influence joint design and welding procedure for groove welds. For example, the weld type (joint design), electrode class and size, number of passes, and the direction of welding for vertical seams in storage tanks usually depend on whether the tanks will be subjected to extremely low temperature or to normal temperature in service. Differences in the joint design and welding procedure for tanks intended for these two types of service are described in the next example.

Example 5. Use of Different Steels, Joint Grooves and Welding Procedures for Tanks Used at Normal and at Low Temperatures (Fig. 28)

Vertical joints in tanks intended for storage of anhydrous ammonia at −28 F were designed and welded differently from those in tanks designed for service at normal temperatures (ranging from outdoor ambient to that of hot asphalt). Figure 28 compares the two joint designs and shows the number and sequence of passes made in welding each. Welding conditions are compared in the table that accompanies Fig. 28.

Tanks for normal service were made of various grades of ASTM A285 low-carbon steel. A double-V-groove joint (Fig. 28a) was used to minimize the amount of deposited metal and to allow enough room for the electrode. E6010 electrodes were used because of their low cost. As shown in Fig. 28(a), the joint was welded in seven passes. Beads in passes 1, 2 and 5 were made with 5⁄32-in. electrodes in the vertical-up position. Beads in passes 3, 4, 6 and 7 (wash passes) were made with 3⁄16-in. electrodes in the vertical-down position. As shown in Fig. 28, pass 1 was back gouged (air carbon-arc) before welding the second side (pass 5). Back gouging was done with a 5⁄16-in.-diam carbon electrode at 300 to 350 amp.

Tanks for low-temperature service were of various grades of ASTM A516 or A537 low-carbon steel. A single-V-groove joint (Fig. 28b) was selected to provide good access and room for electrode manipulation



(a) Joint in tank for normal service (double-V-groove) (b) Joint in tank for low-temperature service (single-V-groove)

Edge preparation ....Gas cut and descale	Voltage and current (dcrp)(b):

Fig. 28. Groove designs and buildup sequences for vertical butt welds in storage tanks for normal service and low-temperature (−28 F) service (Example 5)

for the ½-in. plate thickness. As Fig. 28(b) shows, the joint was welded in 13 passes (ten on one side and three on the other); pass 1 was back gouged before pass 11 was made. Beads in all passes were made with ⅛-in. E8018-G low-alloy steel electrodes (iron-powder, low-hydrogen covering) in the vertical-down position, to minimize heat input and to obtain the greatest tempering effect on previous beads.

For many large storage tanks, the plates are not all of the same thickness. For instance, the lowest ring of a tank that was 120 ft in diameter and 48 ft high had a plate thickness of 0.83 in. The plate thickness of the other rings decreased as tank height increased; the thickness of the second ring was 11⁄16 in.; the third, 9⁄16 in.; the fourth, 0.41 in.; and the fifth and sixth, 5⁄16 in. An alternative approach in fabricating storage tanks is to use steels of various strengths and the same wall thickness, which sometimes reduces welding cost.

Wash passes, such as passes 3, 4, 6 and 7 in Fig. 28(a), are often used in welding seams in tanks. These light finishing passes blend and smooth the bead, improving corrosion resistance.

Thin Sections

The minimum thickness of low-carbon steel that can be welded by the shielded metal-arc process depends on welder skill, welding position, characteristics of the current, type of joint, fit-up, class and size of electrode, amperage, arc length, and welding speed.

Low-carbon steel sheet as thin as 0.036 in. has been welded successfully with flux-covered electrodes. Welding sheet this thin, however, requires exceptional skill and the use of electrodes smaller than 3⁄32 in. Fit-up and position must also be most favorable. Generally, the minimum practical sheet thickness for an average welder is 0.060 in. Procedures for welding steel sheet 0.060 in. thick are given in the paragraphs that follow; a typical procedure is given in Table 14. (See also Recommended Proportions of Grooves, pages 148 to 150.)

Electrodes used should be 3⁄32-in. or 1⁄16-in. E6012 or E6013, preferably with direct current, straight polarity. These electrodes can be used in all positions. If welds are vertical, however, the weld metal is deposited from top to bottom (vertical-down). Of the two types of electrodes, E6012 produces a smaller bead, with moderate penetration. E6013 electrodes, although depositing a larger bead, provide a very soft, low-penetrating arc, and therefore are often preferred for welding thin sheet. When only alternating current is available, E6013 electrodes are preferred for easier starting and arc maintenance.

Fit-up. Tight-fitting joints are essential for producing good welds at maximum welding speeds. At normal levels of welding current, even slight root openings, particularly in butt joints, may cause excessive melt-through, necessitating considerable repair work. Current can be reduced to prevent melt-through when fit-up is poor, but this makes the arc difficult to maintain and reduces welding speed. Melt-through due to poor fit-up can be minimized by the use of copper backing strips, if this is practical. Typical effects of poor fit-up are illustrated in Fig. 25.

Table 14. Typical Procedure for Shielded Metal-Arc Welding Square-Groove Butt Welds in 0.060-In.-Thick Steel Sheet

Electrode. Use 3⁄32-in. E6012 or E6013.
Current. Straight-polarity direct current, 50 to 60 amp at start; vary amperage as required. E6013 electrodes require slightly higher current than E6012 electrodes.
Welding Position. Keep longitudinal axis of joint within 45° to 60° from horizontal. Increasing the slope of the joint decreases both the penetration and the size of the weld; decreasing the slope does the opposite.
Technique. Weld from top to bottom, using a light drag technique with sufficient speed of travel to lead the weld puddle and slag. Electrode lead angle should be 10° to 30°.

Welding Speed and Current. With tight-fitting joints, welding should be done with the highest current and travel speed practical. The proper welding speed is obtained for any set of variables when electrode travel is fast enough to permit the arc to lead the weld puddle, but slow enough to provide the desired bead shape without undercut.

Welding speeds for 0.060-in.-thick steel sheet are so high compared with speeds for thicker sections that welders inexperienced in welding thin sections have difficulty in keeping the arc on the joint. To concentrate the arc on the joint, thus minimizing heat input, welding should be done with a slight drag technique — that is, the tip of the flux covering should lightly touch the work as the electrode is advanced.

Positioning the work so that the axis of the joint to be welded is 45° to 60° from horizontal enables maximum efficiency with good control over the weld deposit, permits the use of maximum welding current and travel speed, and minimizes melt-through.

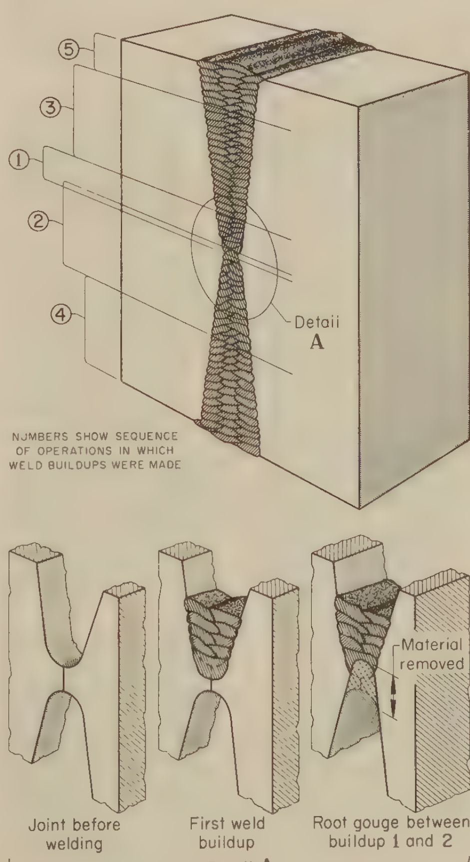

Fig. 29. Typical sequence of buildups in welding of thick sections with a double-U groove, using a root gouge between the first and second buildups

Tack welds should be as small as possible, because weld beads pile up when deposited over them. When uniform welds are required, it is beneficial to grind tack welds before welding, or to deposit them on the opposite side of the joint from which welding is to be done. Tack welds should be close enough to one another to prevent sheets from separating ahead of the arc. Separation of sheets is most prevalent in lap joints.

Thick Sections

All commercial thicknesses of low-carbon steel plate can be welded successfully by the shielded metal-arc process, provided that the root of the joint can be reached with the electrode.

Beveling is used on thicknesses above 3⁄16 or ¼ in. (see Recommended Proportions of Grooves, pages 148 to 150). A single groove is used on thicknesses up to about ¾ in.; a double groove is needed on thicker sections.

Three joint designs used in groove welding of sections over 4 in. thick are illustrated in Fig. 23. Figure 29 shows a typical sequence for welding thick sections with a double-U groove, using the root-gouging technique. In root gouging, the first buildup is made with a series of passes, as shown in the middle view in detail A in Fig. 29. The root of the weld is then gouged (usually by gas cutting or air carbon-arc cutting), as shown in the view at right in detail A in Fig. 29. The sequence of additional buildup operations, each of which consists of a series of passes, is shown in the top view in Fig. 29.

The major troubles that can occur in welding of thick sections are slag entrapment, porosity, transverse shrinkage (discussed below), angular distortion (discussed under "Distortion in Thick Sections", page 18), and cracking (see section "Causes and Prevention of Weld Defects", pages 18 to 20).

Transverse shrinkage is affected by restraint, volume of deposited weld metal, and welding procedure. Transverse shrinkage, which can be ¼ in. or more in full-section welds in plate 6 in. and upward in thickness, cannot be prevented, but it can be controlled or minimized by the use of one or more of the following design or welding practices:

1 Design groove joints for minimum volume of weld metal.
2 Weld temporary strongbacks across the joints before welding.
3 Use a block sequence in welding.
4 Make allowances in design to compensate for estimated shrinkage.
5 Peen all but the root and cover passes, using a blunt-nose tool. Peening should flatten the surface of the weld bead, but not cut into it. To retain notch toughness, do not peen at 500 to 900 F.

Sections of Unequal Thickness

In shielded metal-arc welding, as in other welding processes, special techniques are required when the components to be welded have a large

heat-sink differential (difference in heat-dissipating capacities).

When a thick member is joined to a thin member, the welding current needed to obtain good penetration into the thick member is sometimes too much for the thin member and will result in undercutting of the edges of the thin member and in a poor weld. If the proper amount of current for the thin member is used, the heat will not be sufficient to provide adequate fusion in the thick member, and again a poor weld will result.

A typical application involving components of unequal section thicknesses is the welding of heat-exchanger tubes having 0.093-in. wall thickness to a tube sheet as thick as 10 in. Here, the usual method of avoiding difficulty is to cut a ¼-in.-deep circular groove in the upper surface of the tube sheet around the opening for the tube, as shown in Fig. 30. By restricting heat transfer, this groove minimizes the heat-sink differential between the thin tube wall and thick tube sheet.

A more widely applicable method of minimizing heat-sink differential is to place a copper backing block against the thin member during welding (Fig. 31). The block serves as a chill, or "heat robber", for the thin member. It can be beveled along one edge so that it can be used when horizontal fillet welds are deposited on both sides of a thin member, as in Fig. 31. Copper backing bars or strips are made in a variety of shapes and sizes, to dissipate heat as needed. Often some experimentation is required to obtain the optimum backing location and design.

Another way to obtain equalized heating and at the same time obtain smooth transfer of stress where unequal section thicknesses are being welded is to taper one or both members to obtain a common width or thickness at the joint.

Distortion

Welding of any structure or member results in nonuniform heating and cooling at the point of welding. Thus it follows that welding will be accompanied by some distortion, and some unbalanced residual stress will be present. In practice, the amount of distortion from welding depends on several factors. In some weldments distortion may be so slight that it may be disregarded, while in others it may be so great that special precautions must be taken before welding, or straightening must be done after welding.

In many welded structures the residual stresses have little influence on the service life of the structure. On the other hand, in structures that are subjected to dynamic loading or those that must retain their shape and not distort during their service life, residual stresses are important.

Use of the following practices may assist in control of detrimental stresses and distortion which could impair the usability of a weldment:

1 The forming and preparation of steel sheet and plate induce stresses within the material. These may be released by the heat of welding and cause substantial difficulties. Thus, stress relieving of the components before welding is sometimes required.
2 On multiple-pass welds, angular distortion across the welded joint will increase with the number of passes.
3 A more uniform distribution of heat in a longitudinal seam can be obtained by welding with a backstep sequence or a wandering (skip) sequence. This practice also gives greater rigidity to the seam and results in less distortion.
4 Clamping will not entirely eliminate warping, but is more likely to be effective if the weld is permitted to remain in the clamps until cooled.
5 Peening the weld metal while it is hot has been very effectively used to reduce stresses and to minimize distortion or warping. (However, it is generally desirable to avoid peening in the temperature range of 500 to 900 F, because peening in this range may result in loss of notch toughness.)
6 Stresses may be substantially reduced if welding direction is away from the point of greatest restraint.
7 Changing the speed of welding may either increase or decrease distortion of the weldment. Experimentation may be essential to determine the optimum welding speed for specific joints where freedom from distortion is critical.
8 Residual stresses may be minimized by postweld heat treatment of the completed weldment. Proper support of the weldment is required to prevent warpage and distortion from occurring during stress relief.
9 Welding of parallel joints in opposite directions can sometimes minimize distortion (see Example 3 and Fig. 14).
10 Balancing of stresses by the use of a double groove, or by alternating the welding from one side of the joint to the other (as shown in Fig. 29).

Distortion in Thin Sections. Distortion or buckling is more often encountered in the welding of thin sheet. To minimize distortion, beads should be small and should be deposited as rapidly as possible. The cross section of any weld deposited on 0.060-in.-thick steel will normally be larger than that required for full strength (based on metal thickness). Intermittent welds, clamping fixtures, and copper backing bars effectively minimize distortion.

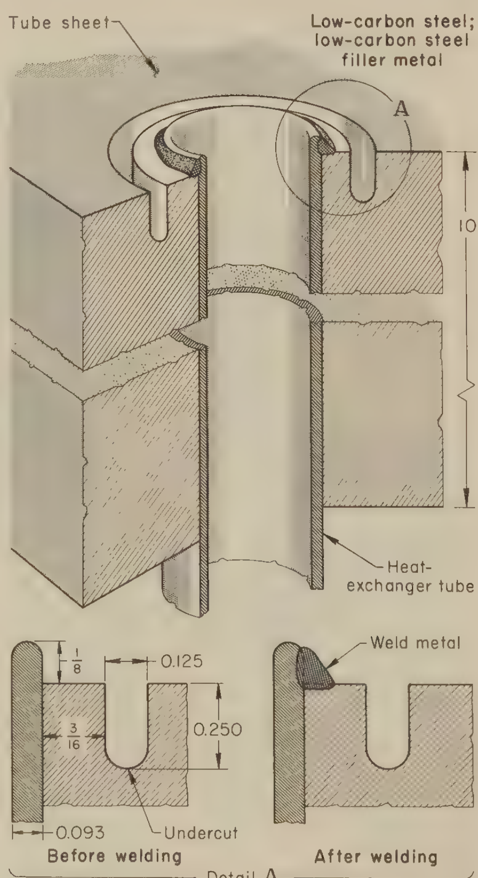

Fig. 30. Thick tube sheet with machined groove for minimizing heat-sink differential during welding of the thin-wall heat-exchanger tube to the tube sheet

Distortion in Thick Sections. Welding of thick sections is accompanied by angular distortion, which is caused by unequal shrinkage across the welded joint. Unequal shrinkage occurs because the welds are deposited in successive layers and because, in most joint designs, the width of the layers increases as the joint is filled.

Eliminating angular distortion in the welding of thick sections is virtually impossible when all welding is from one side. Temporary strongbacks, built-in ribbing, block-sequence welding, preheating, and peening will help to reduce angular distortion.

When individual plates a few inches thick are to be butt welded, presetting the plates opposite to the anticipated direction of angular distortion is effective for offsetting most of the distortion; during welding, the plates are permitted to move as a result of weld shrinkage into a flat plane. However, presetting is seldom possible when the thick sections to be welded are integral parts of structures. Also, presetting is impractical when sections 6 in. thick and thicker are welded from one side, because angular movement resulting from contraction of weld metal will tear apart the joint at the weld root.

Whenever possible, heavy sections should be welded from both sides. Joints should be designed so that both sides require the same volume of weld metal, and a balanced welding technique should be used (see Fig. 29). Balancing the welding on both sides of the joint results in good control over angular distortion, but when welding is done in the flat position, the workpiece must be turned over frequently, unless restraining devices are used.

Joint design is important for control of distortion. Groove angles should be the minimum size that will allow root penetration and accessibility for remaining passes.

Sequencing. Establishing the order of deposit in which the several passes in a weldment will be made is called sequencing. It may be extremely important to the final usability of the weldment that the welds be deposited in a precise order (buildup sequence). For pilot models of critical weldments, it may be necessary to change the sequence several times to obtain the optimum order of passes.

Causes and Prevention of Weld Defects

In the shielded metal-arc welding of steel, slag inclusions and porosity are common weld defects. Other defects that often occur are undercuts, longitudinal (centerline) cracks, underbead cracks, and gaps resulting from incomplete fusion. The appearance and usual locations of these defects are shown in

Fig. 32. Probable causes of several types of weld defects in steel, together with methods of prevention, are discussed in the paragraphs that follow.

Slag inclusions (Fig. 32a) may be the result of (*a*) incomplete deslagging of a previous pass; (*b*) wide weaving, which permits slag to solidify at the sides of the bead; (*c*) erratic progression of travel; (*d*) excessive amounts of slag ahead of the arc, particularly in deep grooves; and (*e*) use of electrodes that are too large. The preventive measures are, respectively: (*a*) to deslag deposits thoroughly before a subsequent weld bead is deposited; (*b*) to restrict the width of weaving so that the entire width of the slag immediately behind the weld puddle remains molten; (*c*) to use a uniform travel speed; (*d*) to keep slag behind the arc by shortening the arc, increasing the electrode angle, or increasing travel speed; (*e*) to use a smaller electrode.

Wagon Tracks. Linear slag inclusions along the axis of the weld are sometimes called "wagon tracks". They ordinarily result from failure to remove slag remaining from previous passes, or from allowing slag to run ahead of the weld puddle. Wagon tracks above the root pass have the same effect on weld quality as other inclusions in the weld metal or base metal.

Porosity that is scattered along the entire length of a weld bead (Fig. 32b) can be caused by (*a*) impurities, such as sulfur or phosphorus, in the work metal; (*b*) contamination of the surface of the work metal by rust, grease, moisture or dirt; (*c*) excessive moisture in electrode coverings; (*d*) improper arc length; (*e*) excessive current; (*f*) welding at a speed too high to permit gases to escape; and (*g*) freezing of the weld puddle before gases escape. The steps for avoiding the above causes of this type of porosity are, respectively: (*a*) changing to work metal of a different composition; (*b*) cleaning the work metal, and removing moisture from joint surfaces; (*c*) redrying electrodes to restore recommended moisture content of coverings (see Table 7); (*d*) using proper length of arc; (*e*) reducing welding current; (*f*) reducing travel speed to permit gases to escape; and (*g*) preheating the work metal or using a different class of electrode, or both.

When porosity occurs within the first ¼ to ½ in. of bead length, the most likely cause is moisture in the covering of the electrode — particularly if the electrode is of the low-hydrogen type. The remedy is to use dry electrodes.

Sometimes porosity occurs within the last inch or two of the weld bead when E6010, E6011 or E6012 electrodes are used. The usual cause is excessive current, which results in overheating and excessive drying of the flux covering. When this occurs, the current should be reduced to the recommended range.

"Wormhole" porosity (see Fig. 32c) is usually associated with moisture entrapped in the joint; when visible at the surface, wormhole porosity is sometimes referred to as "gas shoots". Sulfur in the base metal is also a contributing factor. One means of preventing wormhole porosity is to reduce travel speed to permit gases to escape before the metal freezes.

Undercuts (Fig. 32d) are usually due to excessive welding current, arc length and weaving speed. In horizontal or vertical welding, additional causes are excessive electrode size and incorrect electrode angles. Travel speed should be such that the deposited weld metal completely fills all melted-out portions of the base metal, and when the weaving technique is used, there should be a slight pause at each side of the weld. The arc should be as short as possible without shorting, and current should be appropriate for the electrode size and type and for the welding position.

Hot cracking occurs at elevated temperature, generally just after the weld starts to solidify. Hot cracks, which are for the most part intergranular, can be identified by a coating of oxide on their surfaces. Depending on the magnitude of strain, hot cracks will vary from microfissures to readily visible cracks.

Hot cracks are most likely to occur in the root-pass weld bead, because of the small cross section of the bead compared with the mass of material being welded. Hot cracking often occurs in deep-penetrating welds, and in welds in free-machining steels. If the initial crack is not repaired, it will usually continue through successive layers as they are deposited.

Hot cracking of the root bead may be minimized or prevented by preheating to modify strain, by increasing the cross-sectional area of the root bead, by using low-hydrogen electrodes, or by changing the contour or the composition of the weld bead.

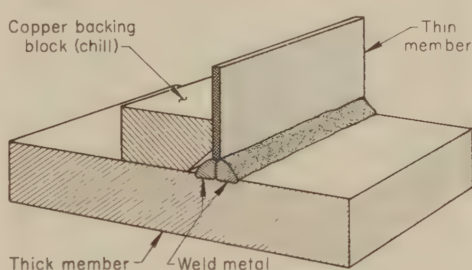

Fig. 31. Use of a copper backing block as a chill to minimize heat-sink differential in welding a thin member to a thick member

Cold cracking normally occurs in the heat-affected zone and near ambient temperature. Its occurrence may be delayed for as long as several days as stresses within the weldment relieve themselves. Cold cracking is generally recognized as being caused by excessive restraint of the joint, or by martensite formation as a result of rapid cooling. Low-hydrogen electrodes are used extensively to overcome cold cracking; preheating is also helpful. Although a stress-relief heat treatment cannot heal cracks that have already formed, it does reduce the residual stress sensitivity from welding, thus reducing susceptibility to fracture.

Centerline cracks (Fig. 32e) are cold cracks that often occur in single-pass concave fillet welds. The usual causes are an incorrect relationship between the size of the weld and the thickness of the work metal, poor fit-up, and overly rigid fit-up.

The usual ways of preventing centerline cracks are (*a*) positioning the joint slightly uphill so as to produce flat or slightly convex bead contours; (*b*) increasing bead size; (*c*) decreasing gap width or filling one side of the joint before welding the parts together; and (*d*) providing a small gap to allow movement during cooling.

Centerline cracks can occur as extensions of cracks in weld craters (see page 20) or root-bead cracks. The first extension of the crack may occur after the weld is completed and is cooling.

In one application of multiple-pass welding, centerline cracking occurred when an E6011 electrode was used for the root pass, an E6012 for the intermediate passes, and an E6020 for the final pass. The cracking was eliminated by reducing the number of passes with the E6012 electrode and increasing the depth of deposit with the E6020 electrode in the final pass.

Underbead cracks (Fig. 32f) are most frequently encountered when welding a hardenable base metal. Excessive joint restraint and the presence of hydrogen are contributing causes. Underbead cracking can be minimized or prevented by using low-hydrogen electrodes or by preheating joints to the temperature range of 250 to 400 F.

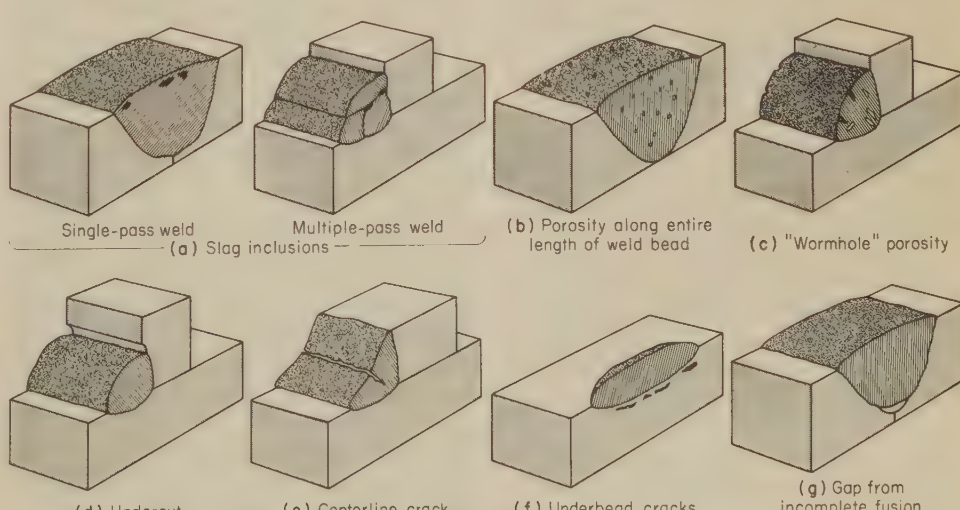

Fig. 32. Appearance and location of several common types of defects that can occur in welds made by the shielded metal-arc process

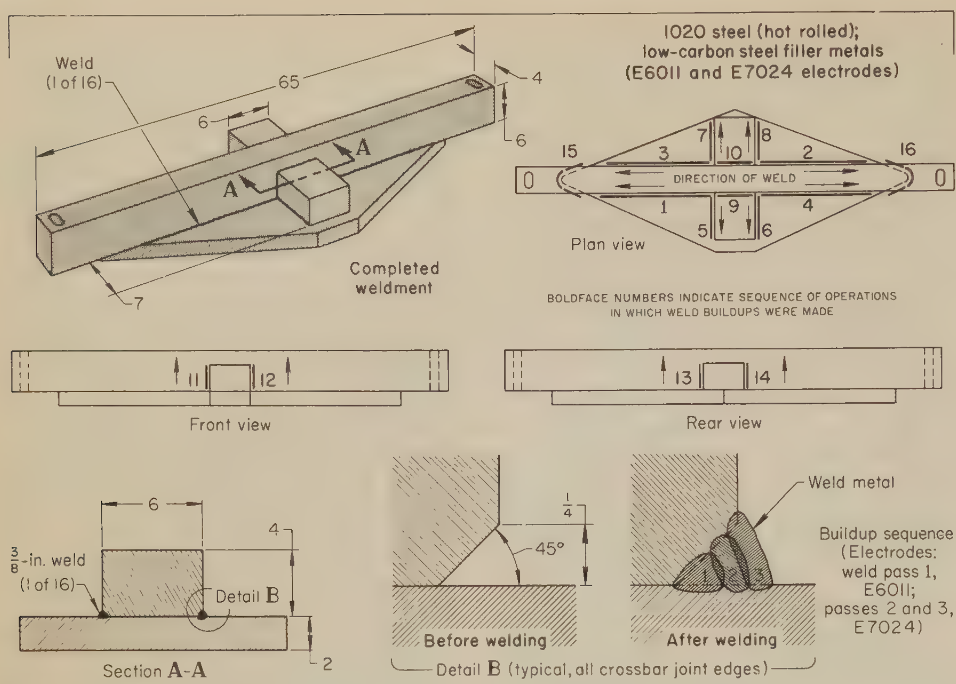

Fig. 33. Truck-axle weldment joined with 16 welds, in which cracking was prevented by beveling joint edges of the two 7-in.-long crossbars, welding in three passes instead of two, and welding in directions of decreasing restraint, in the sequence shown (Example 6)

Base-metal cracking usually originates in the heat-affected zone of the base metal as either hot or cold cracks. Cracks often extend into and through the weld metal. A reduction in welding stresses by, for instance, using weld metal with high ductility may alleviate the problem. The presence of a small slag inclusion or mass of porosity can increase the probability of cracking.

Cold cracks may originate at the toe of a weld and wander off in a random direction. Generally, increasing restraint of the base metal, increasing the thickness of the base metal, or increasing the length of the weld increases cold cracking. The probability can be decreased by preheating the base metal, by postheating after welding, by depositing the weld in an intermittent pattern, or by welding with higher currents.

Microfissuring can normally be detected only by the use of a microscope. It is caused by either hot or cold cracking. Extremely small cracks are not detrimental for many applications, but for applications involving fatigue, they make the weldment unacceptable.

Weld Craters. Weld craters are a recession of the surface and are caused by solidification of the molten weld puddle after the arc has been extinguished. Weld-crater cracks often serve as the origin of linear cracking. They are usually removed by chipping or grinding, and the depression is filled with a small deposit of filler metal.

A backstep or reverse-travel technique to fill each crater before breaking the arc has been found helpful in preventing crater cracking.

Arc Strikes. Striking the arc on the base metal outside the weld joint can result in hardened spots on the surface. Failures can occur due to notch effect. Welders should be cautioned to avoid indiscriminate marking of the base-metal surface with arc strikes, as it is unnecessary and may be harmful. Many codes prohibit striking the arc on workpiece surfaces.

Gaps from incomplete fusion may occur between the weld metal and the base metal (see Fig. 32g) or between the weld beads of a multiple-pass weld. Failure to obtain complete fusion can be caused by excessive travel speed, bridging, excessive electrode size, insufficient current, or poor joint preparation. Gaps usually can be prevented by reducing travel speed, improving joint preparation, or increasing the current.

Oxidation. Surface oxidation occurs when base metal or weld metal has been inadequately protected from the atmosphere. Severe drafts, which disrupt the protection offered by the gas shield, must be avoided, so that the weld metal and adjacent base metal are shielded until they have cooled enough to prevent harmful oxidation.

Sink or concavity is produced by surface tension on the surface of the weld puddle, which pulls the molten metal up into the joint, or by the effect of gravity when welding in the overhead position. If the condition is severe, root-bead cracking can result.

Weld Reinforcement. The reinforcement left on the weld can have a significant effect on the fatigue strength of the weldment at that point. It is customary on highly stressed weldments to remove the reinforcement by grinding it flush with the level of the adjacent base metal. Use of appropriate welding techniques will result in a weld reinforcement that is smoothly blended into the adjacent surface.

Overlapping (protrusion of the weld metal beyond the toe or root of the weld) is caused most often by (*a*) insufficient travel speed, which permits the weld puddle to get ahead of the electrode and cushion the arc; (*b*) incorrect electrode angle, which allows the force of the arc to push molten metal over unfused portions of the base metal; or (*c*) welding away from ground with large electrodes having very fluid weld puddles, such as E6020, E6027, E7024 and E7028.

To prevent overlapping, the travel speed should be such that the arc leads the weld puddle, and the electrode angle should be such that the force of the arc does not push the molten metal out of the puddle and over the cold base metal. Overlapping is corrected by grinding off the excess weld metal.

Excessive weld spatter, if coarse, often is caused by an excessive arc length; if the spatter is fine, excessive current is a likely cause. Weld spatter can be minimized by keeping the arc length at the minimum that will not result in shorting out. A slight drag technique is recommended when using electrodes with iron-powder coverings. Current should be kept within the range recommended for the specific electrode. To improve the surface appearance of the weld, spatter can be removed by grinding.

Effect of Number of Passes. The use of multiple passes is often effective in the prevention of weld cracks. For instance, multiple passes can be effective in fillet welding when cracking has resulted from single-pass welding, either because the carbon equivalent of the steel was borderline or because attempts to minimize distortion caused severe joint restraint in cooling.

The use of multiple passes (preferably a minimum of three) can sometimes eliminate the need for preheating or postheating when conditions are borderline. In multiple-pass welding, the first pass provides some preheating effect for the second pass, and the third pass provides a certain amount of postheating effect for the previous two passes, and so on. Welding should be done quickly, to minimize cooling between passes. Also, the first-pass weld bead must be deep-penetrating, and must be of sufficient size so that it will be strong enough to resist cracking. (If the first-pass bead cracks, the crack will usually propagate through subsequent beads.)

This technique is particularly adaptable to repair welding in the field, and has proved helpful in shop-welding applications as well (see Example 6). It should not be assumed, however, that the technique can always be considered as a substitute for preheating and postheating.

Cracking From Multiple Causes. In shop practice, weld cracking often has two or more causes, rather than a single cause. An application in which this occurred, and the series of corrective steps that were necessary before acceptable welds were produced, are described in the example that follows.

Example 6. Changes in Welding Procedure To Prevent Cracking (Fig. 33)

Figure 33 shows a four-piece 840-lb 1020 steel truck-axle weldment that required 16 fillet welds. In the original procedure, all of the ⅜-in. fillet welds were deposited in two passes with E7024 electrodes. Although the high degree of restraint during cooling of a 2-in.-thick plate would normally indicate the need for preheating to at least 200 F and possibly postheating for stress relief, welding trials made without heating appeared to be satisfactory; no cracking

was detected. However, when the truck axles were put in service, cracks appeared in some of the welds. Because heating facilities were not available at the plant, welding procedures were changed, in an effort to prevent cracking.

In the first revision, the size of the fillet welds was increased to ½ in. This reduced the cracking but did not eliminate it.

In the second revision, fillet size was increased to ¾ in. This further reduced cracking, but magnetic-particle inspection showed occasional cracks in the corners and in the top fillet welds of the two 7-in.-long crossbars. In addition, cost and appearance of the ¾-in. fillet welds were objectionable.

The third revision involved welding in the directions of decreasing restraint, in the sequence shown in Fig. 33. This also reduced cracking, but did not eliminate it.

In a fourth revision, the class of electrodes was changed — first, to low-hydrogen types (with tensile strengths of 70,000 to 110,000 psi), and then, because of their greater ductility, to austenitic stainless steel electrodes — but neither change resulted in a satisfactory solution to the problem.

Finally, the welds were made in three passes (rather than two, as in all previous procedures); a deep-penetrating root pass with a 5⁄32-in. E6011 electrode was followed immediately by two passes with 3⁄16-in. E7024 electrodes. This procedure greatly reduced the amount of cracking — largely because of the preheating effect of the first and second passes. A further improvement was obtained by cutting a ¼-in. bevel on the joint edges of the 7-in.-long crossbars (see detail B in Fig. 33), to increase penetration. Weld size was changed back to ⅜ in.

The three-pass welding and the edge beveling, in combination with the use of the directional welding sequence shown in Fig. 33, eliminated weld cracking.

Rating of Weldability

Some factors that determine whether a steel of a specific composition can be welded by conventional procedures include flexibility or rigidity of the structure, cooling conditions, skill of the welder, and weld-quality requirements. Welds that are good enough for many commercial applications can be made in low-carbon steel that has an abnormal content of inclusions, but these welds would not be good enough for severe service conditions. Furthermore, a steel that contains an abnormal content of carbon or alloying elements may be unsuitable for welding into complex structures, but completely satisfactory for simple structures. Resulfurized steels are highly susceptible to underbead cracking, porosity and hot cracking. In many applications, however, resulfurized steels can be successfully welded with low-hydrogen electrodes.

The weldability of a steel in terms of its susceptibility to cracking can be roughly estimated by use of a carbon equivalent (*CE*), which can be calculated using one of several formulas, such as the following equation (for other equations, see the article on Arc Welding of Alloy Steels, page 200):

$$CE = \%C + \frac{\%Mn}{6} + \frac{\%Cr}{5} + \frac{\%Mo}{4}$$

With this equation, it has been suggested that if the carbon equivalent is not more than 0.45%, the steel is considered weldable without any special precautions, such as preheating, postheating, or the use of low-hydrogen electrodes or of additional passes. However, weldability is dependent upon section thickness, as discussed on page 188 in the article on Arc Welding of Hardenable Carbon Steels.

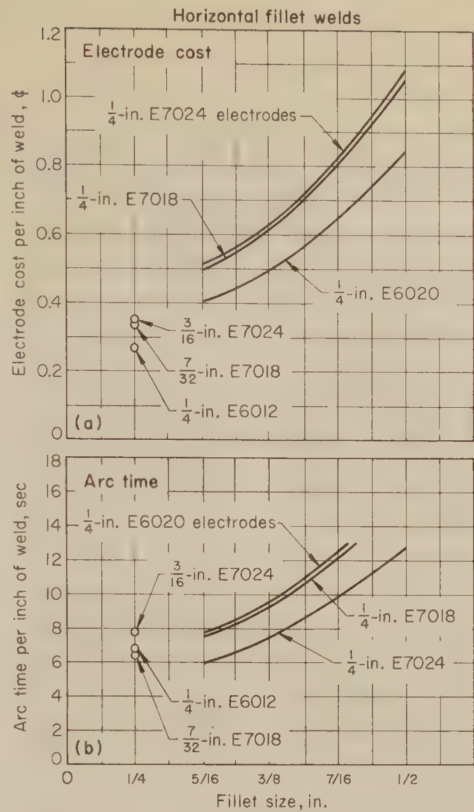

Fig. 34. Effect of electrode selection on electrode cost and on arc time for horizontal fillet welds of various sizes

Most high-strength low-alloy structural steels do not present serious problems in welding, even if their alloy content is high enough to raise their carbon equivalent above 0.45%. Welding practice for such steels, and for higher-alloy steels, is dealt with in the article on Arc Welding of Alloy Steels, which begins on page 200.

Effect of Surface Condition on Weld Quality

Many satisfactory welds are made without surface preparation, but quality is not usually high in such welds. The most common surface contaminants that adversely affect weld quality are carburization (resulting usually from improperly done gas or arc cutting), oxides and mill scale, shop dirt (usually oil and grease), paint, and moisture.

Surface carburization can result in cracking, because, in effect, a high-carbon steel is being welded. Carburized surfaces can be removed by grinding or other mechanical means.

The other contaminants listed above can result in weld porosity, or sometimes microporosity (which usually cannot be detected without magnification).

Abrasive blasting is a widely used method for removing mill scale, rust or other oxides in production welding. Grinding is used for odd jobs or for weldments that cannot be conveniently blasted. Oil and grease can be readily removed by wiping with a clean solvent, and then washing and drying if necessary. Paint must be removed from surfaces to be welded.

Moisture frequently is present on components that are welded outdoors or on components that are brought indoors just before welding. A humid atmosphere often causes a layer of moisture to form on workpiece surfaces. Surfaces should always be dry before welding. A gas torch may be used to drive off surface moisture.

In the following example, removal of surface oxide markedly improved weld quality.

Example 7. Use of Shot Blasting To Remove Surface Oxide and Reduce Porosity

Components of fuel tanks for industrial trucks were joined by shielded metal-arc welding. The components were made of hot rolled low-carbon steel ⅜ in. thick.

Originally, the completed weldment was shot blasted, but the components were not cleaned before welding. Although the surfaces to be welded were normally free from grease and oil, some tightly adherent oxide or mill scale was present on them; as a result, approximately 25% of the tanks leaked, because of porosity in the welds, and required repair.

When the procedure was changed so that shot blasting preceded welding, only 5% of the tanks leaked and the number of leaks per tank was reduced, as shown by the following comparison for an average lot size of 20 tanks:

Item	Shot blasting — After welding	Shot blasting — Before welding
Leaky tanks per lot	5	1
Leaks per tank	3	1
Time for repair and testing, minutes:		
Each tank	17	12
Total per lot	85	12

Cost

Many cost studies made to compare shielded metal-arc with submerged-arc welding and gas metal-arc welding have shown that, when welding conditions (mainly welding position, accessibility, and the amount of welding done without changing classes or sizes of electrodes) are favorable, shielded metal-arc welding is the most costly of the three processes. (See the examples that deal with costs in the articles on Submerged-Arc Welding and Gas Metal-Arc Welding in this volume.) Cost studies have also shown that if shielded metal-arc welding is used in a production application and electrodes of the same class and size are used for more than half the welding time, the use of a process that utilizes a continuously fed electrode should be considered.

Conversely, in applications where welding must be done in a variety of positions, or some areas are difficult to reach, or where specifications require frequent changes in class and size of electrode (or where all three conditions prevail), shielded metal-arc welding often is the lowest-cost process, and may well be the only practical one.

Effect of Electrode Selection on Welding Cost. Cost of electrodes and electrode performance must both be evaluated in calculating the effect of electrode selection on welding cost. Figure 34 compares electrode cost and arc time per inch of weld for horizontal fillet welds of various sizes made with electrodes of four different classes. Note that for ¼-in. electrodes used in making fillet welds ranging in size from 5⁄16 to ½ in., E7024 electrodes cost the most

but had the shortest arc times (best performance); at the opposite extreme, E6020 electrodes cost the least but had the longest arc times.

The example that follows presents a detailed analysis of costs for the use of E6013 versus E7024 electrodes in making ¼-in. horizontal fillet welds.

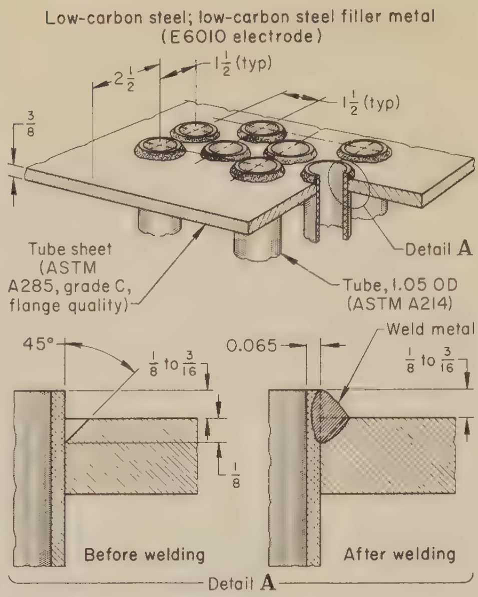
Example 8. Change From E6013 to E7024 Electrodes To Reduce Welding Cost (Table 15)

A cost study was made to compare the costs of ¼-in. horizontal fillet welds made with a conventional, all-position electrode (E6013) and with an iron-powder electrode (E7024). Three electrodes of each type were used for welding test pieces that consisted of two plates tack welded to form a T-section. Results of the cost study are presented in detail in Table 15. As this comparison shows, total cost was reduced nearly 10% when the E7024 electrodes were used, mainly because of decreased arc time. The E7024 electrodes cost slightly more per pound than the E6013, but this increase in electrode cost was partly offset by the decrease in weight of electrode used per inch of weld with the E7024 electrodes.

A disadvantage of the cost comparison in Example 8 is that all electrode variables cannot be evaluated without experience on similar jobs or additional data on the actual job. Cleaning costs, for instance, were not included.

Costs for chipping and repairing of defective welds are often major, and should be included in welding costs for assemblies.

Another variable is the ease of operation or the skill required to use an electrode. For example, a skilled welder might produce a horizontal fillet weld of good quality with a high-speed electrode, but an inexperienced welder might require a slower electrode to produce a fillet weld of equal quality.



Joint type	Circumferential corner
Weld type	Partial-penetration groove
Edge preparation	Holes drilled and beveled
Preheat	None (metal at 70 F min)
Welding position	Flat
Number of passes	One
Electrode	⅛-in. E6010, 12 to 14 in. long
Power supply	400-amp motor-generator
Current	80 to 120 amp, dcrp
Voltage	24 to 28 v
Arc length	⅛ to 3/16 in.
Electrode consumption	3 welds per electrode
Postheat	None

Shielded metal-arc welding was used because the available automatic machine for gas metal-arc welding (the process that had originally been used) could not accommodate the varying projection (⅛ to 3/16 in.) of the tubes above the tube sheet.

Fig. 35. Tube-to-tube-sheet weldment that was shielded metal-arc welded under the conditions shown in the table (Example 10)

When quality requirements are stringent, analysis must include the cost of inspection and repair. In the following example, cost analysis including costs for repair and reinspection showed that the use of more costly electrodes reduced welding cost.

Example 9. Cost Analysis Including Costs for Repair and Reinspection for E6010 or E6013 Electrodes vs Low-Hydrogen Electrodes

Repairs and reinspections were required in about 20% of the length of butt welds made in pressure vessels with E6010 or E6013 electrodes, but in only about 5% of the length of welds made with low-hydrogen electrodes. Although the low-hydrogen electrodes had a higher initial cost than the E6010 or E6013 electrodes, their use reduced the total cost of welding, as the following analysis shows:

- 1.0 = the cost of E6010 or E6013 electrodes plus the cost of depositing 1 ft of butt weld.
- 1.5 = the cost of low-hydrogen electrodes plus the cost of depositing 1 ft of butt weld.
- 5.0 = the cost of radiographing 1 ft of weld.
- 2.0 = the cost of repairing 1 ft of defective weld when E6010 or E6013 electrodes were used.
- 3.0 = the cost of repairing 1 ft of defective weld when low-hydrogen electrodes were used.

Using the five factors itemized above, the total relative costs for 100 ft of weld were calculated as follows:

E6010 or E6013 Electrodes (20% Repair)	
Original weld cost (100 × 1.0)	100.0
Inspection cost (100 × 5.0)	500.0
Repair cost (0.20 × 100 × 2.0)	40.0
Reinspection cost (0.20 × 100 × 5.0)	100.0
Total cost per 100 ft of weld	740.0
Cost per foot	7.4
Low-Hydrogen Electrodes (5% Repair)	
Original weld cost (100 × 1.5)	150.0
Inspection cost (100 × 5.0)	500.0
Repair cost (0.05 × 100 × 3.0)	15.0
Reinspection cost (0.05 × 100 × 5.0)	25.0
Total cost per 100 ft of weld	690.0
Cost per foot	6.9

Shielded Metal-Arc Welding vs Alternative Welding Processes

When more than one welding process can produce acceptable results, the choice depends primarily on equipment available, skill of the welders, number of similar weldments to be produced, and cost.

Shielded metal-arc welding is the most versatile arc welding process, but it is not always the lowest in cost or the fastest.

Although there are applications for which several welding processes may be suitable alternatives to shielded metal-arc welding, for most applications gas metal-arc welding and flux-cored arc welding are the two closely competitive processes. Both are faster than shielded metal-arc welding in terms of rate of metal deposited. Because both are semiautomatic processes (that is, the filler metal is supplied at an established rate from a coil), arc time can be a higher percentage of total time than in shielded metal-arc welding. In addition, both welding processes can be fully automated. Aside from these important advantages, however, gas metal-arc and flux-cored arc welding generally are less versatile than shielded metal-arc welding.

The two examples that follow describe applications for which shielded metal-arc welding was selected in preference to alternative processes.

Table 15. Analysis of Costs for Making ¼-In. Horizontal Fillet Welds With E7024 vs E6013 Electrodes, Computed From Rate of Welding (Example 8)

Data on Assembly To Be Welded	
Length of ¼-in. fillet weld specified on assembly drawing	250 in.
Labor cost per hour (including overhead)	$8.00
Labor time other than arc time required for making weld	16 min
Weight of linear inch of ¼-in. fillet weld	0.00884 lb

Item	3/16-in. E7024 electrode	1/4-in. E6013 electrode
Cost Comparison		
Electrode cost per pound	$0.14	$0.13
Weight of three electrodes	0.810 lb	0.931 lb
Weight of tacked specimen	10.00 lb	10.10 lb
Weight of specimen after welding	10.56 lb	10.72 lb
Weight of deposited metal	0.56 lb	0.62 lb
Arc time to make weld	3.85 min	5.32 min
Theoretical length of weld	$\frac{0.56}{0.00884} = 63.3$ in.	$\frac{0.62}{0.00884} = 70.1$ in.
Weight of electrode used per inch of weld	$\frac{0.810}{63.3} = 0.0128$ lb per in.	$\frac{0.931}{70.1} = 0.0133$ lb per in.
Cost of electrode to make an inch of weld	0.0128 × $0.14 = $0.00179	0.0133 × $0.13 = $0.00173
Time required to make an inch of weld	$\frac{3.85}{63.3} = 0.0608$ min per in.	$\frac{5.32}{70.1} = 0.0759$ min per in.
Labor cost per minute	$\frac{\$8.00}{60} = \$0.133$ per min	$\frac{\$8.00}{60} = \$0.133$ per min
Labor cost per inch of weld	$0.133 × 0.0608 = $0.00809 per in.	$0.133 × 0.0759 = $0.01010 per in.
Cost for arc time per inch of weld	Labor $0.00809 Electrode 0.00179 $0.00988 per in.	Labor $0.01010 Electrode 0.00173 $0.01183 per in.
Cost for arc time for assembly	250 × $0.00988 = $2.47	250 × $0.01183 = $2.96
Cost of labor other than for arc time	$0.133 × 16 = $2.13	$0.133 × 16 = $2.13
Total cost of welding assembly	$2.47 2.13 $4.60	$2.96 2.13 $5.09

Example 10. Change From Automatic Gas Metal-Arc Welding to Shielded Metal-Arc Welding Because of Wide Tolerances in Weldment Components (Fig. 35)

Figure 35 shows a tube-to-tube-sheet weldment used in a heat-transfer chamber for the condensation of refrigerant. Originally, automatic gas metal-arc welding was used for the partial-penetration groove welds in the circumferential corner joints (detail A in Fig. 35), but results were unacceptable because the head of the available automatic welding machine could not be adjusted for the varying projection (⅛ to $\frac{5}{16}$ in.) of the tubes above the tube sheet. For successful use of the machine, all tubes would have had to project a uniform distance. Because manufacturing tolerances were not that accurate, the process was changed to shielded metal-arc welding, under the conditions listed in the table that accompanies Fig. 35.

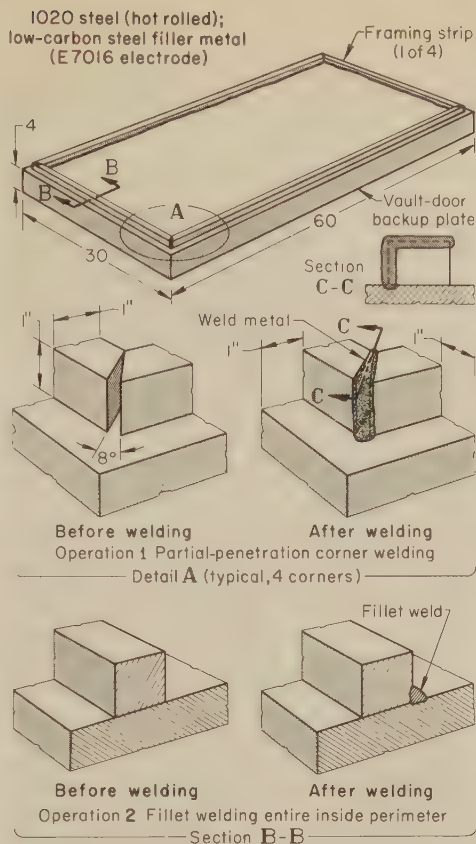
Shielded metal-arc welding, done in accordance with the ASME boiler code, produced complete fusion and leakproof joints (one leak in about 8000 welds). All joints were tested under water, with dry air at 300 psig.

Example 11. Use of Shielded Metal-Arc Welding Because of Low Production Quantity (Fig. 36)

For welding 1-in.-sq-bar framing strips to a vault-door backup plate (Fig. 36), shielded metal-arc welding was selected as the most practical process because production quantity was low. Both the plate and the framing strips were made of hot rolled 1020 steel.

After having been prefitted by gas cutting the edges at a 41° angle, the framing strips were positioned on top of the 30-by-60-in. backup plate and held in place with C-clamps.

Welding was done in two operations. First, the 1-in.-square bars were joined with partial-penetration welds at the corners (detail A and section C-C in Fig. 36) to form a frame (which served as a guide during final assembly of the vault door). Then the frame was joined to the plate by a fillet weld along the base of the entire inside perimeter of the frame (section B-B in Fig. 36). Quality was controlled by means of 100% visual inspection and spot checking with dye penetrant; rejection rate was zero.



Edge preparation (corner joints)	Gas cutting
Preheat and postheat	None
Welding positions	Vertical and horizontal
Number of passes per weld	One
Electrode	⅛-in. E7016, 14 in. long
Power supply	450-amp constant-voltage transformer-rectifier
Current	125 amp, dcrp
Voltage	22 to 24 v

Fig. 36. Vault-door backup plate to which framing strips were joined by shielded metal-arc welding, selected because production quantity was low (Example 11)

Safety

Invisible ultraviolet and infrared rays emitted in shielded metal-arc welding can injure unprotected eyes and skin. Therefore, protection for the eyes and skin is mandatory.

The best protection for the face and eyes is provided by a helmet that covers the face and contains a slit-type opening covered by a filtered lens. The optimum shade of the lens varies for different welders. It should be dark enough so that the arc can be viewed without discomfort, but not so dark that visibility during welding is impaired. The following shade numbers for use with specific electrode sizes are suggested: No. 10 for electrode sizes of $\frac{1}{16}$ to $\frac{5}{32}$ in.; No. 12 for sizes of $\frac{3}{16}$ to ¼ in.; and No. 14 for $\frac{5}{16}$-in. and ⅜-in. electrodes.

Protective clothing must be fire resistant, and heavy enough to prevent passage of harmful rays. Heavy gloves should be worn to protect hands from harmful rays, and to prevent burns. Safety shoes should also be worn. The welding area should be isolated by curtains or shields, for protection of persons in the vicinity.

During deslagging of welds, helmets or safety glasses should be worn to protect eyes from flying particles.

The welding area must be adequately ventilated, because heavy concentrations of smoke and fumes are generated. Arc welding also produces ozone, which is another reason for providing good ventilation. When welding is done in small, confined areas, such as inside a tank, an external air supply furnished by use of a mask or special helmet may be required. In addition, a second person should be stationed at the tank manhole to provide assistance to the welder if necessary.

Special ventilation is required when metals coated with copper, zinc, lead or cadmium are welded, because fumes from these metals are toxic.

Precautions in installing and operating the electrical components used in shielded metal-arc welding are the same as those for other electrical devices with similar output and voltage capacities. Grounding should be solid.

Rules and regulations for installation and operation of welding equipment vary among states. Therefore, the State Industrial Commission and local governments should be consulted on applicable safety regulations before equipment is installed.

For detailed information on the safety practices discussed above, and on other precautions, safe practices, contaminants and hazards in welding, the reader is referred to "Safety in Welding and Cutting", ANSI Z49.1, American National Standards Institute.

Shielded Metal-Arc Welding of Metals Other Than Low-Carbon Steel

As stated earlier, shielded metal-arc welding is commonly done on many metals other than low-carbon steel. Table 16 lists the examples elsewhere in this volume that describe shielded metal-arc welding of other metals.

Table 16. Examples of Shielded Metal-Arc Welding Presented Elsewhere in This Volume

Metal welded	Example number	Subject of example
Low-carbon steel	12, 13, 22, 23, 27-31	Shielded metal-arc vs flux-cored arc welding
	69	Comparison of costs for four welding processes
	70-75	Shielded metal-arc vs submerged-arc welding
	76	Welding conditions for three processes
	104	Comparison of costs and welding conditions, shielded metal-arc vs gas metal-arc welding
	107-120	Comparison with gas metal-arc welding (production rates and welding conditions)
	152	Hard facing a plate
Medium-carbon steel	149, 150, 155	Hard facing selected surfaces
	181	Welding heavy channel sections back-to-back
Alloy steel	148	Hard facing an austenitic manganese steel
	198	Conditions for welding 5145 steel to 1020 steel
	208, 209	Conditions for welding various alloy steels
	211	Welding of manganese steel to alloy steel
	216, 218	Shielded metal-arc vs gas metal-arc welding
	220	Welding 3½% nickel steel pipe
	223	Weld porosity, using 2% Mn steel electrodes
Stainless steel	196, 210	Conditions for welding stainless to Cr-Mo steel
	244, 269	Conditions for welding type 347 stainless pipe
Tool steel	163, 206	Repair welding of cracked and worn dies
	165, 166	Hard facing of cutting edges on shear blades
Cast steel	199	Welding of cast steel to low-carbon steel
	204	Welding for repair of casting defects
	267	Joining of stainless steel castings
Gray iron	229, 230	Welding to repair cracks and casting defects
	231, 233	Welding of gray iron to low-carbon steel
	232	Conditions for joining of two castings
Ductile iron	234	Repair of machining and casting defects
	235	Conditions for joining of two castings
Malleable iron	238	Welding of malleable iron to low-carbon steel
Heat-resisting alloy	284	Repair of a defect in a Thermalloy B casting
Copper alloy	336	Welding aluminum bronze to low-carbon steel
	338	Butt welding alloy 715 (copper nickel) pipe
Nickel alloy	354	Welding Monel to nickel-plated steel pipe
	356	Welding Monel to Monel and to low-carbon steel

Flux-Cored Arc Welding

*By the ASM Committee on Gas Metal-Arc Welding and Flux-Cored Arc Welding of Steel**

FLUX-CORED ARC WELDING is a process in which the heat for welding is produced by an arc between a tubular consumable electrode wire and the work metal, with shielding provided by gas evolved during combustion and decomposition of a flux contained within the tubular electrode wire, or by the flux gas plus an auxiliary shielding gas. Thus, there are two major versions of the process: one that uses both an auxiliary shielding gas (usually carbon dioxide) and shielding obtained from the flux core of the electrode; and the self-shielding method, which depends for shielding on combustion and decomposition of flux-core compounds.

Both methods of flux-cored arc welding are closely related to other arc welding processes. The method that uses an auxiliary gas shield is similar to gas metal-arc welding, which employs a solid consumable electrode and depends on an externally applied gas shield for protecting the arc and molten metal from contamination by the atmosphere. The self-shielding method is more closely related to shielded metal-arc welding, which also depends on the combustion and decomposition of a solid flux to provide the gaseous shield. In shielded metal-arc welding, the flux is on the outside of the electrode, which limits the form of the electrode to a straight length (a "stick electrode"), whereas in flux-cored arc welding, the flux is inside a tubular electrode, which can be coiled and supplied to the arc as a continuous wire. (For a size comparison, see the bottom row in Fig. 5.)

Applicability

Applications of the two methods of flux-cored arc welding overlap considerably. However, the specific characteristics of each process make it suitable for different operating conditions.

Flux-cored arc welding with auxiliary gas shielding is used mainly for welding carbon and low-alloy steels and has been used successfully for welding stainless steels. The method is applicable to semiautomatic work (manually manipulated electrode holder) and to the various machine and automatic welding procedures (in which the electrode holder is held mechanically). It is also adaptable to arc spot welding.

Originally, flux-cored arc welding with auxiliary gas shielding was restricted to welding in the flat and horizontal positions, because tubular electrode wires were available only in relatively large diameters. With these large-diameter wires, the welder was unable to control the weld puddle when welding in the vertical and overhead positions. This position restriction no longer holds, partly because small-diameter electrode wires (as small as 0.035 in. in diameter) have become available and partly because electrode-wire compositions that are better suited to out-of-position welding have been developed. Now, flux-cored arc welding with auxiliary gas shielding is an all-position process. It is applicable to a wide range of work-metal thicknesses, beginning with metal as thin as $\frac{1}{16}$ in.

Because of the protection offered by auxiliary gas shielding, a spray-type arc, at high current density, can be used, which results in maximum joint penetration. An arc producing globular transfer and a short-circuiting arc can also be used. The latter types of arcs are produced at lower current density and result in shallower penetration, and are therefore better suited to the welding of thin sections and to out-of-position welding. (All three types of arc are shown in Fig. 2, page 79, in the article on Gas Metal-Arc Welding.)

Joints made by flux-cored arc welding with auxiliary gas shielding meet the quality requirements of many codes; radiographs of welds show that sound deposits that meet exacting face and root bend tests can be produced. In many applications, flux-cored arc welding with an auxiliary gas shield is competitive with gas metal-arc welding; in other applications, it is competitive with submerged-arc welding.

A disadvantage of flux-cored arc welding is that the deposit is covered with solid slag, much the same as, although thinner than, the deposit made by shielded metal-arc welding. This slag is usually removed between welding passes. (With certain flux-cored electrodes, slag removal is not required on two-pass horizontal fillet welds.) Consistency and adherence of the slag depend on the composition of the electrode wire. Some slag coverings crack during cooling and can be easily removed with a wire brush; others adhere firmly and must be broken up with a deslagging hammer to permit removal by wire brushing.

Flux-Cored Arc Welding With Self Shielding. This method of flux-cored arc welding has become popular for many applications, mainly because of the simplicity of operation that results from the absence of the equipment necessary for gas shielding. In addition, the electrode holder is simpler than that required for use with auxiliary shielding gas. Because the self-shielding method does not penetrate as deeply as the auxiliary-gas-shielded method, it can be used under conditions of poor fit-up to better advantage. The self-shielding method is used mainly for welding carbon steels, but has been used successfully for welding some low-alloy steels, and at least one company has developed flux-cored electrode wires for welding austenitic stainless steels.

The self-shielding method can be used for out-of-position welding by selection of a small-diameter electrode wire of suitable composition, just as for the auxiliary-gas-shielded method. The range of work-metal thickness is the same for both methods.

Flux-cored arc welding without an auxiliary gas shield is not suited to a spray-type arc. Because metal is transferred from the outside of the electrode to the weld puddle, protection from oxidation in this area is minimum without an auxiliary gas shield. When a fine spray is developed, the total surface area of the metal particles is large, which results in excessive oxidation. Therefore, the self-shielding method should be operated with globular or short-circuiting metal transfer.

The quality of welds made by self-shielding flux-cored arc welding is gen-

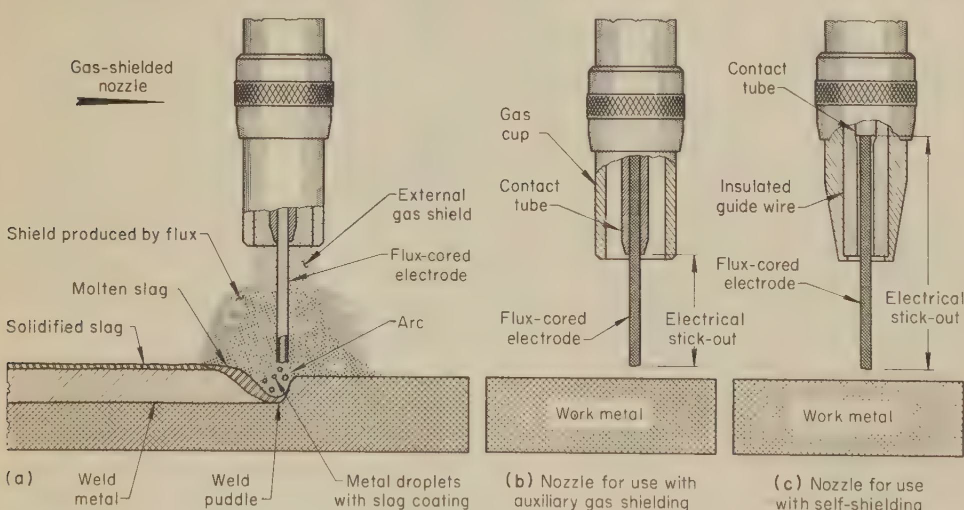


Fig. 1. (a) *Operating principles for flux-cored arc welding with auxiliary gas shielding;* (b) and (c) *nozzles for auxiliary-gas-shielded and for self-shielding methods of flux-cored arc welding (note difference in lengths of electrical stickout).*

*For committee list, see page 78. More than half of the examples presented in this article were contributed by members of other Metals Handbook welding committees. A total of 13 examples of flux-cored arc welding appear in other articles in this volume, as recorded in the table at the end of this article (page 45).

erally lower than that of welds made with auxiliary gas shielding. The main cause of lower weld quality is the greater contamination of the weld deposit by the atmosphere during welding; another cause is the presence of gas-forming and deoxidizing elements in the flux core of the electrode wire. The mechanical properties adversely affected are ductility and impact strength, particularly at low temperature. Some codes do not permit the use of self-shielding flux-cored arc welding for steels having a yield strength greater than 42,000 psi.

A major advantage of the self-shielding method is that it can be used in a draft, as can shielded metal-arc welding — although such practice is not recommended for either process.

Fundamentals of the Process

Basic equipment requirements for flux-cored arc welding are essentially the same as for gas metal-arc welding — that is, a power supply, a wire feeder to advance the electrode wire as it melts to form the weld deposit, an electrode holder, and, when appropriate, a means of supplying auxiliary shielding gas. These components are shown in Fig. 1 of the article on Gas Metal-Arc Welding (see page 78).

Likewise, the arc characteristics that can be obtained in flux-cored arc welding are essentially the same as those in gas metal-arc welding. The spray arc, the globular type of transfer, and the true short-circuiting arc are shown in Fig. 2 of the article on Gas Metal-Arc Welding (see page 79).

Principles of Operation. The flux-cored wire is the main difference between gas metal-arc welding and flux-cored arc welding with an auxiliary gas shield (see Fig. 1a). The flux core provides a molten slag that covers the weld metal, and a gas that assists in shielding of the arc. The necessary equipment, including the electrode holder, is essentially the same for both of these processes.

Aside from the use or nonuse of auxiliary shielding gas, the self-shielding and auxiliary-gas-shielded methods differ mainly in the type of electrode holder used and in the length of electrical stickout. As illustrated in Fig. 1(b), with the type of electrode holder used with the auxiliary-gas-shielded process, the contact tube extends nearly to the end of the gas cup, so that the electrical stickout (distance from the end of the contact tube to the weld puddle) is nearly the same as the visible stickout (distance from the end of the gas cup to the weld puddle). Electrical stickout is the more meaningful term and is generally what is referred to when the word "stickout" is used without qualification. In many electrode holders, the distance from the end of the contact tube to the end of the gas cup is ⅜ in. or more, about the same as for gas metal-arc welding. Electrical stickout is commonly about ¾ to 1 in.

For the self-shielding method, a much greater electrical stickout is used — 2½ in. or more — as indicated in Fig. 1(c). Because no provision need be made for shielding gas, the space at the end of the electrode holder can be occupied

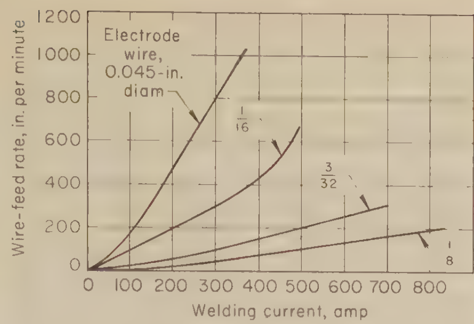

Fig. 2. Interrelation of wire-feed rate and welding current for four sizes of electrode wire, using carbon dioxide shielding gas

by an insulated wire guide, which prevents the wire from touching the end or nozzle portion of the electrode holder. The use of a longer electrical stickout allows a higher deposition rate, since the electrode wire is preheated more because of the greater distance along which the welding current flows through the electrode.

Power Supply

Alternating current is seldom used for welding with flux-cored electrode wires. Direct current supplied by a rectifier, motor-generator, or engine-driven generator and operated with reverse polarity is generally used; straight polarity is also used, although only to a limited extent.

Either of two general types of power supply can be employed: the constant-current type (drooping voltage characteristic), such as is commonly used for shielded metal-arc welding, or the constant-voltage type, originally developed for use with gas metal-arc welding. When a constant-current power supply is employed, it is usually matched to an arc-voltage-sensing electrode-wire feeder. A constant-voltage power supply, which is the type most often used for flux-cored arc welding, should be employed only for continuous-feed electrode-wire processes. The electrode wire is fed into the arc at a specific rate, and it automatically draws the amount of current from the constant-voltage power supply required to maintain the preset arc voltage. If wire-feed rate is increased, current increases and, of course, deposition rate increases. This system is simple to control. Figure 2 shows the interrelation of wire-feed rate and welding current for four common sizes of flux-cored electrode wire.

Various models and sizes of constant-voltage power supplies are available, most of which incorporate slope and inductance control. Power supplies that can be varied in slope and inductance are more versatile and can be used for a wide variety of conditions.

For further discussion of power supplies suitable for flux-cored arc welding and gas metal-arc welding, see page 80, in Gas Metal-Arc Welding.

Electrode Holders

Electrode holders for auxiliary-gas-shielded flux-cored arc welding are similar to those used for gas metal-arc welding. Various sizes, ratings and styles, suitable for both semiautomatic and automatic welding, are available. Both air-cooled and water-cooled electrode holders are made. Air-cooled holders depend on radiation of heat to the surrounding air for cooling, although the shielding gas, which is quite cold as it passes through the holders, helps to cool them. Choice of holder depends largely on the welding current and shielding gas used. When current is 500 amp or more, a water-cooled electrode holder is usually employed. Some welders prefer water-cooled holders when using welding currents of less than 500 amp.

Three types of electrode holders are shown on page 82, in the article on Gas Metal-Arc Welding, together with additional discussion of electrode holders for use with a shielding gas.

Electrode Holders for the Self-Shielding Method. The same electrode holder can be used for self-shielding flux-cored arc welding as is used for the auxiliary-gas-shielded method, by not making the gas connections. Ordinarily, the electrode holder requires minor modification for use without auxiliary gas shielding — for example, a longer stickout is used (Fig. 1). Actually, it is uncommon to use the same electrode holder for self-shielding welding as for welding with an auxiliary gas shield. Electrode holders of various sizes and styles are made especially for self-shielding flux-cored arc welding. Typical hand-manipulated and mechanically manipulated electrode holders are shown in Fig. 3.

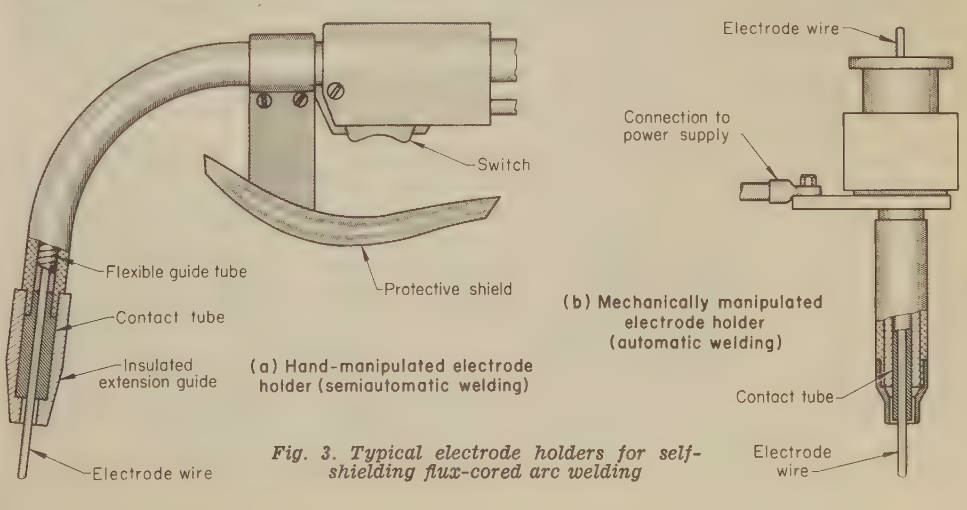

Fig. 3. Typical electrode holders for self-shielding flux-cored arc welding

Cooling systems for water-cooled electrode holders are of two types. In the most widely used system, water is obtained from a pressurized fresh water source, passed through the electrode holder, and discharged. If the welding location is not near a water line, a tank about the size of a common 200-cu-ft compressed-gas cylinder and an electric-motor-driven pump to recirculate the water are employed. This system can be mounted on the portable truck that holds the other welding equipment.

Wire-Feed Systems

Because constant-voltage power supplies are used most often for both methods of flux-cored arc welding, a constant wire-feed system is needed (see section on Power Supply, page 25).

A push-type wire-feed system is universally employed for both methods, for three reasons: (*a*) electrode-wire diameter is fairly large — the smallest size made is 0.035 in. in diameter and the smallest size commonly used is 0.045 in. in diameter; (*b*) because all electrode wires are made of steel and are stiff, feeding is greatly facilitated with a push-type feeder; and (*c*) because the feed mechanism is not located in the electrode holder, the holder weighs less and is easier to manipulate.

The system used for feeding flux-cored wire is similar to that used for feeding solid wire (see the section dealing with wire-feed systems on page 82 in "Gas Metal-Arc Welding").

Push-Type Systems. In a push-type wire-feed system, the electrode wire is pulled from a reel by feed rolls and pushed through a flexible wire conduit to the electrode holder and thence into the arc. A constant rate of feed is mandatory in a constant-voltage system, but the feed rate must be capable of adjustment in order to obtain the required welding current.

A four-roll feeder is shown in Fig. 4(a). In this feeder, all four rolls are driven. Push-type feeding systems vary considerably among manufacturers. Some have only two rolls — one driven roll and one pressure roll. The design must ensure that the roll speed and pressure can be varied and that the rolls can be changed quickly.

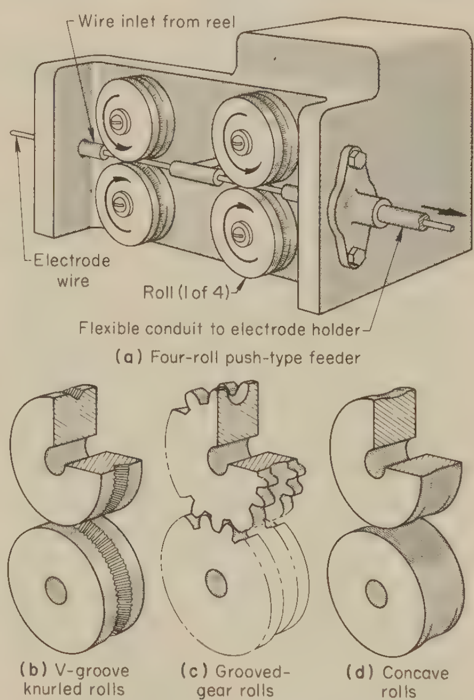
Push-type wire-feed systems are coupled electrically to the power supply. For convenience, wire feeders are most often mounted on the power supply, although they have been separated from the power supply by distances up to 200 ft. They can be mounted on overhead jib cranes or booms, thus allowing the welder to cover a large area, and they can be located on the shop floor, on the ground, or on overhead scaffolding.

Table 1. Composition Requirements for Weld Metal From Flux-Cored Electrodes (AWS A5.20-69) (a)

AWS classification	Weld-metal composition, %, max(b) Mn	Si	Ni	Al
E60T-7	1.50	0.90	0.50	1.8
E60T-8	1.50	0.90	0.50	1.0
E70T-1	1.75	0.90	0.30(c)	...
E70T-4	1.50	0.90	0.50	1.8
E70T-5	1.50	0.90	0.30(c)	...
E70T-6	1.50	0.90	0.80	...

(a) Composition is not specified for E70T-2, E70T-3 or E70T-G electrodes. Also, carbon, phosphorus and sulfur are not specified for any flux-cored electrodes. (b) 0.20 Cr, 0.30 Mo, and 0.08 V may be present, but are not included intentionally. (c) May be present, but is not included intentionally.

A given joint may require the use of electrodes of two different sizes. A typical application would call for a root pass to be made by gas metal-arc welding, employing a very-small-diameter solid wire and for the weld to be completed by flux-cored arc welding, using a larger-diameter wire. A wire-feed system capable of supplying electrode wire to either of two electrode holders is available for such applications. This type of wire feeder has two electrode-holder-and-cable assemblies and two sources of wire. By actuating a switch and picking up the appropriate electrode holder, the welder can select gas metal-arc welding or flux-cored arc welding. A single power supply is used. With some models, two motors are employed for driving the two wire feeders, and in other models, the two wire feeders are driven by a single ¼-hp motor and a dual drive.



(a) Four-roll push-type feeder, in which all rolls are driven. (b) V-groove knurled feed rolls, used for electrode wire of medium to large diameter. (c) Grooved-gear feed rolls, used for soft flux-cored electrode wire. (d) Concave, smooth-face rolls, used for small-diameter wire.

Fig. 4. Electrode-wire-feed system and three designs of feed rolls

Feed Rolls. Because of their tubular construction, flux-cored electrode wires are easily flattened. As a result, the design of the feed rolls is critical. Various types of grooved, grooved and knurled, and concave rolls have been used successfully (see Fig. 4).

It is important to select rolls that are compatible with the wire size; rolls must be changed when there is an appreciable change in wire diameter. The V-groove knurled rolls shown in Fig. 4(b) are commonly used for feeding wires with a diameter greater than about 1/16 in. This type of roll is lightly knurled so that the wire can be fed without slipping and without the use of excessive pressure.

Another type of feed roll, shown in Fig. 4(c), is used in a two-roll wire feeder. Each roll is a gear having a round groove with the same radius as the wire to be fed. The groove is cut into both rolls but is cut only part way through the tooth. The grasp of the wire is by the relatively flat surface of the groove. The advantage in this type of roll is that it does not mar the surface of soft flux-cored wires.

Small-diameter wires (for example, 0.045 in.) are less easily flattened than are larger-diameter wires, and simple concave rolls without knurls, as shown in Fig. 4(d), are usually satisfactory.

Maintenance of Feed Systems. Wire-feeding mechanisms require scheduled regular maintenance to ensure a smooth and constant delivery of wire to the arc. The guides, feed rolls, and reels must be properly aligned and adjusted, and the wire conduit must be cleaned at regular intervals, normally before a fresh reel of wire is put into service. This should be done by removing the wire and blowing clean air or shielding gas through the conduit.

Flux-Cored Electrode Wires

Flux-cored electrode wire consists of a low-carbon steel sheath surrounding a core of fluxing and alloying material.

Manufacture of flux-cored electrode wire is a specialized and precise operation. Most flux-cored electrode wire is made by passing low-carbon steel strip through contour-forming rolls that bend the strip into a U-shape cross section. The U-shape product is then filled with a measured amount of granular core material (flux) by passing it through a filling device. Next, the flux-filled U-shape strip passes through closing rolls that form it into a tube and tightly compress the core materials. The tube is then pulled through drawing dies that reduce its diameter

Table 2. Shielding and Current Type for Flux-Cored Electrodes, and Mechanical-Property Requirements for Weld Deposits (AWS A5.20-69)

AWS classification	Shielding gas	Current and polarity	X-ray	Minimum properties of weld metal: Tensile strength, psi	Yield strength, psi	Elongation in 2 in., %	Charpy V-notch impact, ft-lb

(a) Not required. (b) Not specified. (c) For multiple-pass electrodes.

and further compress the core materials. The drawing operation secures the core materials inside the tube. The electrode may or may not be baked during or between drawing operations, depending on its type.

Additional drawing operations are performed to produce different sizes of electrode wire. The standard sizes are 0.045, 1/16, 5/64, 3/32, 7/64, 1/8 and 5/32 in. in diameter (0.035-in.-diam wire is available in limited quantities). The 3/32-in.-diam wire is the size most widely used; 5/64-in. wire is also popular.

The finished electrode wire is wound into a continuous coil or onto spools, as required. Various standardized methods of packaging are in use; most electrode wire is wound into 25-lb and 50-lb spools and 60-lb coils, but other sizes and forms are used on occasion. The spools and coils are placed in moistureproof plastic bags and then in shipping boxes, to ensure that deterioration does not occur.

Functions of the compounds contained in the core (see the Appendix to this article) are similar to those in the covering on the stick electrodes used for shielded metal-arc welding, which are:

1 To act as deoxidizers or scavengers to help purify the weld metal and produce a sound deposit
2 To form slag to float on the molten weld metal and protect it from the atmosphere during solidification
3 To act as arc stabilizers to produce a smooth welding arc and reduce weld spatter
4 To add alloying elements to the weld metal to increase weld strength and to provide other required weld-metal properties
5 To provide shielding gas.

Construction. Several styles of flux-cored electrodes are shown in cross section in Fig. 5. In the three styles shown in the top row of the illustration, the steel portion of the electrode comprises about 75 to 85% of the total weight and about 75% of the cross-sectional area of the electrode.

The amount of flux contained in the core of a flux-cored electrode is less than is used on flux-covered stick electrodes of comparable size (see bottom row in Fig. 5), because the covering on stick electrodes must contain binders to keep the covering adherent and continuous, and constituents that enable it to be extruded.

Comparison of a typical flux-covered electrode with a typical flux-cored electrode shows the percentage of steel in each to be as follows:

	Flux-covered E7016	Flux-cored E70T-1
Steel by area	45%	75%
Steel by weight	76%	85%

Metal transfer from consumable electrodes across an arc is by the spray, globular or short-circuiting mode.

On cored electrodes, the molten droplets form on the periphery (or sheath) of the electrode. A droplet forms and is transferred, and then another droplet forms at another location on the metal sheath and is transferred. The core material appears to transfer to the weld-puddle surface independently.

At low current densities, the droplets are larger than at high current densities. For instance, the transfer from a 3/32-in.-diam flux-cored electrode was observed at 350, 425 and 550 amp, respectively. At 550 amp, it appeared that some metal was being transferred by spray. Large droplets, which formed at lower current densities, caused splashing as they entered the weld puddle, thus increasing the amount of visible weld spatter. This explains why there is less visible spatter, the arc appears smoother, and deposition efficiency is higher when current density is high.

Classification of Electrodes. Nine types of flux-cored electrodes are covered by AWS specification A5.20-69, although the manufacturers of electrodes produce numerous other types that have not been classified by the American Welding Society. The composition requirements for weld metal deposited from six standard electrodes are given in Table 1. Note that no carbon content is specified. The carbon content of an actual weld will depend largely on the carbon in the base metal, somewhat on the carbon in the electrode, and to a slight extent on the shielding gas, if carbon dioxide gas is used (for typical carbon contents of weld metal, see Tables 21, 22, and 25 to 29 in the Appendix of this article). Additional information on nine electrodes, including use and nonuse of auxiliary shielding gas, inspection requirements for deposits, and minimum mechanical properties of deposits, is given in Table 2 and in the Appendix.

The classification system for flux-cored electrodes follows the system established for gas metal-arc electrodes. For example, in the designation E70T-1, E indicates an electrode; 70 indicates a minimum as-welded tensile strength of 70,000 psi; T indicates a tubular-type electrode; and 1 indicates a specific composition of the deposited weld metal, use of auxiliary shielding gas, and a usability factor.

Characteristics of specific electrode wires are summarized below, including properties of weld deposits. (See also the Appendix, pages 40 to 45.)

E60T-7 electrode wires are used without auxiliary gas shielding for single-pass and multiple-pass welding in the flat and horizontal positions. They are used with straight-polarity direct current, resulting in shallow joint penetration. Weld deposits have low sensitivity to cracking and good notch toughness.

E60T-8 electrode wires are used without auxiliary gas shielding, and with reverse-polarity direct current. Tensile strength and yield strength of deposits are generally lower than for deposits made with E60T-7, but notch toughness is high (see Table 2).

E70T-1 electrode wires are intended to be used with auxiliary gas shielding, for single-pass and multiple-pass welding in the flat position and for horizontal fillet welds. For some electrodes in this classification, joints must be free of oil, excessive oxide, and scale, so that welds of radiographic quality can be obtained. A quiet arc, high deposition rate, low spatter loss, a flat to slightly convex bead, and easily controlled and removed slag are characteristics of these electrodes. Weld deposits have good impact properties.

E70T-2 electrode wires are also used with auxiliary gas shielding. They are designed primarily for single-pass welding in the flat

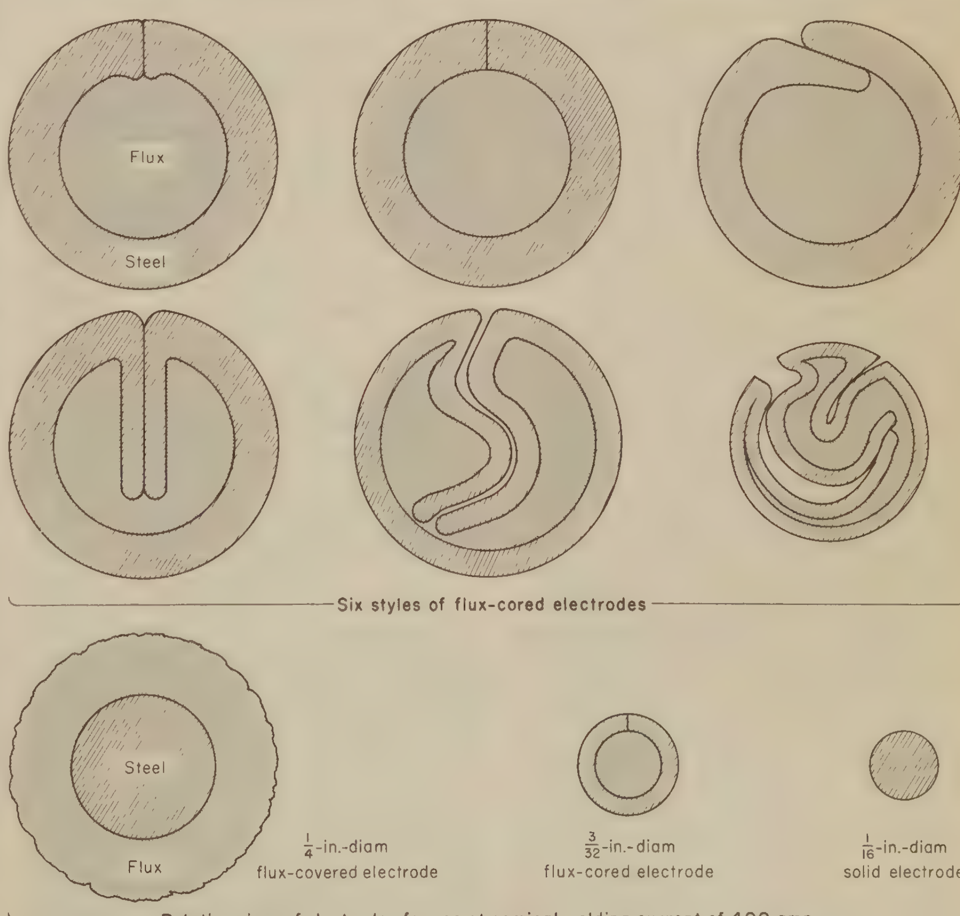

Fig. 5. Several styles of flux-cored electrodes, and size comparison of flux-covered, flux-cored and solid metal electrodes for use at the same nominal welding current

position and for horizontal fillet welds. However, multiple-pass welds can be made when the weld beads are heavy and appreciable admixture of base and filler metals occurs. These electrodes can be used for welding steel that has heavier mill scale, rust, or other foreign material on the surface than can be tolerated by some electrodes of the E70T-1 classification, and they will still produce welds that will pass radiographic inspection. The arc characteristics and deposition rates of the E70T-2 electrode wires are similar to those of the E70T-1 electrodes.

E70T-3 electrode wires are used without auxiliary gas shielding and are intended primarily for depositing single-pass welds at high speed in the flat and horizontal positions on relatively thin steel. These electrodes should not be used to weld heavy sections or for applications requiring multiple passes.

E70T-4 electrode wires are used without auxiliary gas shielding for single-pass and multiple-pass welding in the flat and horizontal positions. Due mainly to shallow joint penetration, the weld deposits have low sensitivity to cracking.

E70T-5 electrode wires are intended primarily for flat fillet or groove welds, with or without auxiliary gas shielding. Horizontal fillet welds can be satisfactorily made, but at lower deposition rates than are obtainable for flat groove welds. Welds made using auxiliary gas shielding have better quality than those made with no auxiliary gas shielding. E70T-5 electrodes can be used in single-pass and multiple-pass applications, with minimum surface preparation. These electrodes give globular transfer, shallow penetration with the self-shielding method and medium to deep penetration with the auxiliary-gas-shielded method, and a slightly convex weld bead, and they produce a thin, easily removed slag. Weld deposits have good impact properties (see Table 2).

E70T-6 electrode wires are generally similar to those of the E70T-5 classification, except that they are intended for use without auxiliary gas shielding.

The E70T-G classification covers tubular electrodes that are not included in the preceding classes. They may be used with or without auxiliary gas shielding, for multiple-pass or single-pass welding. Welds are not required to meet composition, radiographic inspection, or impact-property requirements; however, they are required to have minimum tensile strength of 72,000 psi, minimum yield strength of 60,000 psi, and minimum elongation of 22% in 2 in.

Flux-cored electrode wires are considered to be low-hydrogen electrodes, because the materials used in the cores do not contain hydrogen. However, certain of the materials are hygroscopic and may absorb moisture when exposed to a high-humidity atmosphere. Electrode wires are therefore packaged in a moisture-proof bag with a desiccant. It is recommended that, after removal from their original container, flux-cored electrode wires be treated in the same manner as low-hydrogen flux-covered electrodes are treated after removal from their original container (see page 7 in the article on Shielded Metal-Arc Welding in this volume).

A special series of flux-cored arc welding electrode wires is available for welding high-strength structural steels and high-strength alloy steels (see the article on Arc Welding of Alloy Steels, which begins on page 199). Electrode wires of this series are for use with auxiliary gas shielding. The core of the electrode wire carries alloying elements in addition to the normal gas-formers, fluxing elements, and deoxidizers. The alloying elements in the core melt in the arc and mix with the molten low-

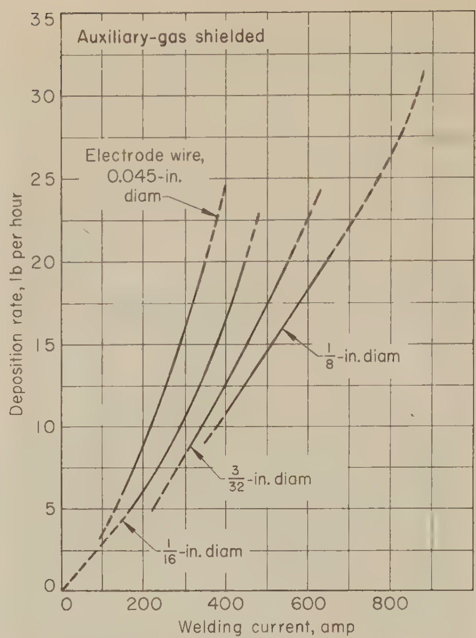

Fig. 6. Effect of welding current and electrode-wire diameter on deposition rate. The solid part of each curve indicates the normal current range for that size of electrode.

carbon steel outer sheath to produce the required composition of deposited weld metal. One major advantage of flux-cored electrode wires over solid electrodes is that the cored wires can readily be made to match virtually any base-metal steel composition.

Shielding Gases

Gases used for auxiliary-gas-shielded flux-cored arc welding can be the same as those used for gas metal-arc welding, which include carbon dioxide, 98% argon with 2% oxygen, and 75% argon with 25% carbon dioxide, but almost always carbon dioxide is used alone. The chemical reactions of carbon dioxide with the carbon steel base metal and with the cored electrodes make it desirable as a shielding gas. In addition, carbon dioxide is less costly than the mixtures containing argon, based on the cost of gas per pound of weld metal deposited.

Characteristics of Carbon Dioxide. At room temperature, dry carbon dioxide is an inactive gas that has no adverse effect on the metals with which it comes in contact; but at the high temperature of the welding arc, it dissociates, in the following reaction:

$$2CO_2 \leftrightarrows 2CO + O_2$$

This dissociation leaves considerable oxygen available in the arc to oxidize metallic elements. Molten iron, for example, reacts with carbon dioxide to produce iron oxide and carbon monoxide, as follows:

$$Fe + CO_2 \leftrightarrows FeO + CO$$

The oxidizing characteristics of carbon dioxide have been considered in the development of flux-cored electrodes, and deoxidizing materials are added to the flux core to compensate for it. Some of the carbon monoxide produced during the reaction between iron and carbon dioxide may dissociate to carbon and oxygen. The carbon released by this reaction is available to dissolve in the weld metal, thereby increasing the carbon content.

Depending on the carbon content of the base metal and of the electrode, a carbon dioxide atmosphere may be either carburizing or decarburizing. Carbon content in the weld deposit usually ranges between 0.05 and 0.12%. If the carbon content of the electrode metal and of the base metal is lower than 0.05%, the weld metal will pick up carbon from the carbon dioxide shielding atmosphere. Conversely, if the carbon content of the electrode metal and of the base metal is greater than 0.12%, the weld metal may lose carbon. This loss of carbon can occur as follows:

$$FeO + C \leftrightarrows Fe + CO$$

When the above reaction occurs, carbon monoxide gas can be trapped in the weld deposit, where it may produce porosity. The reaction is avoided by keeping the level of the deoxidizing elements in the core of the electrode sufficiently high.

In general, joint penetration with flux-cored arc welding with carbon dioxide shielding is much greater than with shielded metal-arc welding using low-hydrogen iron powder electrodes, but not as deep as with gas metal-arc welding using solid electrode wire and carbon dioxide shielding, operating in the same range of welding current.

Containers for Carbon Dioxide. Carbon dioxide is available in cylinders or in bulk. The most widely used container is the ICC-approved high-pressure steel cylinder. Cylinders containing carbon dioxide are always labeled "CO_2", and for welding applications they should be labeled "Welding Grade".

A cylinder from which no gas has been drawn contains, at 70 F, gaseous carbon dioxide and liquid carbon dioxide. The gas occupies about one-third of the volume of the cylinder, and when gas is withdrawn, liquid vaporizes and maintains the gas pressure. When all the liquid carbon dioxide has been vaporized, the pressure starts to fall. Originally, the weight of liquid carbon dioxide is about 90% of the weight of the contents of a cylinder. In order to determine how much remains in a partly used cylinder, the cylinder should be weighed (pressure is not a reliable indication of cylinder content). The tare weight of the (empty) cylinder is usually stenciled on the cylinder neck. At 70 F, 8.47 cu ft of carbon dioxide weighs 1 lb at standard pressure.

As the pressure drops from cylinder pressure to discharge pressure in the regulator, carbon dioxide absorbs a considerable amount of heat. If the flow rate is too high, the heat absorption can cause freezing of the regulator and flowmeter, which interrupts gas flow. Heaters are available that will prevent regulator freeze-up. Excessive rates of gas flow also can result in the withdrawal of liquid carbon dioxide from the cylinder.

A positive pressure should always be maintained in the cylinder (the valve should be closed before the cylinder is removed from service) to keep moisture or other contaminants from backing into the cylinder. Carbon dioxide cylin-

ders should always be kept in an upright position and held firmly in place when in use at the welding station. If it is placed in a horizontal position, carbon dioxide will be drawn off as liquid instead of as gas.

Siphoned-tube cylinders require a heater to transform the liquid to gas. Nonsiphoned-tube cylinders operating at flow rates greater than 35 cu ft per hour should be manifolded to reduce flow rate and prevent freezing.

Flow rate for carbon dioxide shielding gas is at least 30 cu ft per hour for most welding applications. When welding outdoors or at a drafty site, the operation should be protected by a wind shield, and the flow rate should be increased to 50 cu ft per hour.

Purity. Welding-grade carbon dioxide is required. The purity of the gas is based on the percentage of moisture present, which is indicated by a dew-point temperature of −40 F (or −40 C). At −40 F (or −40 C) dew point, the percentage of moisture by weight is 0.0066, or 66 parts per million.

Equipment Installations

Support equipment required for flux-cored arc welding is about the same as for gas metal-arc welding. Less equipment may be needed if no auxiliary gas shielding is applied. It can range from completely portable to large, highly mechanized stationary setups. Support equipment is dealt with in the section on Equipment Installations, page 89, in the article on Gas Metal-Arc Welding in this volume.

Holding and Handling of Workpieces

Jigging and fixturing requirements for flux-cored arc welding are the same as those for gas metal-arc welding. Holding and handling devices are discussed and illustrated in the section beginning on page 90 in the article on Gas Metal-Arc Welding in this volume. Applicable techniques are discussed also in the section on Accessory Equipment in the article on Gas Tungsten-Arc Welding, and in the section on Jigs, Fixtures and Positioners in the article on Shielded Metal-Arc Welding.

The importance of positioning workpieces so that they can be welded in as flat a position as possible is no less, and may be greater, than when welding by the gas metal-arc method. In most arc welding methods, maximum efficiency is obtained when welding is done in the flat position. Flux-cored arc welding can be done in all positions, but it is generally less amenable to out-of-position welding than is gas metal-arc welding, because it usually (but not always) employs larger-diameter electrode wires and deposition rates are higher. Out-of-position welding increases production time, restricts electrode selection, requires greater skill, and may impair weld quality.

Deposition Rate

As is true for all arc welding processes, the deposition rate for flux-cored arc welding depends on the welding current and the electrode diameter. Typical relations between current and deposition rate for four different electrode-wire diameters are given in Fig. 6, which indicates for each electrode-wire diameter the current range that is normally appropriate. Deposition efficiency in flux-cored arc welding is generally high, sometimes as high as 92%.

Effects of Operating Variables

The principal operating variables that must be controlled are arc voltage, current, travel speed, and electrical stickout. The effects of changes in these variables are summarized in the paragraphs that follow:

Arc voltage variations have the following effects:

1 Excessive arc voltage results in heavy spatter and porosity.
2 Increasing the arc voltage flattens and widens the weld bead.
3 Decreasing the voltage may cause a convex bead having a ropey appearance.
4 Extremely low voltage causes the electrode to "stub" on the workpiece. The electrode dives through the molten weld puddle and strikes the unmelted base metal at the bottom of the puddle.
5 With higher current, higher voltage can be used without causing porosity. Using the highest voltage possible (without causing porosity) will result in a weld bead shape that is satisfactory for most applications.

Current variations have the following effects when arc voltage, travel speed, and electrical stickout are all held constant:

1 Excessive current produces convex weld beads, which result in waste of weld metal and poor appearance.
2 Melting rate, deposition rate, and penetration are increased by increasing the current.
3 Large-droplet transfer results from too low current, causing difficulty in maintaining a uniform weld bead.
4 Increasing the current also increases the maximum voltage that can be used without causing porosity.

Travel speed variations have the following major effects when arc voltage, current, and electrical stickout are held constant:

1 Convexity of the weld bead, with uneven edges, and shallower penetration result from too high a travel speed.
2 Slag interference and slag inclusions, together with a rough, uneven weld bead, result from too slow a travel speed.

To obtain weld beads of even contour, maintenance of uniform travel speed is essential. The welder should maintain a uniform distance between the end of the electrode and the molten slag behind the electrode.

As in all other welding processes in which the molten weld puddle is protected by slag or flux, a travel speed should be used that will produce the desired weld size and appearance by maintaining a proper relationship between the positions of the molten weld puddle and the slag that protects it.

Electrical stickout is the distance between the electrode nozzle contact tip and the workpiece (see Fig. 1). If voltage, current setting and travel speed are held constant, variations in electrical stickout have the following major effects:

1 Increasing stickout decreases the welding current; decreasing stickout increases current.
2 When stickout is increased, actual arc voltage is lowered. Lower arc voltage increases weld bead convexity and reduces the likelihood of porosity.
3 When stickout is excessive, spatter and irregular arc action will result.
4 Short stickout gives greater penetration than long stickout.
5 When stickout is too short, spatter will build up on nozzle and contact tube.

Groove Welding

Welding position, work-metal thickness, shape of the groove, and use or nonuse of backing affect procedures and techniques employed in making groove welds. Typical welding conditions for several types of grooves welded in various positions are given in Tables 3 to 7. Specific applications may necessitate considerable deviation from the practices suggested in these tables; for instance, conditions given in the examples later in this article do not always agree with those given in Tables 3 to 7. However, the data shown in these tables are based on extensive development work and should provide useful guidelines for establishing welding procedures for specific applications. For additional information on design of grooves, reference should be made to "Recommended Proportions of Grooves for Arc Welding", pages 148 to 151.

Fillet Welding

As with groove welding, procedures for fillet welding vary widely among different shops. The welding conditions shown in Tables 8 and 9 provide guidelines for several sets of conditions.

Welding position has a major influence on technique. For example, Table 8 shows that a ½-in. fillet weld can be made in two passes in the flat position, whereas Table 9 indicates that three passes are required for a ½-in. fillet weld in the horizontal position.

Angle of the electrode wire to the joint has considerable effect on the appearance of the completed weld deposit. The electrode wire should point at the bottom plate close to the corner of the joint if best bead shape is desired on horizontal fillet welds 5⁄16 in. and larger. The angle between the electrode wire and the bottom plate should be less than 45°, because with this position the molten metal is caused to wash up onto the vertical member. If root porosity occurs, it may be decreased by pointing the electrode directly into the joint and using an angle of 45° to 55°, but this may cause some weld spatter, as well as a convex weld bead. For ¼-in. and smaller fillet welds, the electrode wire should be pointed directly into the joint and at an angle to the joint about 40° above horizontal.

Multiple-Position Welding

The development of small-diameter electrode wire (0.045 in. or less) has made it possible to employ flux-cored arc welding in the vertical position, thereby extending the use of the process to building construction and tank fabrication. The desirability of using flux-cored arc welding for structural

members helped to establish conditions that meet code requirements. Typical electrode sizes, and amperage and voltage ranges are given in Table 10. These conditions apply to both groove and fillet welding.

With a choice of 1/16-in. and 5/64-in.-diam electrode wires, and using the appropriate type of flux and suitable process adjustments, welding can be done in any position.

Downhill and vertical-down welding can be done in low-cost single-pass welds. About a 60° downhill angle and 5/64 or 3/32-in. electrode wires result in maximum deposit speed, although the smaller 1/16-in. electrode can be used also. To make such deposits, stringer beads and currents in the middle to high part of the amperage range should be used. If the electrode holder is tipped in the direction of travel so that the arc force tends to hold the molten metal in the joint, the deposits will appear much more uniform. Welding should be done as fast as is possible for the desired size and shape of weld bead.

Out-of-position welding can be done if a few basic rules are followed: (*a*) do not whip or move the arc around rapidly; (*b*) do not break the arc too rapidly; (*c*) do not move out of the weld puddle too fast; (*d*) do not move too fast in any direction; and (*e*) use current in the low part of the amperage range.

Thick Sections

The high deposition rates and deep joint penetration obtainable with auxiliary-gas-shielded flux-cored arc welding have proved the process to be economical for welding sections more than ½ in. thick.

Sections ½ to ¾ In. Thick (Comparison of Processes). The two examples that follow describe practice used for, and indicate specific advantages of, auxiliary-gas-shielded flux-cored arc welding as compared with shielded metal-arc welding for sections between ½ and ¾ in. thick.

Examples 12 and 13. Advantages of Flux-Cored Over Shielded Metal-Arc Welding

Example 12 — Increased Deposition; Smaller Fillets (Fig. 7). The weldment shown in Fig. 7, consisting of two flat plates ½ in. thick and one formed plate ¾ in. thick, was originally joined by shielded metal-arc welding, using ⅜-in. fillet welds. Deposition rate was 6 to 10 lb of weld metal per hour.

By changing to auxiliary-gas-shielded flux-cored arc welding, deposition rate was

	⅛	3	500	28 to 30	12

(a) Weld size (*s*) is usually the same as steel thickness (*t*) for the range of steel thicknesses given here.

increased to 12 to 18 lb per hour. In addition, because of the deeper penetration obtained in auxiliary-gas-shielded flux-cored arc welding, it was possible to use a ¼-in. fillet weld. The strength of the joint was equal to that of the joint made with the ⅜-in. fillet weld deposited by shielded metal-arc welding. The higher deposition rate and smaller fillet weld made flux-cored arc welding more economical. Welding details for the flux-cored arc process are given in the table accompanying Fig. 7.

Example 13 — Deeper Penetration; Increased Deposition and Arc Visibility (Fig. 8). Bulldozer blades were assembled from several low-carbon steel components that had relatively thick sections, generally ½ in. or more (see Fig. 8). Most welds were ¼ to ½-in. fillet welds. A few were groove welds.

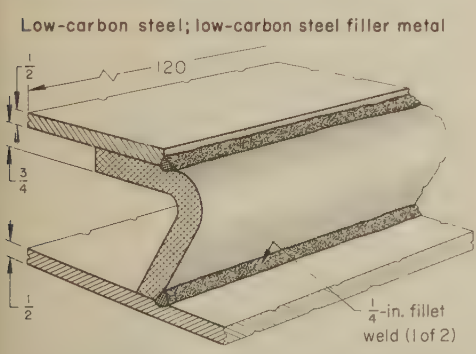
Flux-cored arc welding with auxiliary gas shielding was selected for this application in preference to shielded metal-arc welding for three reasons: (*a*) deeper joint penetration, permitting the use of smaller fillets without decreasing the strength of the joint; (*b*) higher deposition rate; and (*c*) greater visibility of the arc to the welder, resulting in a better weld.

The difference in joint penetration for the two processes is shown in Fig. 8. Details for flux-cored arc welding are given in the table accompanying Fig. 8.

Sections 3 to 15 In. Thick. Thicknesses much greater than those discussed in Examples 12 and 13 are often welded by auxiliary-gas-shielded flux-cored arc methods. The three examples that follow describe applications of this process for such sections.

Example 14. Use of Auxiliary-Gas-Shielded Flux-Cored Arc Welding and a High-Strength Electrode Wire for Welds Subjected to Heavy Loads (Fig. 9)

The shank portion of the weldment shown in Fig. 9, a component of an earthmoving machine, was subjected to heavy loads in service. Auxiliary-gas-shielded flux-cored arc welding with a high-strength electrode was selected to join the 3-in. section to the 3½-in. section, because it provided the required strength and weld quality and was faster than the shielded metal-arc welding process. Welding details, including the sequence of passes, are given in the table accompanying Fig. 9.



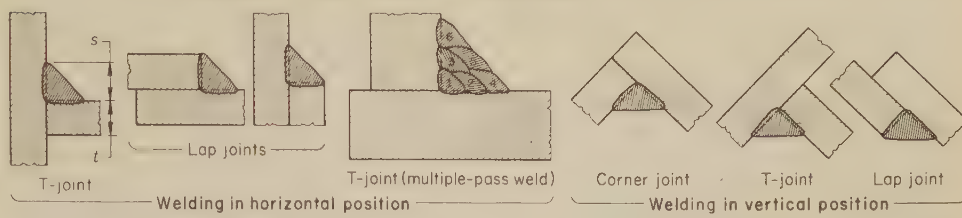
Auxiliary-Gas-Shielded Flux-Cored Arc Welding

Joint type	Lap and modified T
Weld type	¼-in. fillet
Welding position	Horizontal
Number of passes	One
Shielding gas	Carbon dioxide, at 35 cfh
Electrode	3/32-in.-diam flux-cored wire
Electrode feed	160 to 175 ipm
Current	420 to 450 amp
Voltage	29 to 31 v
Travel speed	14 to 15 ipm
Deposition rate	12 to 18 lb per hour

When shielded metal-arc welding was used, ⅜-in. fillet welds were required and deposition rate was only 6 to 10 lb per hour.

Fig. 7. Weldment of thick plates, for which process was changed from shielded metal-arc to flux-cored arc welding (Example 12)

Table 9. Typical Conditions for Flux-Cored Arc Fillet Welding in the Horizontal and Vertical Positions, Using Auxiliary Gas Shielding (CO_2 at 35 Cfh) (a)



Steel thickness (*t*), in.	Electrode diameter, in.	Number of passes	Current (dcrp), amp	Voltage, v	Travel speed, ipm
Horizontal Position

	1/8	6	470	28 to 30	20
Vertical Position					
3/8	0.045	1	180	21	3 to 4

(a) Weld size (*s*) usually equals steel thickness (*t*) for the range of thicknesses given here.

Table 10. Typical Conditions for Multiple-Position Flux-Cored Arc Welding of Grooves and Fillets, Using Various Sizes of Electrodes (a)

Electrode diameter, in.	Amperage (dcrp) and voltage (b): Flat — Amperes	Flat — Volts	Horizontal — Amperes	Horizontal — Volts	Vertical — Amperes	Vertical — Volts
0.045	150 to 225	22 to 27	150 to 225	22 to 26	125 to 220	22 to 25
1/16	175 to 300	24 to 29	175 to 275	25 to 28	150 to 200	24 to 27
5/64	200 to 400	25 to 30	200 to 375	26 to 30	175 to 225	25 to 29
3/32	300 to 500	25 to 32	300 to 450	25 to 30	...	...
7/64	400 to 525	26 to 33	...	...	...	...
1/8	450 to 650	28 to 34	...	...	...	...

(a) Flow rate of shielding gas is 30 to 45 cu ft per hour, depending on electrode size. (b) Current ranges can be expanded. Higher amperage can be used with automatic travel. Voltage will increase when longer electrical stickout is used.

Example 15. Welding 4-In.-Thick Plates for I-Beam Flange Sections (Fig. 10)

The plates shown in Fig. 10 were successfully butt welded by the flux-cored arc process with auxiliary gas shielding, using a double-V type of groove. Runoff tabs attached to both ends of the joint, after fit-up but prior to welding, provided a means for starting and stopping the weld. After welding, the runoff tabs were removed and the edges of the plates were ground smooth.

Welding was started on the side with the 60° groove (side A in Fig. 10) and was continued until that groove was about one-quarter full. The plates were then turned over and the groove area was back gouged until sound weld metal was reached. Welding was then continued on the side with the 80° groove until this groove was about half full. The plates were turned again, and welding was completed on the 60°-groove side. The plates were turned once more to the 80°-groove side, and welding was completed. Turning the plates during welding minimized distortion.

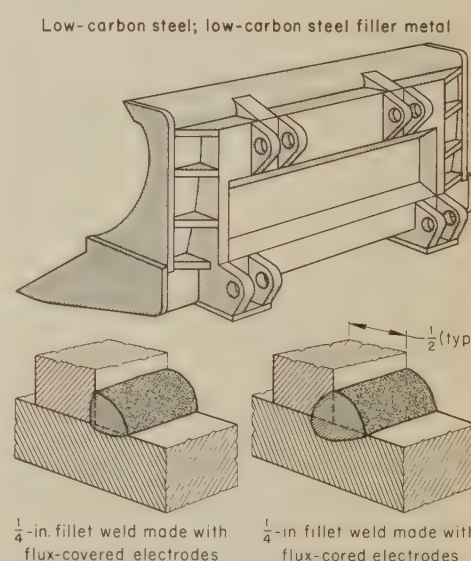
Weldments were essentially free of defects, as determined by radiographic examination and testing of side-bend specimens. Tests of transverse tensile specimens showed that the tensile strength of the welds in the stress-relieved condition ranged from 75,000 to 80,000 psi.

Welding details are given in the table accompanying Fig. 10.

Example 16. Welding of 24-by-15-In. Cross Sections (Fig. 11)

The ring shown in Fig. 11 was welded, joining two semicircular sections that had been gas cut from 24-in.-thick plate (ASTM A515, grade 70). The finished ring had a 96-in. OD and a 66-in. ID. The two welds were 15 in. thick by 24 in. long.

Semiautomatic flux-cored arc welding with auxiliary gas shielding was used. Welding operations are described in the table that accompanies Fig. 11. Joint pene-



Auxiliary-Gas-Shielded Flux-Cored Arc Welding

Joint type	Corner
Weld type	Fillet; some groove
Weld size	¼ to ½ in.
Welding position	Flat; horizontal
Number of passes for fillet welds:	
For ¼ and 5/16-in., flat position	One
For ⅜-in., horizontal position	Two
For 7/16 and ½-in., flat position	One
For 7/16 and ½-in., horizontal position	Three
Shielding gas	Carbon dioxide, at 35 cfh
Electrode	3/32-in.-diam flux-cored wire
Current	450 amp
Voltage	30 to 32 v
Electrode feed	206 ipm

Auxiliary-Gas-Shielded Flux-Cored Arc Welding

Joint type	Butt
Weld type	Double-J groove
Welding position	Flat
Shielding gas	Carbon dioxide, at 35 cfh
Electrode	3/32-in.-diam high-strength flux-cored wire
Current	450 amp, dcrp
Voltage	30 to 32 v
Electrode feed	206 ipm

Sequence of Passes

First side. Make four passes without weaving. Turn to second side.
Second side. Back gouge to obtain complete joint penetration and weld four passes as on the first side.
Alternate sides. Make two passes per side until 13 passes have been made on the first side and 15 passes on the second side. Weld from center to end; deslag after each pass; use weaving technique. Use copper dams for the last three passes on each side.

Fig. 9. Thick-section earthmover part that was flux-cored arc welded (Example 14)

tration was 100%, and distortion was held to within ½ in. of flatness. Electrode deposition efficiency was 92%.

The ring could have been welded by the submerged-arc process, but several factors favored the use of flux-cored arc welding. In the first place, a larger bevel (60° included angle) would have been needed for submerged-arc welding, which would have required twice the amount of weld metal. Secondly, slag entrapment at the bottom of the groove was less likely with flux-cored arc welding. Finally, no runoff tabs were required for flux-cored arc welding, whereas they would have been required for submerged-arc welding. In flux-cored arc welding, the welder can see and thus control the weld puddle, but in submerged-arc welding, the puddle is larger and invisible, therefore requiring runoff tabs.

Pipe Welding

When pipe sections can be rotated during welding, the operation is greatly simplified, because all of the welding can be done in the most favorable position, but when elbows or other irregular sections are involved, welding must be done with the workpieces in a fixed position unless special manipulating fixtures are provided.

Fixed-Position Welding. Although the larger sizes of flux-cored electrode wires are not suitable for welding pipe in the fixed position, development of the smaller (0.045-in.-diam) flux-cored electrode wire for welding with auxiliary gas shielding enables this to be done on low-carbon and low-alloy steel pipe sections to a quality standard that satisfies requirements of the ASME Boiler and Pressure Vessel Code.

Joint designs for welding with small-diameter flux-cored electrodes are the same as those used for shielded metal-arc welding. Joint design and pass sequence for fixed-position welding of pipe having a wall thickness of ½ in. are shown in Fig. 12. Typical welding conditions are given in the table that accompanies Fig. 12.

Rotation of the workpieces is greatly preferred for pipe welding and is done whenever possible. In the example that follows, thick-wall pipe and tube were rotated during welding.

Example 17. Butt Welding of Large-Diameter Thick-Wall Pipe and Tube (Fig. 13)

Steel pipe and tube, ranging in outside diameter from 8 to 36 in. and in wall thickness from ½ to 3 in., were butt welded in the horizontal-rolled position. The groove design used is shown in Fig. 13.

The root pass was made by gas metal-arc welding, using a 0.035-in.-diam solid electrode and argon – carbon dioxide shielding. Pipe was preheated to 70 F, 125 F or 200 F, depending on wall thickness (see the table accompanying Fig. 13). After preheating, maximum root opening was 3/32 in. The root pass was made with a hand-held electrode holder positioned 45° above the horizontal centerline as the pipe rotated away from the welder.

For subsequent passes (3 to 17, depending on wall thickness), flux-cored arc welding was used, with a 7/64-in.-diam flux-cored electrode wire and carbon dioxide shielding. To control the weld puddle during these passes (because a large-diameter electrode wire was employed), the electrode holder was held ½ to ¾ in. below the vertical centerline, with the pipe rotating away from the welder. Maximum width of weave was 1¼ in.

Welding Sequence

1 The two semicircular sections were mounted on a standard positioner so that the ring stood upright, permitting one groove on the outside to be at the top in the flat position.
2 The groove at the top was filled by multiple passes with weld metal to a depth of 3 in.
3 The ring was rotated 180°.
4 The groove at the top was filled by multiple passes with weld metal to a depth of 3 in.
5 With the ring in the same position, the groove on the inside of the first weld (now at the bottom) was root gouged with a carbon arc to obtain sound metal, and filled by multiple passes to a depth of 3 in.
6 The ring was rotated 180°.
7 The groove on the inside of the second weld (now at the bottom) was root gouged and filled by multiple passes with weld metal to a depth of 3 in.
8 The above sequence was continued (without root gouging) until all grooves were filled.

(a) 0.09 C, 1.00 Mn, 0.45 Si. (b) Constant voltage.

Fig. 11. Large ring made by joining two 15-in.-thick semicircular sections by flux-cored arc welding (Example 16)

table with Fig. 13. As the depth of weld buildup increased, lessening the possibility of melt-through, voltage and amperage were increased to the high end of these ranges. Travel speed varied with pipe diameter; it was controlled to ensure that slag did not run ahead of the arc. Slag was removed between passes. Deposition rate for flux-cored arc welding ranged from 15 to 25 lb per hour.

Further details of procedures and equipment are given in the table that accompanies Fig. 13.

Typical mechanical properties of the weld metal were 76,000 psi tensile strength, 67,000 psi yield strength, 32% elongation, and 68% reduction of area. Charpy V-notch impact values of the weld metal at selected temperatures were as follows: 92 ft-lb at 75 F, 75 ft-lb at 0 F, 48 ft-lb at −40 F, and 30 ft-lb at −75 F.

The joint and procedures were qualified by tests made according to Section IX of the ASME Boiler and Pressure Vessel Code; ANSI B31.3, American National Standard Code for Pressure Piping; and U.S. Navy S-9-1, General Specification for Ships.

Arc Spot Welding

In arc spot welding, a weld is made in a lap joint through one piece of metal into the other piece. There is no travel of electrode holder or workpiece. For thin sheets, the weld is a melt-through weld, made without preparing a hole in the top sheet.

Thickness and Position Limitations. Flux-cored arc spot welding is used to make lap joints in low-carbon steel 1/16 to 1/4 in. thick. Sheet or plate of the same or of different thicknesses can be welded together. If stock of different thicknesses is being welded, the weld should be made from the side of the thinner member. Arc spot welding is best done in the flat position, although thin sheet can be welded in other positions.

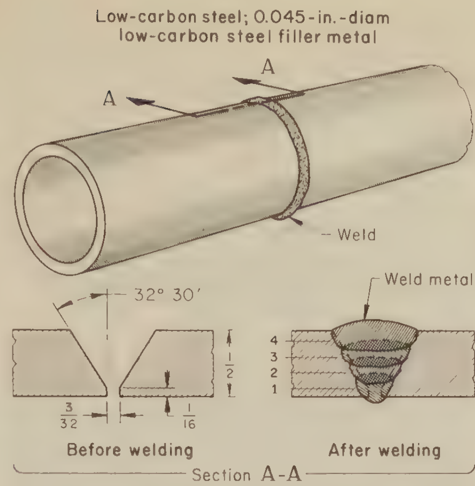
Typical Procedures and Conditions. In flux-cored arc spot welding, an air-cooled electrode holder equipped with a special nozzle is held against the top member of a lap joint. The arc, which is maintained by the continuously fed electrode, melts through the top sheet and into the bottom sheet, and fuses the two sheets together. The electrode continues to feed for a preset arc time and produces a slightly convex spot on the upper surface of the top sheet.

Most flux-cored arc spot welding is done with carbon dioxide shielding, because shielding provides deeper penetration. However, the self-shielding method can be used for arc spot welding of thin sheet (up to 1/8 in. thick).

Typical welding conditions for flux-cored arc spot welding of steel from 1/16 to 1/4 in. thick are given in Table 11.

Weld Characteristics. The strength of arc spot welds produced by flux-cored arc welding is about the same as that produced by resistance welding in steel of the same thickness. Typical values of shear strength of arc spot welds are given in Table 11.

Arc spot welding with a flux-cored electrode offers several advantages over arc spot welding with a solid electrode. Generally, the weld nugget is larger at the interface when welding through metal of the same thickness, which results in higher strength per spot. Also, with a flux-cored electrode, there is a slag cover on the surface of the weld, which results in a smoother surface and, for some applications, eliminates



Pass	Current (dcrp), amp	Voltage, v	Gas (CO_2) flow, cfm	Travel direction
1	100	20	25	Down
2, 3, 4	120	20	25	Up

Interpass temperature 300 F; pipe axis horizontal

Fig. 12. Joint design and pass sequence for fixed-position welding of 1/2-in.-wall pipe with a 0.045-in.-diam electrode wire

the necessity for a finishing operation.

A flux-cored electrode has been found to be better than a solid electrode for spot welding galvanized steel; it provides smoother surfaces and deeper penetration. Also, weld spatter from flux-cored electrodes does not adhere to galvanized surfaces. For spot welding of galvanized steel, the current is reduced slightly and the arc time is increased, compared with spot welding of uncoated sheet of the same thickness.

Automatic Welding

Flux-cored arc welding can be done automatically, using essentially the same techniques as for gas metal-arc welding. Electrode holders used for automatic gas metal-arc welding can be used also for automatic flux-cored arc welding (see the section on Electrode Holders, page 25). Power supply, wire feeders, and other basic equipment for automatic welding are described on pages 25 and 26.

The quantity of similar weldments required determines whether or not automatic welding is feasible and the degree of automation that is appropriate. For some applications, quality requirements are so high that they can be met economically only by automatic welding.

Automatic welding is most advantageously applied to long in-line welds such as long seam welds and girth welds on large pipes. Tooling cost for an application of this type is generally moderate, but increases as weld complexity increases.

In most applications, tooling can be simplified by moving the components to be welded while the electrode holder remains stationary. If the workpiece is large or of complex shape, moving it past the electrode holder may not be practical, and the more costly alternative of moving the electrode holder will have to be adopted.

Circumferential welding is usually easy to automate, because round workpieces of all sizes can almost always be held and rotated without difficulty. In practice, the electrode holder remains stationary and makes the weld as the workpiece slowly rotates.

The three examples that follow describe applications in which automatic welding was advantageous.

Table 11. Typical Conditions for Flux-Cored Arc Spot Welding and Shear Strength Per Spot

Steel thickness, in.	Current (dcrp), amp	Voltage, v	Arc time, sec	Shear strength per spot, lb
With Carbon Dioxide Shielding(a)				
1/16	400	30	0.6	2,550
1/8	500	34	0.8	3,400
3/16	650	38	1.6	7,050
1/4	750	40	2.2	10,300
Self-Shielding(b)				
1/16	500	29	0.5	2,250
1/8	500	29	1.5	2,450

Fig. 14. Heat-exchanger shell and fitting, and joint designs for shielded metal-arc and automatic flux-cored arc welding (Example 18)

Example 18. Change From Shielded Metal-Arc Welding to Automatic Flux-Cored Arc Welding of Heat-Exchanger Components (Fig. 14)

A shell and a fitting for a heat exchanger were originally joined by shielded metal-arc welding. Because of the relatively small diameter of the workpiece (3-in. schedule 40 pipe) and the requirement for 100% joint penetration, a 3/32-in.-diam electrode wire was the maximum size that could be used. Welding was slow, because of the small size of the electrode wire and the need for removal of slag between passes. An average of 13 min was required to complete the peripheral V-groove weld, using the joint design shown in Fig. 14. Even under these conditions, and with the services of a highly skilled welder, rejections were excessive because of slag inclusions and inadequate joint penetration.

In contrast, after procedures were established, fully automatic welding, using a 5/64-in.-diam flux-cored electrode wire (E70T-5) completed a root pass and a cover pass in 38 sec. For automatic flux-cored arc welding, the joint was redesigned as shown in Fig. 14, although the 37½° bevel angle was retained on the shell. This change in joint design prevented slag inclusions and lack of penetration. Because use of electrode wire E70T-5 results in a very thin friable slag layer, it was possible to make the two-pass weld without removing slag between passes. Even with a relatively unskilled operator, acceptable parts were produced more consistently.

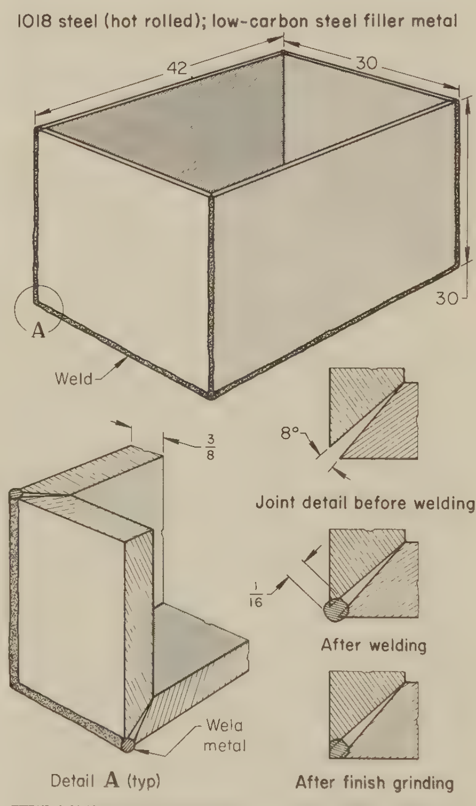
Conditions for automatic flux-cored arc welding are given in the table that accompanies Fig. 14. A mechanically held, retractable, air-cooled electrode holder was used. Other special tooling included an air-operated internal chucking device to pull the shell into intimate contact with the fitting, equipment for automatic loading and unloading of shells, and a mechanism for variable-speed rotation.

It was required that the welding procedure be qualified by tests performed in accordance with Section IX of the ASME Boiler and Pressure Vessel Code.

Example 19. Automatic Flux-Cored Arc Welding for Fabricating Security Boxes (Fig. 15)

An open-top box (Fig. 15), 42 in. long by 30 in. wide by 30 in. deep, made of 3/8-in.-thick low-carbon steel, was used as the inner receptacle of a government security file. A partial-penetration seal weld, deposited from the outside, was adequate for joining the five plates of which the box was made. Automatic flux-cored arc welding with carbon dioxide shielding was selected because a high production rate was desired and because the uniform joint conditions were well suited to automatic welding.

The special equipment needed for automatic welding consisted of an electrode holder mounted on a motor-driven carriage, a 4-ft-diam indexing turntable, and a toggle-clamp fixture for assembling the box and maintaining joint alignment during welding. Electrode-holder travel, gas flow, water flow, welding current, and wire feed were initiated by a starting switch and terminated by a limit switch.



Joint type	Corner
Weld type	8° groove
Edge preparation	Bevel to 41°
Welding position	Horizontal
Fixture	Toggle clamp
Preheat and postheat	None
Number of passes	One
Shielding gas	Carbon dioxide, at 30 cfh
Electrode	3/32-in.-diam flux-cored wire
Electrode-feed rate	130 ipm
Power supply	500-amp constant-voltage rectifier
Current	300 amp, dcrp
Voltage	24 v
Wire feeder	Constant feed
Production time	21 min per box

Fig. 15. Inner box for security file that was produced by automatic flux-cored arc welding, and joint details (Example 19)

Joint edges were beveled to 41° and then the plate sections were assembled on the turntable in the toggle-clamp fixture, with the 30-by-30-in. sides in the horizontal position. The turntable was indexed under the electrode holder for a horizontal single-pass weld on one corner. After this weld was completed, the turntable was indexed for each of the succeeding welds, until one side was completed (three joints). The box was then turned over manually, and the process was repeated for the three joints on the opposite side. The two 42-in. joints were then welded in a similar manner. The completed welds were ground to size as shown in Fig. 15. Conditions for welding are given in the table with Fig. 15.

Total welding time per box was 21 min: 2.5 min for each of the six short welds and 3 min for each of the two long welds.

Requirements for the welded joints were that they be completely sealed against passage of light and moisture, and that they have high strength and a joint penetration of approximately 0.060 in. Sample welds that were produced along with the boxes were examined microscopically for penetration, and 2% of the weldments were tested for tensile strength. Rejection rate averaged 0.5%.

Example 20. Welding Long Channel Sections by Automatic Flux-Cored Arc Welding (Fig. 16)

The fully automatic equipment for flux-cored arc welding shown in Fig. 16 was developed to butt weld two structural channels into a box section for a hitch for a gang plow. Originally, the box sections had been produced by shielded metal-arc welding. Cost of welding was reduced about 40% by using the auxiliary-gas-shielded flux-cored arc method. A principal factor in the decrease in cost was reduction of labor from two welders to one operator.

The channels were cut to length and all holes were punched in a progressive die so as to make a pair of channels, one a right-hand section and the other a left-hand section. Channel length was from 30 in. to 13½ ft for different designs.

The operator slid a pair of channels onto a roller conveyor, ahead of the entry end of the welding machine, and aligned the channels to form the box. The channels were then pushed into the welding machine on rollers, which became the bottom supporting surface for the workpiece during welding. A pin was inserted through holes in the frame of the machine and through matching holes in each end of the pair of channels, to hold hole alignment. Next, air cylinders were actuated by a foot switch to clamp the workpiece. The electrode holder was brought into line, the drive was locked, and the start button was pushed to begin welding on the first side. The locating pins were removed as the welding head progressed along the seam.

On completing the first seam, the welding head was returned to the starting position, the air clamps were released, and by means of an air-operated linkage, the rollers supporting the channels were raised above the machine frame so that the workpiece could be turned over to weld the second side. The rollers were then lowered, the workpiece was reclamped, and the second side was welded. On completion of the second weld, the air clamps were released, the weldment was struck six or more blows with a hammer to free flux deposits, and the workpiece was pushed out onto a conveyor table.

Because the equipment operated automatically, the operator was free to prepare the next pair of channels while the pair in the machine was being welded. While the second pair was being welded, the completed workpiece was removed from the exit conveyor table to a skid, by means of a bridge crane.

The welding machine was extremely versatile. Various sizes of channels were welded, ranging from 4 by 1¾ to 6 by 3 in.

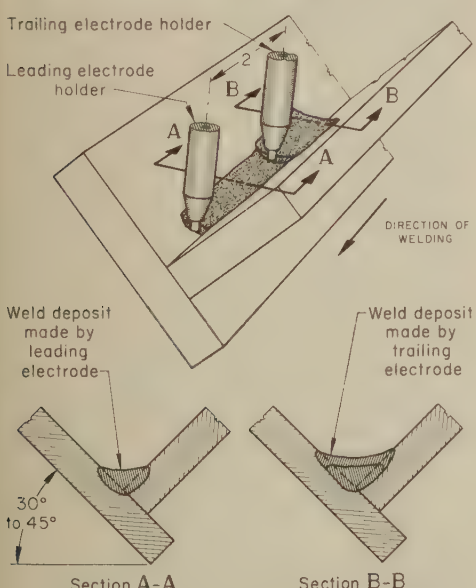
and in length from 30 in. to 13½ ft. V-notches were added to the clamping jaws to make possible welding of straight-line corner joints joining pairs of angles into box sections, and the gas nozzle on the electrode holder was pointed 8° to 10° in the travel direction, to expel dirt, rust and oil from the joint area and to spread the weld deposit. Joint penetration was found to be 90 to 95%.

In the original method (shielded metal-arc welding), a 5/32-in.-diam E7018 electrode was operated at 275 amp dcrp, 30 to 31 volts, at a travel speed of 10 to 12 in. per minute.

Submerged-arc welding was considered as an alternative process for joining the structural channels, but the channels did not match up evenly enough for this type of welding. In addition, it was estimated that the removal of unfused flux would require too much time, and that the consumption of flux would be excessive.

Details for automatic flux-cored arc welding of the channel sections are given in the table that accompanies Fig. 16.

Twin-Electrode (Twin-Wire) Welding. When automatic welding equipment is used, two electrode holders can be mounted on a single carriage for twin-electrode flux-cored arc welding (see Fig. 17). For example, the twin-electrode technique was used for depositing horizontal fillet welds ¼ to ⅜ in. in size and flat fillet welds up to ¾ in. in size. Both of the electrode wires were ⅛ in. in diameter, and they were in line along the weld joint, with one electrode trailing about 2 in. behind the other. Thus, there were two arcs and two separate weld puddles. The two weld puddles were smaller and were more easily controlled than the single, larger puddle that would have resulted if a weld of the same size had been deposited from a single electrode in one pass. Electrode positions used for the twin-electrode technique are shown in Fig. 17, and typical welding conditions for depositing ½ and ⅞-in. fillet welds are given in the table that accompanies Fig. 17.



Fillet size, in.	Electrode diam, in.	Total current (dcrp), amp	Voltage, v	Travel speed, ipm
½	⅛	1300	35 to 36	34
⅞	⅛	1300	35 to 36	13

Cost

Flux-cored arc welding competes successfully with other arc methods used for welding steel, and for many applications, it is less costly than the other arc methods.

Costs for specific welding applications are given in the five examples that follow. The first three compare the cost of flux-cored arc welding with the cost of another arc welding process.

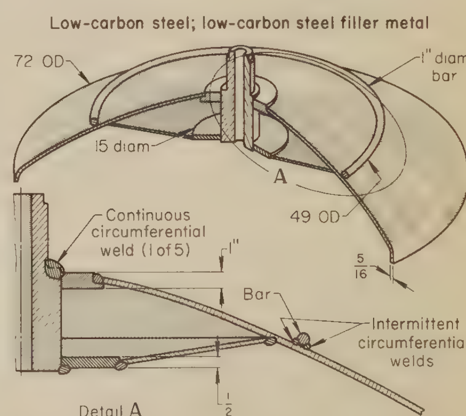
Example 21. Cost of Welding Trunnions on Tank Heads — Flux-Cored Arc Welding vs Submerged-Arc Welding (Fig. 18)

Substantial quantities of tank heads with reinforced trunnions were required for processing vessels that would be rotated. A typical 6-ft-diam head made of 5/16-in.-thick low-carbon steel, with the trunnion assembly welded in place, is shown in Fig. 18. Originally, the parts were assembled on a table, tack welded in place, and welded with the shielded metal-arc process. Because of the quantity involved, the possibility of using an automatic process was examined. A fixture in the shape of a circular cradle was constructed to hold the head and the trunnion in proper alignment, the cradle was mounted on a welding positioner, and, as the equipment was available, the welds were made by the submerged-arc process. This procedure reduced production time and resulted in welds that were more uniform and had a better appearance.

Further study showed that considerable time was being spent in setting up the submerged-arc equipment for each of the seven circumferential welds. For the shorter welds especially, setup time was high compared with arc time. It was therefore decided to try automatic flux-cored arc welding with auxiliary gas shielding.

The only new equipment needed was a wire feeder, an electrode holder, hoses and shielding gas. The electrode holder was clamped to a stationary support as before, and the same cradle fixture was used.

As shown in the comparative cost data accompanying Fig. 18, production time per part was cut in half by flux-cored arc welding and welding cost was reduced by approximately one-third.



Item	Submerged-arc welding	Flux-cored arc welding
Time and Cost per Assembly(a)		
Production time, hr	4	2
Labor & overhead ($10/hr)	$40.00	$20.00
Electrodes (about 22½ lb)	4.50	10.10
Flux (about 10 lb)	1.30	....
Total cost per assembly	$45.80	$30.10(b)

(a) Estimate; accurate within 10%. (b) Cost of carbon dioxide shielding gas was negligible.

Fig. 18. Head-and-trunnion assembly for which automatic flux-cored arc welding was less costly than automatic submerged-arc welding (Example 21)

Example 22. Cost of Making Fillet Welds — Flux-Cored Arc Welding vs Shielded Metal-Arc Welding (Table 12)

To compare the cost of making single-pass fillet welds by shielded metal-arc welding and by flux-cored arc welding without externally applied gas shielding, a 60-day study was conducted. The cost elements were: (a) labor and overhead for depositing 100 lb of weld metal, and (b) electrode cost for depositing 100 lb of weld metal.

Table 12. Cost for Making Single-Pass Fillet Welds by Shielded Metal-Arc Welding and Flux-Cored Arc Welding Without Auxiliary Gas Shielding (Example 22) (a)

Item	Shielded metal-arc welding	Flux-cored arc welding(b)

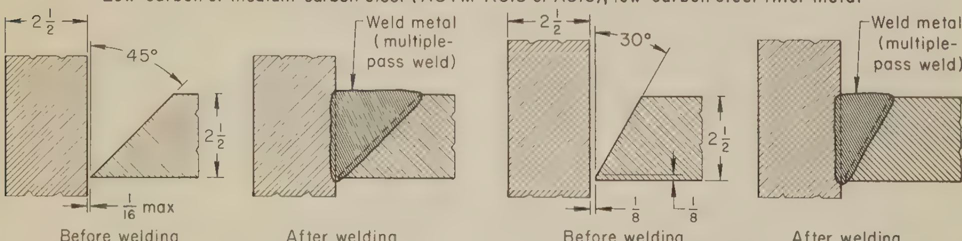
Low-carbon or medium-carbon steel (ASTM A515 or A516); low-carbon steel filler metal



Original method (shielded metal-arc welding, E7018 electrode)
Improved method (flux-cored arc welding, E70T-1 electrode)

The fillet welds (shown in Table 12) ranged in size from 3/16 in. to 3/8 in. They were single-pass welds, deposited in the flat and horizontal positions. All welds could be made by both of the processes being studied. Steel thickness was ¼ to ½ in.

For shielded metal-arc welding, a 3/16-in.-diam E7024 iron powder electrode was used because it produced smooth welds at high speed, with low spatter. The flux-cored electrodes were of low-carbon steel and were 3/32 in. in diameter. A 400-amp motor-generator was used for shielded metal-arc welding; welding current was 275 amp, dcrp. A 600-amp motor-generator and wire feeder were used for flux-cored arc welding; welding current was 350 amp, dcrp.

Table 12 summarizes the results of this study. Electrode-deposition efficiency was lower for shielded metal-arc welding than for flux-cored arc welding because a greater part of the weight of the flux-covered electrodes was flux [see the comparison of flux-covered and flux-cored electrodes on page 27], spatter loss was greater, and electrode stub ends had to be discarded. The operator factor for shielded metal-arc welding was also less because of the time consumed in changing electrodes and restriking the arc. As a result, electrode consumption per 100 lb of deposited weld metal was considerably higher for shielded metal-arc welding, as were man-hours per 100 lb of deposited weld metal. Table 12 shows cost for flux-cored arc welding to be less than one-half the cost for shielded metal-arc welding.

Example 23. Cost of Welding 2½-In.-Thick Steel Plates — Flux-Cored Arc Welding vs Shielded Metal-Arc Welding (Table 13)

Press-platen assemblies, each made of more than 30 plates of 2 to 2½-in.-thick steel (ASTM A515 or A516), were originally welded by the shielded metal-arc process. After a cost and processing study, flux-cored arc welding with auxiliary gas shielding was adopted for these assemblies.

Most of the welds joining the plates were full-penetration single-bevel groove welds made at T-joints. Single-bevel, rather than double-bevel, design was used because the holding fixtures used for assembly limited access to the joint.

A typical single-bevel groove in a T-joint is shown in Table 13. For shielded metal-arc welding, a 45° single bevel with a minimum root opening was used, but for flux-cored arc welding with carbon dioxide shielding, a 30° bevel could be used, thereby reducing the volume of filler metal required by more than a third. A smaller groove could be used because of the deep-penetration characteristic of flux-cored arc welding and the use of a reasonably long electrical stickout (1½ in. with a ¾-in.-OD nozzle).

Other advantages of auxiliary-gas-shielded flux-cored arc welding were: (a) higher deposition rate, (b) higher operator factor, and (c) lower electrode cost. Power cost was not considered significant, and shielding gas cost was a relatively minor factor. Cost factors and welding conditions for both processes are given in Table 13. The three principal items affecting cost were:

1 **Deposition rate,** in pounds of weld metal deposited per arc-hour, which was determined by actual measurement of weld metal deposited for specific electrical conditions during a specific time interval (usually 10 min)

2 **Electrode consumption,** in pounds of electrode required per foot of weld deposit, which was obtained from an actual job analysis

3 **Operator factor,** the ratio of actual welding time (arc-hours) to total payroll time, determined on a daily basis and expressed as a percentage. (The relatively low operator factor in this application was still better than normal for manual and semiautomatic welding of this type. The welder did other work besides welding.)

Example 24. Cost of Fillet Welding Condenser Shells (Table 14)

Two-pass fillet welds that were from ¼ to 3/8 in. in size and less than 10 ft long

were required in fabricating shells of surface condensers. Typical ⅜-in. fillet welds made by flux-cored arc welding with auxiliary gas shielding are shown in Table 14; cost and welding data are also given.

Welding was done in the horizontal position. The welder held the torch at a lead angle of 5° to 15° pointed in the direction of the completed weld (backhand welding). For the first pass, the angle of the electrode to the work was approximately 45°, with the tip of the electrode pointed ⅛ in. outside the intersection of the joint. For the second pass, the 45° angle was used again, and the electrode tip was directed so as to deposit the second bead above the first bead.

The cost data in Table 14 were obtained from production figures and were averaged out. The average values were then converted to rates. The operator factor takes into account various duties associated with weld deposition (such as cleaning slag between passes) and operator rest time.

Example 25. Cost of Auxiliary-Gas-Shielded Flux-Cored Arc Welding To Supplement Automatic Submerged-Arc Welding for Making Pump Casing Bends (Table 15)

Pump casings that were intended to deliver large volumes of water under pressure were fabricated from hot rolled low-carbon steel plate (ASTM A285, grade C), in accordance with Section VIII of the ASME Boiler and Pressure Vessel Code. Longitudinal and circular joints were welded by the submerged-arc process, because with this process fixturing for automatic arc travel was simple. However, on offsets, segmented elbows, and bends, the mitered girth joints were not suited to automatic travel because of the elliptical contour and the angle made with the axis of the casing. For joints of this type, flux-cored arc welding with auxiliary gas shielding was used. A typical 30° bend in a three-section, 50-in.-OD casing, with two mitered girth joints, is shown in Table 15.

Edges were prepared for the two mitered joints by gas cutting the segments from a single length of fabricated casing. Contour and bevel were cut in the same operation in the gas cutting machine. The center section was rotated 180° from its original location, and the joints were tack welded and checked for dimensional accuracy. Next, the flange at one end of the assembly was bolted to the faceplate of a rotating positioner. The preheat temperature requirement of 70 F was met by warming the workpiece with a gas torch, when necessary.

Cost and welding details are summarized in Table 15. Use of semiautomatic flux-cored arc welding permitted the welder to guide the arc visually to the contour of the joint. In addition, the deposition efficiency (weight of electrode deposited as usable metal compared to weight consumed) was 80 to 85%.

Flux-Cored Arc Welding vs Alternative Welding Processes

For applications in which two or more welding processes can produce acceptable results, the choice of process depends mainly on the equipment available, the skill of the welders, the number of similar weldments to be produced, and the cost. For some applications, shielded metal-arc, gas metal-arc, and submerged-arc welding compete with flux-cored arc welding.

Flux-Cored Arc Welding vs Shielded Metal-Arc Welding. Although flux-cored arc welding is less versatile than shielded metal-arc welding, it is usually faster, because it uses a continuously fed electrode wire. Also, the flux-cored method with auxiliary gas shielding results in deeper penetration, which often permits a smaller fillet to be used to achieve the required joint strength, thus requiring less filler metal.

Development of small-diameter flux-cored electrode wires has increased the versatility of flux-cored arc welding. Prior to this development, flux-cored arc welding was generally restricted to welding in the flat and horizontal positions. The example that follows compares flux-cored arc welding with shielded metal-arc welding for making vertical welds.

Example 26. Flux-Cored Arc Welding With Auxiliary Gas Shielding vs Shielded Metal-Arc Welding for Vertical Groove Welds (Table 16)

A study was conducted to compare flux-cored arc welding with shielded metal-arc welding for making ¼-in. vertical groove welds 12 in. long on ¼, ⅜ and ½-in.-thick steel plates. The time required to make these welds is shown in Table 16. Flux-cored arc welding proved to be three to four times faster than shielded metal-arc welding.

Joint design for the two processes is shown in Table 16. The ⅛-in. flux-covered electrode required a relatively wide root opening for the root pass, but a narrow root opening could be used for making the root pass with the 0.045-in. flux-cored electrode. The lower total time for flux-cored arc welding resulted from fewer passes (for the ⅜ and ½-in.-thick plates), less arc time, and less cleaning time.

Examples 12, 13, 22 and 23 in this article also compare flux-cored arc welding with shielded metal-arc welding. In the 18 examples that follow, flux-cored arc welding was selected because of the higher production rates resulting from smaller fillets, fewer passes, and a higher operator factor. In Examples 29, 30 and 31, flux-cored arc welding without gas shielding was used; in the other examples, carbon dioxide shielding was used.

Example 27. Flux-Cored Arc Welding With Auxiliary Gas Shielding vs Shielded Metal-Arc Welding for Production of Brake Supports (Fig. 19)

Brake supports for earthmoving equipment were built from several components that varied in thickness from ¼ to ¾ in.

Production rate, pcs/hr	1⅞	5

Fig. 19. Joints in brake supports that were welded by shielded metal-arc welding and flux-cored arc welding, showing fillet size and joint penetration (Example 27)

Originally, the components were joined by shielded metal-arc welding. To obtain adequate joint penetration, two passes were needed and slag had to be removed after each pass. By this method, production rate was 1⅞ supports per hour.

By changing to flux-cored arc welding, depth of penetration was increased, and fillet size could be decreased to ⅜ in. from the original ½ in. The ⅜-in. fillet weld was made in a single pass. Production rate was increased to five supports per hour and electrode consumption was reduced 44%.

Typical joints are shown in Fig. 19, and other welding details for the two processes are given in the accompanying table.

Example 28. Flux-Cored Arc Welding With Auxiliary Gas Shielding vs Shielded Metal-Arc Welding for a Filter-Shell Assembly (Fig. 20)

A filter-shell assembly, shown in Fig. 20 without fittings and appurtenances, was a pressure vessel made of three major components: a flanged, dished head; a cylindrical shell; and a cast steel flange ring for mounting a door. The vessel was designed for a working pressure of 75 psi, and was fabricated in accordance with the ASME Code for Unfired Pressure Vessels.

Originally, the two circumferential joints and the longitudinal joint were butt welded by the shielded metal-arc process, using E7018 low-hydrogen electrodes. For this method, joint design consisted of a 60° V-groove with a 1/16-in. root face and a 1/16-in. root opening. The groove opened to the outside of the vessel, and a root pass and three filler passes were made from the outside. The root was then back gouged and welded from the inside. Travel speed was about 2 in. per minute. Electrode size and welding current were as follows:

	Electrode diam, in.	Current (dcrp), amp
Root pass	5/32	160
Three filler passes	3/16	200
Backing pass	5/32	160

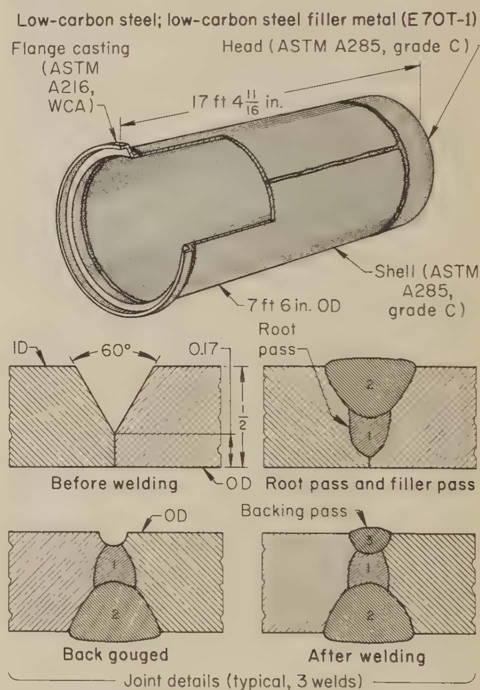
When welding of the filter shell was later changed to the flux-cored arc process, no additional tooling was required. Edges for the three joints were prepared by machining 30° bevels to a depth of approximately two-thirds the plate thickness so that, after fit-up, the 60° groove opened to the *inside* of the vessel. There were two reasons for doing this: (*a*) the weld puddle had high fluidity, and this could be controlled better if a major fraction of the welding could be done in flat position at the bottom interior of the vessel where the walls sloped upward, rather than at the top of the vessel where the walls sloped downward; and (*b*) back gouging of the root bead could be done by the air carbon-arc method more conveniently on the exterior of the vessel than on the interior, where flying sparks would interfere with the operation. With the flux-cored electrode, only one root pass and one filler pass were needed to fill the groove. The root-pass bead was back gouged and the final backing pass was made (Fig. 20).

All three joints on the vessel were essentially the same. The neck of the flange ring was tapered to shell thickness at the joint. On the head, to meet thickness requirements at the knuckle radius, where thinning occurred during forming, the material at the joint was slightly more than ½ in. thick, but the greater thickness was not enough to affect welding. Details of the welding procedure are given with Fig. 20. Travel speeds for the three passes were 18, 12 and 9 in. per minute, respectively. The travel speed for the completed joint was computed to be 4 in. per minute, or twice that of the shielded metal-arc method.

Major operations in fabricating the vessels were as follows. After layout, resquaring and beveling, the shell plate was rolled to size and tack welded. The head and the flange ring were then fitted and tack welded, and the vessel was checked for roundness. Welding was done as described above. All weld beads were carefully wire brushed, inspected for soundness, and repaired if necessary. Vessel openings, fittings, supports and inside track rails were then fitted and welded in place. Next, the vessel was stress relieved and checked for roundness, and the door was mounted to the flange ring and sealed. A hydrostatic test of 115 psi was applied, after which the vessel was cleaned and coated.

Examples 29 to 31. Flux-Cored Arc Welding Without Auxiliary Gas Shielding vs Shielded Metal-Arc Welding for Fillet Welds (Table 17)

A manufacturer of welded steel plate products reviewed welding procedures for



Conditions for Flux-Cored Arc Welding

Joint type	Butt
Weld type	60° V-groove
Welding position	Flat
Preheat	None
Shielding gas	Carbon dioxide, at 45 cfh
Electrode	5/64-in.-diam E70T-1
Electrode holder	300 amp, air cooled
Power supply	500-amp rectifier, slope control
Postheat	Heat in a furnace to 1050 to 1100 F, hold ½ hr, furnace cool

	Root pass	Filler pass	Backing pass
Electrode feed, ipm	172	176	176
Current, amp	300	340	340
Voltage, v	29	32	32
Travel speed, ipm	18	12	9

In shielded metal-arc welding (the process originally used), the first passes were made on the outside of the vessel, and the backing pass was made on the inside; the groove for each joint opened to the outside of the vessel, and had a 1/16-in. root opening.

Fig. 20. Filter shell (pressure vessel) that was flux-cored arc welded, using the joint design shown (Example 28)

(a) ⅛ in. for first pass only. Remainder of passes, use 5/32-in. electrodes. (b) All times based on making a 12-in.-long weld in each thickness.

fillet welds. All fillet welds were being made by shielded metal-arc welding. Three types of semiautomatic welding were initially considered: gas metal-arc, flux-cored arc with carbon dioxide shielding, and flux-cored arc without auxiliary gas shielding. After reviewing costs of equipment, shielding gas, welder training, and portability and operability in the field, it was decided to limit the comparative study to flux-cored arc welding without auxiliary gas shielding and shielded metal-arc welding.

Two important objectives of the investigation were to determine the actual length of weld that could be deposited per hour, and the amount of electrode consumed per foot of weld, for the two processes. To do this, three types of joints commonly used in shop fabrication were selected. Joints of each type were welded by the two processes and data pertinent to the comparison were recorded. Shielded metal-arc welding was done according to the procedures then in use in the shop. Flux-cored arc welding was done using electrodes of the same size and type, and essentially the same current and electrode-wire feed rate, for all three joints.

Example 29 — T-Joint. A T-joint in ¼-in. plate was selected for this test. The requirement was to deposit a single ¼-in. fillet weld in the flat position, as shown in the view for this example in Table 17. When arc-time studies were made, a special electric clock was hooked up with the welding circuit, and an "operator factor", which reflected the time a welder spent depositing metal as compared to his total time, was derived. The operator factor was important in this comparison because when the shielded metal-arc process was used considerable time was spent in changing covered electrodes and restriking the arc.

The actual number of feet welded per hour (on the average) was obtained by converting welding speed in inches per minute to feet per hour and multiplying by the operator factor. Flux-cored arc welding produced more than three times as much weld per hour as shielded metal-arc welding.

For the flux-covered electrodes, electrode consumption in pounds per foot of weld was obtained by dividing the consumption in inches of weld per electrode by 12 to obtain feet of weld per electrode and dividing this figure into the weight of one electrode. For the continuous flux-cored electrode wire, consumption in pounds of electrode per foot of weld was obtained by multiplying the number of pounds purchased by 85%, the electrode-deposition efficiency usually accepted for flux-cored electrodes.

Example 30 — Corner Joint. For this joint, strength was of minor importance. The joint, which is often used in box construction, consisted of two ¼-in. plates assembled at a right angle, with the inside-corner edges touching so as to form a 90° groove, which was filled by welding (see Table 17).

Welding was done in the flat position. This type of weld is often used in low-stress applications. The iron-powder E7024 electrode selected for shielded metal-arc welding is intended for high-speed fillet welding. The data shown in Table 17 for this weld were obtained in the same manner as described in Example 29.

The production rate for flux-cored arc welding, expressed as actual feet welded per hour, was twice that obtained for shielded metal-arc welding.

Example 31 — Corner Joint. The corner joint for this comparison called for a ⅜-in. horizontal fillet weld as shown in the view for Example 31 in Table 17, and was made between plates ½ and ¾ in. thick. For shielded metal-arc welding, the low-hydrogen iron-powder E7018 electrode was selected because of its resistance to underbead cracking in higher-strength steels. Because of the thicker sections involved, cooling rate for the weld was higher than in the two previous examples. Three passes were required to fill the joint. The same type of electrode was used for each pass. The data shown for this weld were obtained in the manner described in Example 29. Production rate for flux-cored arc welding was three times that obtained for shielded metal-arc welding.

Because the types of joints described in Examples 30 and 31 are generally used in applications involving low stress, strength tests and quality inspection were not made.

Table 17. Production Rate, Electrode Consumption and Welding Variables for Fillet Welds Made by Shielded Metal-Arc Welding (SMAW) vs Flux-Cored Arc Welding (FCAW) Without Auxiliary Gas Shielding (Examples 29 to 31) (a)

Item	Example 29 — T-joint FCAW	SMAW	Example 30 — Corner joint FCAW	SMAW	Example 31 — Corner joint FCAW	SMAW
Welding position	Flat	Flat	Flat	Flat	Horizontal	Horizontal
Number of passes	One	One	One	One	One	Three
Electrode type	E70T-4	E7014	E70T-4	E7024	E70T-4	E7018
Electrode diameter, in.	³⁄₃₂	³⁄₁₆	³⁄₃₂	⁵⁄₃₂	³⁄₃₂	³⁄₁₆
Electrode length, in.	Continuous	14	Continuous	24	Continuous	14

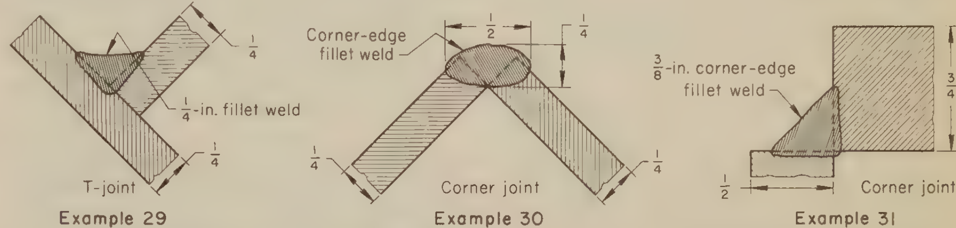
Voltage, v	31	(b)	30	(b)	31	(b)
Electrode-feed rate, ipm	126	6.5	126	11	126	9.5
Length of weld per electrode, in.(c)	...	10.5	...	20.5	...	10.25
Operator factor, %(d)	50	35	50	35	50	35
Welding speed, ipm	18	6.5	25.5	16.2	8.85	4(e)
Welding speed, ft per hour (actual)	45	11.4	63.75	31.85	22.1	7(e)
Electrode consumption per foot of weld, lb	0.171	0.191	0.133	0.133	0.346	0.480



(a) Power consumption was not considered, because it was not significant. (b) Not metered. (c) For covered electrodes only. Takes into account average stub loss of 2 in. per electrode. (d) Average; arc time divided by man-hours times 100. (e) For three passes.

Examples 32 to 44. Flux-Cored Arc Welding With Auxiliary Gas Shielding vs Shielded Metal-Arc Welding for 13 Different Applications (Table 18)

For each of the 13 applications listed in Table 18, shielded metal-arc welding had been used, and the process was changed to flux-cored arc welding, at a substantial saving in welding time, generally from 35 to 50%. Continuous electrode feed, higher deposition rate, and faster travel speed were mainly responsible for the decreased welding time. Also, better visibility of the weld to the welder helped save time and improve weld quality.

Details about the work metal, the type of weld, and welding conditions for auxiliary-gas-shielded flux-cored arc welding are included in Table 18.

Table 18. Operating Conditions for 13 Applications of Auxiliary-Gas-Shielded Flux-Cored Arc Welding (Examples 32 to 44) (a)

Example number	Workpiece	Work metal	Size and type of weld	Electrode diameter, in.	Current (dcrp), amp	Voltage, v	Power supply rating, amp	Flow rate of CO_2 shielding gas, cfh	Travel speed, ipm
32	Semitrailer frame	Low-carbon steel	¼ to ⅜-in. fillet	³⁄₃₂	450	28	500	35	35 to 45
33	Press gear	1020 to 1045 steel	½-in. fillet	³⁄₃₂(b)	600	32	600	45	10
34	River-barge bottom	¼-in. low-carbon steel	Butt; seam	³⁄₃₂	400	27	500	35 to 40	60
35	Condenser shell	¼-in. low-carbon steel	Butt; pretacked	³⁄₃₂	250 to 280	25	500	35	41
36	Bulldozer blade	High-strength low-alloy steel	¼ and ⅜-in. fillet(c)	⅛	425 to 500	27 to 29	500	35 to 40	14 to 21
37	Mine car	½-in. low-carbon steel	V-groove butt; fillet(d)	⅛	450	30	500	45	...
38	Vibrator trough	½-in. low-carbon steel	Horizontal fillet(e)	³⁄₃₂	400	27	500(a)	45	...
39	Concrete pile boxes	⅝-in. low-carbon steel	Fillet	⁵⁄₆₄	380	30	500	35 to 40	13
40	Press gear	1020 to 1045 steel	V-groove, fillet	⁷⁄₆₄	600 to 700	32 to 34	750	35 to 40	(f)
41	Coiling spool	1¼-in. low-carbon steel(g)	Double-V; butt; seam(h)	⅛	650	30	900	25	...
42	Crown assembly	1½ to 2½-in. low-carbon steel	Fillet; T-joint	⅛	425	29	500	35 to 40	13(j)
43	Pipe-straightener frame	2 to 6-in. low-carbon steel	(k)	⅛	500	30 to 35	500	45 to 50	...
44	Press side section	4-in. low-carbon steel	Double-V; butt(m)	⅛	625	33	500	40 to 50	12 to 14(n)

(a) A constant-voltage motor-generator was used for all examples except No. 38, where a rectifier was used. (b) Electrode was in an automatic electrode holder mounted on a manipulator. (c) A positioner was used, and welding was in both flat and horizontal positions. (d) Fillets welded in both flat and horizontal positions. (e) Welded in flat position. (f) Metal deposition was 24 lb per hour. (g) Plate was rolled to 24-in. diameter. (h) Welded in flat position. (j) On a 1-in. fillet weld. (k) Double-V-groove and single-V-groove welds and double-fillet welds, in the flat and horizontal positions. (m) Longitudinal seam. (n) For first and second passes. Third and final passes were at 6 ipm.

Flux-Cored Arc Welding vs Gas Tungsten-Arc Welding. Gas tungsten-arc welding is not extensively used for welding carbon and low-alloy steels, although there are applications in which it has proved advantageous. The example that follows describes an application in which replacement of gas tungsten-arc welding by flux-cored arc welding resulted in improved weld quality and higher production.

Example 45. Flux-Cored Arc Welding vs Gas Tungsten-Arc Welding for Better Quality and Faster Welding (Fig. 21)

The three 4-by-6-in. blocks of ⅜-in.-thick 1020 steel shown welded to a vault door in Fig. 21 served as guides for the closing mechanism of the door. The door slab, also of 1020 steel, was 30 in. wide, 60 in. long and 4 in. thick. The frame, of 1-in.-square 1020 steel bars (see Fig. 21), had been joined to the door by shielded metal-arc corner and peripheral fillet welds as described in Example 11.

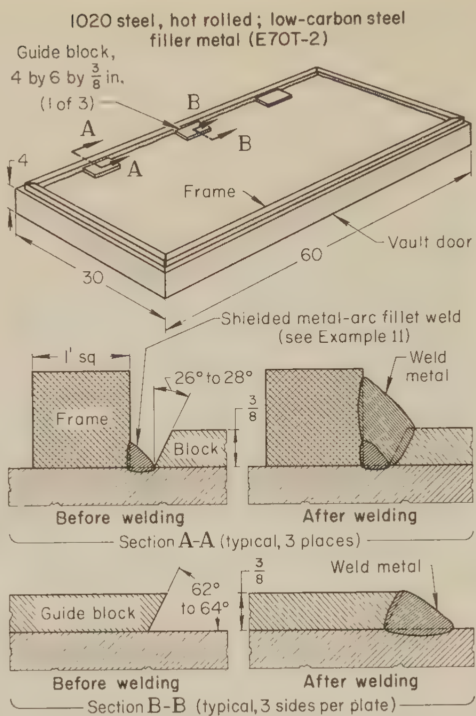
Originally, gas tungsten-arc welding with a low-carbon steel filler metal was used for joining the guide blocks to the frame and door, because this process seemed suitable to the six short welds (involving two welding positions and several changes in direction) that were required for each guide block.

However, experience revealed two drawbacks to this procedure: (*a*) excessive weld porosity, and (*b*) the length of time required to weld a guide block (14 to 16 min).

To overcome these shortcomings, flux-cored arc welding with carbon dioxide shielding was tried and eventually adopted. All six joint edges of the blocks were beveled 26° to 28° by milling without a cutting fluid (to eliminate a cleaning operation). Toggle clamps were used to hold the blocks during welding to maintain a ±0.005-in. tolerance on alignment of drilled holes. Each guide was completed before welding was started on the next guide block.

Results were satisfactory. Welds were uniformly sound, and welding time per guide block was reduced to 1½ min. Cleaning to remove slag and weld spatter was minimal. Some finish grinding was required, to remove rough spots that appeared occasionally where the weld changed direction.

Details for flux-cored arc welding are given in the table that accompanies Fig. 21.



Conditions for Flux-Cored Arc Welding

Joint type	Butt and lap
Weld type	Groove, with fillet reinforcement
Welding position	Horizontal (4 sides); vertical (2 sides; joints not shown in illustration)
Number of passes	One
Preheat	None
Fixtures	Toggle clamps
Shielding gas	Carbon dioxide, at 30 psi
Electrode	⅛-in.-diam E70T-2
Electrode-feed rate	325 to 350 ipm
Power supply	Rectifier, high/low ranges
Current	350 to 375 amp, dcrp
Welding time per guide block	1½ min

Originally, the guide blocks were welded by the gas tungsten-arc process, but welds were porous and welding time per block was ten times that for flux-cored arc welding.

Fig. 21. Vault door with three guide blocks that were joined to door and frame by flux-cored arc welding (Example 45)

Flux-Cored Arc Welding vs Submerged-Arc Welding. These two welding processes are often competitive (see Example 21). Both are capable of high deposition rates and deep joint penetration, although flux-cored arc welding with auxiliary gas shielding usually penetrates deeper. Weld position and length of weld often influence the choice of process. The example that follows describes an application where flux-cored arc welding with auxiliary gas shielding proved more satisfactory.

Example 46. Flux-Cored Arc Welding With Auxiliary Gas Shielding vs Submerged-Arc Welding for Tube-and-Gland Assemblies (Fig. 22)

The tube-and-gland assembly shown in Fig. 22 served as a liner in a cylinder used for pumping abrasive materials such as coal and crushed ore. Joining the gland to the liner tube called for two circumferential partial-penetration groove welds.

Originally, welding was done by the automatic submerged-arc process. The two components were rough machined for a loose fit (0.035-in. clearance) to allow for shrinkage. The joint was prepared for welding by machining the gland as shown in the "Original method" in Fig. 22, and then both the tube and the gland were cleaned with a detergent. The liner and gland were assembled in a rotatable chuck, with the tube axis at an angle of 20° from vertical. No tack welding was needed. Three weld passes were made by rotating the assembly under a stationary electrode holder. Continuous rotation was made possible by mounting an air chisel directly behind the electrode holder, to remove the slag as welding progressed. The workpiece was then turned end for end and the second weld was made by the same procedure. No preheat was used, but the part was stress relieved after welding and prior to final machining, which included removal of the weld reinforcement. Details of the welding operation are given in the table with Fig. 22. Joints were examined for cracking, visually and by magnetic-particle inspection.

Submerged-arc welding was too slow, because to obtain required strength, fill, and joint penetration it was necessary to use a joint that entailed preparation of two surfaces and that had to be welded in three passes. Moreover, about 5% of the weldments were rejected because of defects, and required repair.

To increase production, the joint was redesigned for flux-cored arc welding. The weld groove was changed to the 45° bevel shown for "Improved method" in Fig. 22. As a result, the flux-cored arc process could be used to complete the weld in one pass. The simpler joint design was not suitable for submerged-arc welding because it would not allow sufficient penetration. Flux-cored arc welding completed the single weld pass required in 1½ min arc time, whereas the submerged-arc process required three passes with an average arc time of 1¾ min per pass (5¼ min total).

In addition to obtaining a reduction in arc time of over two-thirds, the welds were more uniform and the rejection rate dropped to an average of 0.75%. Over-all saving in production cost was estimated at 50%. Fixtures for flux-cored arc welding were essentially the same as those used for submerged-arc welding. Conditions for welding by both processes are given in the table accompanying Fig. 22.

APPENDIX

Composition and Selection of Flux-Cored Electrodes

By D. C. SMITH*

FLUX-CORED electrodes for surfacing applications date back beyond the 1930's and thus are not a modern development. They were originally used with what was known as the "open-arc" process, with no auxiliary gas shielding of the weld metal. Their diameter sizes were usually 5⁄64 in. and larger, so the feeding problems that develop with smaller electrode wires were never encountered. The methods now employed with flux-cored electrodes for general fabrication are relatively new.

The general use of flux-cored electrodes externally shielded by carbon dioxide began in the United States in the early 1960's, and there has been a steady growth, the growth rate being considerably greater for the auxiliary-shielded electrodes than for the self-shielding electrodes.

Classification. Nine types of flux-cored electrode wires are covered by AWS A5.20-69 (see Tables 1 and 2, page 26). Characteristics of the nine types are described on page 27. In the AWS specification, there has been no attempt to classify flux-cored electrodes according to the type of material in the core, as is done with the coverings on electrodes for manual shielded metal-arc welding.

Flux-Cored Electrodes for Use With Auxiliary Carbon Dioxide Shielding

The fluxes in flux-cored electrodes for use with auxiliary carbon dioxide shielding are of three types, which we will designate as:

1 High-titania
2 Lime-titania
3 Lime.

In the first (high-titania) type, the slag and weld-metal characteristics are somewhat similar to the E7014, E7024 and E6013 types of covered electrodes for shielded metal-arc welding. The principal difference lies in the depth of penetration of the weld and the absence of hydrogen-forming compounds in the flux core. Covered electrodes have much shallower penetration, whereas the flux-cored electrodes for carbon-dioxide-shielded welding provide deep penetration, permitting a much smaller fillet weld with the same throat thickness.

*Welding consultant. This Appendix is a condensation of Dr. Smith's article in *Welding Journal*, July 1970, pages 535 to 547.

The second (lime-titania) type of flux-cored electrode is comparable to the formerly used covered electrode designated as the lime-ferritic low-hydrogen type, which contained about 8% titanium dioxide along with high fluorspar and some carbonate in the flux. This type forms a basic slag but contains some titanium dioxide slag-forming compounds. The calcium compounds, especially fluorspar, are less, but the volume of slag is usually greater than for all-basic slag of type 3.

The third (lime) type of flux-cored electrode forms a basic slag and contains no titanium dioxide slag-forming compounds and only a small amount of silicon dioxide slag-forming compounds.

Type 1 (high-titania) was the first type developed for use with auxiliary carbon dioxide shielding and has the highest welder appeal. This type has low spatter, smooth bead, good penetration, and deposits fillets of excellent shape. Horizontal fillets are nearly flat and positioned fillets are slightly concave. Weld-metal compositions (manganese and silicon) and mechanical properties of all-weld-metal specimens deposited from four brands of type 1 electrode are given in Table 19.

Type 2 (lime-titania) has good arc stability and fairly low spatter and, in general appearance, falls between the titania type and the lime type but closer to the lime type. Horizontal fillets from lime-titania electrodes show a slight rollover on the lower leg, and positioned fillets have a slight convexity. Type 3 (lime) shows more rollover on the lower leg of a horizontal fillet and more convexity in a positioned fillet. Although it may be difficult to differentiate between types 2 and 3 by the shape of their fillets, it is easy to differentiate type 1 from the other two types by fillet shape.

Because no hydrogen-bearing compounds are used in the fluxes and the shielding is done with carbon dioxide gas, all of these flux-cored electrodes are classed as low-hydrogen. Some of the lubricants used when the electrode is coiled may be a source of the small amount of hydrogen liberated in the welding arc. (Generally, drawing compounds are baked off from the finished drawn wire, and a light coat of lubricant is applied during coiling.)

Although type 1 (high-titania) electrodes can be designated as low-hydrogen, as explained above, these electrodes do not yield weld deposits of the same quality as the common low-hydrogen covered electrodes for shielded metal-arc welding. Also, type 1 does not have a basic-type slag like the low-hydrogen covered electrodes, whereas types 2 and 3 do.

The AWS specification does not differentiate among these three types. The third type may be classed as E70T-5, if it is used without auxiliary gas, and the other types may be classified as E70T-1 if they are multiple-pass electrodes, or as E70T-2 if they are single-pass electrodes. This results in some confusion to the user, because he may have several types of one brand falling in the same classification. For example, most manufacturers make three or four electrodes of the high-titania type (E70T-1), varying the manganese and silicon contents of the weld metal (Table 19). Both type 2 and type 3 may be classed in the E70T-1 category, making it difficult for the user to order by classification rather than brand.

Table 19. Manganese and Silicon Contents and Mechanical Properties of Weld Metal From Four Brands of E70T-1 Electrodes

Brand	Mn, %	Si, %	Mechanical properties TS, psi	YS, psi	El, %	RA, %
A	0.85	0.40	75,000	65,000	25	61
A1 ...	1.20	0.60	85,000	75,000	28	60
A2 ...	1.35	0.33	85,000	76,000	30	62
A3 ...	1.65	0.75	95,000	85,000	25	60

This same confusion exists with the fluxes in alloy steel electrodes. Because of the low hydrogen content of the arc, a high-titania-type flux can be used successfully with low-alloy high-tensile weld metal. However, if maximum notch toughness along with maximum resistance to cracking (either hot or cold) is desired, this is not the best flux to use.

In countries outside the United States, most flux-cored alloy steel electrodes are made with the basic (lime-type) flux, and a titania-type flux is used only for welding mild steel. For making critical welds in alloy steel with flux-cored electrodes, manufacturers in this country are reverting to the basic (lime-type) flux, even though weldability suffers somewhat.

To combine low hydrogen content with a basic-type flux gives the best slagging medium, particularly in welding steel of high tensile strength. It is not known exactly what function calcium performs, but it is quite well confirmed that a beneficial effect results from the presence of only a small percentage of calcium. A small content of calcium appears to have a favorable influence on the solidification process, on ferrite and cementite formation, and on bulk properties of ferrite.

Calcium fluoride is one of the best fluxing and scavenging mediums known to designers of electrodes; the presence of this compound, together with calcium carbonate, results in a basic slag, which in turn is responsible for the better quality of weld metal, as measured by notch toughness and resistance to cracking.

Typical flux and slag compositions of the three types of flux-cored electrodes used with carbon dioxide shielding are given in Table 20. These three types correspond to AWS classifications as follows:

Type 1 (high-titania) E70T-1 or E70T-2
Type 2 (lime-titania) E70T-1
Type 3 (lime) ....E70T-1 or E70T-5

The compounds given in Table 20 can be added to the flux core by various means. For example, silicon dioxide may be added as one of the many natural silicates, as pure sand, as ground glass, or as ferrosilicon. Each brand may vary somewhat in the percentage of these constituents. The main difference is the high titanium dioxide and silicon dioxide contents of the high-titania type as compared to the other types, and the high content of calcium oxide in the two basic types, as compared to virtually no calcium oxide in the high-titania type.

The types designated as lime-titania have properties intermediate between those of the high-titania and high-lime types and may be used where both appearance and quality are desired. However, where the greatest resistance to cracking and the highest notch toughness at low temperature are desired, the lime type (all-basic) is usually the best choice.

The lime type has another advantage: it is less sensitive to the carbon dioxide shielding and thus will be affected less readily by air currents created by fans or by open-field air circu-

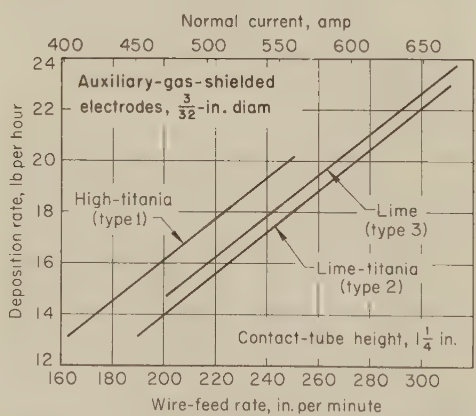

Fig. 23. Effect of wire-feed rate on deposition rate for the three types of auxiliary-gas-shielded flux-cored electrodes

lation. Some of these types can operate satisfactorily without auxiliary gas shielding if an electrical-contact-tube height (stickout) of 2½ to 3 in. is used. When trying to use the electrode without auxiliary gas shielding with this longer electrical-contact-tube height, however, penetration of the weld metal will decrease and slag may be trapped and show up as defects in radiographic inspection. The mechanical properties of the weld metal likewise will not be the same. Table 21 illustrates the difference for an alloy steel brand of this type of electrode with and without auxiliary gas shielding.

Table 22 gives the results obtained with one brand of mild steel basic-type flux-cored electrode with and without auxiliary gas shielding. This table shows the decrease in manganese and silicon contents with a corresponding decrease in tensile and yield strengths and an increase in notch toughness as the type of shielding is changed. Argon shielding gas protects the manganese, silicon and carbon from oxidation as the metal transfers across the arc. In the self-shielding transfer of weld metal, some of the manganese, silicon and carbon are oxidized in the arc, resulting in lower amounts in the weld metal. When carbon dioxide is used as shielding gas, manganese, silicon and carbon are oxidized still more, further decreasing these elements in the weld metal.

Table 22 also shows an increase in tensile strength with increase in manganese and silicon, and a corresponding drop in low-temperature Charpy impact values when welding is done without carbon dioxide shielding. Welding with argon gas increases the manganese and silicon in the weld-metal deposit above that produced by welding with no gas shielding or with carbon dioxide shielding. This result is to be expected because of the oxidizing effect of carbon dioxide shielding and the atmospheric oxidizing effect of no gas shielding on the manganese and silicon contents. The tensile and yield strengths increase proportionately as these alloying elements increase, and the notch toughness increases to an optimum and then decreases.

The chemical composition of the slag from a flux-cored basic (type 3) mild steel electrode when using different types of shielding is given in Table 23. The table shows that argon shielding protects the manganese and silicon, which go into the weld metal instead of into the slag. With carbon dioxide shielding, more manganese and silicon are oxidized and go into the slag. In self-shielding flux-cored arc welding, manganese and silicon are oxidized more than would normally be expected, because the long electrical stickout heats the electrode to a higher temperature than the short stickout used in the carbon-dioxide-shielded type, which gives more exposure of the weld metal to atmospheric oxygen and nitrogen. However, the high volume of carbon dioxide surrounding the auxiliary-gas-shielded type is more oxidizing, resulting in at least as much reduction of manganese and silicon as when the self-shielding electrode is used with long stickout. For maximum retention of manganese and silicon in the weld metal, therefore, argon shielding is preferred.

A comparison of the deposition rates of the three types of electrodes that are shielded with carbon dioxide is shown in Fig. 23. These values were obtained on typical electrodes of three different brands in the amperage and voltage ranges recommended by the manufacturer. The center of the range represents the optimum condition recommended for the 3/32-in.-diam size. At optimum settings there is little difference in deposition rates. Type 3 (lime-type) shows slightly higher efficiency and deposition rate at the optimum setting; this can be attributed to the higher content of iron powder in the flux. Some brands in these classifications are designed for higher efficiencies and have higher deposition rates. For this article, however, the more common types were used to plot the curves.

Self-Shielding Flux-Cored Electrodes

Self-shielding flux-cored electrodes have sometimes been referred to as covered electrodes turned inside out. All the shielding must come from the flux on the inside of the metal sheath, whereas the covered electrode has the flux on the outside of the solid metal core. In most covered electrodes, the greatest amount of shielding is done by gases formed during the decomposition of the fluxes with the heat of the

electric arc. This method of shielding is effective, because the gas shield surrounds the weld metal as it enters the weld puddle.

Because flux-cored electrodes have the flux on the inside of the metal as it enters the weld puddle, gas-forming ingredients cannot be used effectively in the flux. Gas formers would increase weld spatter and push the metal out into the air instead of shielding the metal from the air. Therefore, other means of cleaning and shielding the weld metal from atmospheric contamination are required.

Four types of self-shielding flux-cored electrodes are available today (July 1970):

1 Fluorspar-aluminum
2 Fluorspar-titania
3 Fluorspar-lime-titania
4 Fluorspar-lime.

Most self-shielding electrodes marketed today are of the first and second types, with the third type next, and type 4 last. Type 4 may also be considered as a type 3 electrode for use with auxiliary carbon dioxide shielding and thus fall into classification E70T-5 of AWS A5.20-69, designed for use both with and without carbon dioxide shielding.

The principal difference in the use of all the self-shielding electrodes, in comparison with the electrodes used with auxiliary carbon dioxide shielding, is the electrode holder used by the welder. With most self-shielding flux-cored electrodes, an electrical-contact-tube height (stickout) from 2½ to 5 in. is required, whereas with carbon dioxide shielding, stickout of ¾ to 1 in. is required. The electrode holder designed for the self-shielding electrode has a hidden, insulated, contact-tube height of 1½ to 4 in., so the visible stickout is the same for both carbon-dioxide-shielded and self-shielding types.

A cutaway section of the two types of nozzles is given in Fig. 1, on page 78. The voltage requirements for the two are about the same. Because of the large difference in electrical stickout, however, the amperage will be much less for the self-shielding types, even though the electrode feed may be the same or higher. Details of these properties are discussed later in this article.

Typical compositions of the fluxes of the four groups of self-shielding flux-cored electrodes are given in Table 24. The percentages of the constituents vary depending on the amount of iron powder used and the thickness of the strip from which the tube is formed. The thickness of the strip determines the flux-steel ratio. For the samples given, the flux varied from 15 to 28%. The percentage of flux varies with different brands, but all that were checked fell within this range. Table 24 represents 12 different brands from five different manufacturers.

Slag Characteristics and Mechanical Properties of Weld Metal Deposited From Self-Shielding Electrodes

As shown in Table 24, the slags formed from the four types of self-shielding electrodes differ considerably in chemical composition. The carbon and alloy contents of the weld metal deposited also may vary significantly (Tables 25 to 29), with consequent variations in mechanical properties.

Type 1 — Fluorspar-Aluminum. This type of flux-cored electrode is characterized by an aluminum-colored low-density slag that forms with the emission of a fairly heavy volume of smoke. The welding characteristics of the electrode are generally rated by welders as good, the greatest complaint being the heavy volume of smoke when welding is being done in unventilated areas. The appearance of the weld bead is generally very good, with the shape of horizontal fillet welds approaching a flat surface and with equal leg lengths. The weld metal feathers out well on both the upper and lower legs of horizontal and positioned fillet welds. Slag removal is generally good except when the weld metal is highly diluted with base metal. Such a condition may cause the slag to cling to the surface more tightly. Because of the high aluminum content of the weld metal, this electrode sometimes is not satisfactory for tacking joints together for subsequent welding. The weld metal does not arc-air gouge like other mild steel weld metal, so when the arc-air torch is used to smooth out the weld surface, more difficulty may be encountered than with other mild steel welds.

If the welder uses proper technique to avoid entrapment of slag, x-rays are generally water-clear. As with all types of self-shielding flux-cored electrodes, penetration is not nearly so good as with the auxiliary-gas-shielded types, primarily because of the long contact-tube height (3 in.), which consumes energy for preheating the electrode. On the other hand, the short contact-tube height (1 in.) allows this energy to go into the base metal, thus increasing the penetration to some extent.

The notch toughness of weld metal deposited from the fluorspar-aluminum type of self-shielding electrode is rather low. When used in a flat position and when the weld metal is alloyed with 0.50 to 0.75% nickel, Charpy impact values may be as high as 20 ft-lb at 0 F. The standard commercial electrode gives a lower notch toughness and falls in the AWS E70T-4 classification. When modified for higher notch toughness, it meets the E60T-8 classification.

Small-size electrodes of this type (5⁄64 in. in diameter and smaller) with some modification of the flux composition are designed for out-of-position welding. The stickout is generally 1¼ in. (similar to carbon-dioxide-shielding types); low voltage (18 to 22 volts) and straight polarity, with correspondingly low amperage, are used. Electrodes designed for this out-of-position application fall into the AWS E60T-7 classification. However, the quantity of electrodes used for such applications is small at present (1970).

Typical mechanical and chemical properties of weld metal deposited from electrodes of the fluorspar-aluminum type are given in Table 25 (E70T-4) and Table 26 (E60T-7).

In welding with electrodes of the fluorspar-aluminum type, metal transfer is globular, bordering on the spray type. With the smaller electrode sizes, transfer becomes spray type when straight polarity and 1 to 1¼-in. stickouts are used, as is common for out-of-position welding. The typical voltage and amperage requirements for the 5⁄64-

in.-diam electrode used for out-of-position welding are 18 to 22 volts and 150 to 250 amp.

Type 1 (fluorspar-aluminum) E70T-4 and E60T-8 electrodes are intended for welding both heavy and light sections, including machinery and machinery parts, structural fabrication, field erection, column splices, beam-to-column connections, and repair of heavy machinery. The E60T-7 electrodes, in 5/64-in. and smaller diameters, are designed for all-position welding, have similar flux compositions, and likewise fall into this same classification. Applications involving joints with poor fit-up and high-carbon, high-sulfur, and other difficult-to-weld steels are successfully welded with this type of electrode, provided the application does not require high notch toughness at low temperature. For vessels and structural work where compliance with rigid codes is necessary, the use of this type of electrode is generally restricted. Some brands are particularly well suited for high deposition rates.

Type 2 — Fluorspar-Titania. This type of self-shielding flux-cored electrode is characterized by a heavy, dense slag similar to that from type 3 electrodes and may or may not have a golden color on the underside of the slag. It is designed to yield a fast-follow weld metal, which makes it excellent for high-speed, usually automatic, welding of light metal frames. It is usually employed for single-pass fillet welds and is seldom used in multiple-pass applications. When used in high-speed welding, the electrical-contact-tube height is 3/4 to 1 in., using high amperage and moderate voltage.

Because this type of electrode is not designed for multiple-pass operation, few data on mechanical properties of the weld metal are published. Some brands of this type, when used in a multiple-pass operation with the usual long stickout technique, give fairly good mechanical properties. The chemical and mechanical properties of weld metal obtained from one brand when welding according to AWS A5.18-65T are given in Table 27.

Applications of type 2 electrodes generally are automatic operations involving high-speed welding, as in automotive frame welding. Short stickouts of 3/4 to 1 1/4 in. are used with travel speeds up to 200 in. per minute. Type 2 electrodes can also be successfully used for a single pass or for fillet welds of unlimited size in multiple passes. Likewise, heavy sections can be butt welded where service conditions do not require weld metal of high ductility and notch toughness; for welds for such service, the usual long stickout (2 1/2 to 3 in.) should be used.

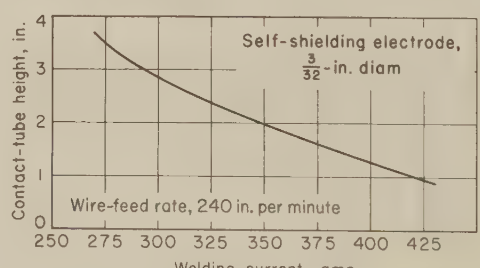

Fig. 25. Relationship between contact-tube height and welding current at a constant wire-feed rate for a typical self-shielding flux-cored electrode

Type 3 — Fluorspar-Lime-Titania. This type of self-shielding electrode is characterized by a heavy, dense slag with a golden color on the underside. The appearance of the slag is much like that of the slag from E7018 electrodes for shielded metal-arc welding, except that the slag from the E7018 electrode does not have the golden color on the underside.

Type 3 flux-cored electrodes give the best mechanical properties of all four types when used with self-shielding. If auxiliary carbon dioxide shielding is used, type 4 excels in notch toughness. A horizontal fillet weld from a type 3 electrode is more convex and exhibits a little more rollover on the lower leg than similar welds from types 1 and 2 electrodes, but has an excellent bead appearance in the flat position. The deposition rate is usually the highest of all four types. This type is excellent for welding high-carbon, high-sulfur, and other difficult-to-weld steels, because of its low penetration and excellent weld-metal quality. Because of the low carbon content of the weld metal and the low-hydrogen slag, the fluorspar-lime-titania flux is excellent for alloying the weld metal for steels of high tensile strength. Thus, it should find wide use in the repair welding of steel castings. It is not satisfactory for high travel speed on light frame stock, because the weld metal does not follow fast enough.

Typical mechanical and chemical properties of weld metal obtained from type 3 electrodes are given in Table 28.

Applications for type 3 self-shielding electrodes have few limitations in mechanical properties. If high penetration is desired, to get down into the root of a heavy weld, a short stickout and auxiliary carbon dioxide shielding can be used; then the joint is filled, using long stickout (2 1/2 to 3 in.) and a self-shielding electrode. Nozzles are available that can be adapted to either of these requirements.

Type 3 electrodes are ideally suited for high-carbon and other difficult-to-weld steels. Like type 1, they can be used for welding machinery and machinery parts, structural fabrications, field erections, column splices, beam-to-column connections, repair of heavy machinery, and repair of castings made of either carbon or alloy steel.

Type 3 is not intended for out-of-position welding. When drawn in 1/16-in. and smaller diameters, however, it can be used on straight polarity with low voltage (18 to 23 volts) and low amperage for out-of-position work. Normal application of the 3/32-in. and larger sizes of electrode requires a constant-voltage reverse-polarity type of power supply.

Type 4 — Fluorspar-Lime. This type of self-shielding electrode is characterized by a thin, light-brown slag. Its

flux and weld metal are similar to those of the lime-type electrode designed for use with auxiliary carbon dioxide shielding, but the weld metal is more likely to roll over at the lower leg of a horizontal fillet weld, and the surface is more convex. The fillet shape resembles that made with E7018 electrodes in shielded metal-arc welding. The bead appearance is not quite as smooth, and weld spatter is somewhat greater than for any of the other types of self-shielding electrodes. The multiple-pass weld metal shows a fairly high tensile strength, with fair elongation and reduction in area. Notch toughness is good, but x-ray soundness may be unsatisfactory. None of the brands tested met the x-ray standards of AWS A5.18-65T; they did meet grade II of AWS A5.1-64T. Typical properties are given in Table 29.

This type of flux-cored wire makes a versatile electrode that can be used with or without carbon dioxide shielding and is excellent for difficult-to-weld steels. When carbon dioxide shielding is used, the weld quality exceeds that of any other flux-cored electrode. This type of electrode can also be used successfully for welding frame steel at high speed with a short stickout (¾ to 1 in.). When this electrode is used as a self-shielding type, weld-metal transfer is globular and can easily trap slag. Moreover, the weld metal can contain considerable porosity that does not show on the surface of the metal if the voltage used is too high for the welding current or the electrode-feed rate.

Applications of type 4 as a self-shielding electrode are limited, particularly when x-ray quality is required. Likewise, type 4 yields the poorest-shape fillet of the four types. However, its high notch toughness makes it a good choice for low-temperature applications. When alloyed, its x-ray quality improves. Thus, for the repair of medium-carbon alloy steel castings such as 4140 and 4340, it can be used successfully. It is intended for both heavy and light weldments, similar to the applications listed for types 1 and 3. Like type 3, it is versatile, and when used with carbon dioxide shielding for deep root penetration, it gives the highest-quality weld of all types, including other carbon-dioxide-shielded types. Its inferior x-ray quality, however, restricts its application in comparison with type 3.

A comparison of the deposition rates of 3⁄32-in.-diam self-shielding electrodes of the four types is given in Fig. 24.

Figure 25 shows the relationship between contact-tube height (stickout) and amperage at a constant electrode-feed rate of 240 in. per minute for a typical 3⁄32-in.-diam self-shielding flux-cored electrode. Figure 26 gives relationships between amperage and wire-feed rate. Figure 27 compares deposition rates of covered electrodes for shielded metal-arc welding with auxiliary-gas-shielded and self-shielding flux-cored electrodes.

[Source article has illustrations of fillet welds in T-joints, and of horizontal welds in butt joints, made with auxiliary carbon dioxide shielding and with self-shielding electrodes.]

Submerged-Arc Welding

*By the ASM Committee on Submerged-Arc Welding of Steel**

SUBMERGED-ARC WELDING is an arc welding process in which the heat for welding is supplied by an arc (or arcs) developed between a bare-metal, consumable electrode (or electrodes) and a workpiece. The arc is shielded by a layer of granular and fusible flux, which blankets the molten weld metal and the base metal near the joint, and protects the molten weld metal from atmospheric contamination.

Principles of Operation

In submerged-arc welding, the electric current flows through the arc and the weld puddle, which consists of molten flux and molten weld metal. The molten flux is usually highly conductive, although cold flux does not conduct electricity. In addition to acting as a protective shield, the flux cover may supply deoxidizers and scavengers that react chemically with the weld metal. Fluxes for submerged-arc welding of alloy steel may also contain alloying ingredients that modify the composition of the weld metal.

Figure 1 shows how a submerged-arc weld is made. Electric current from a generator, transformer-rectifier, or transformer passes through the contact tube, and thence through the electrode wire, to produce an arc between the electrode and the base metal. The heat of the arc melts the electrode, flux, and some base metal, forming a weld puddle that fills the joint.

In all types of equipment, mechanically powered drive rolls continuously feed the bare-metal, consumable electrode wire through a contact tube (nozzle) and through the flux blanket to the joint being welded. The electrode wire, generally a low-carbon steel of closely controlled chemical composition, is coiled on a reel or in a drum. The electrode wire melts off at the weld zone and is deposited along the joint. Granular flux is deposited ahead of the arc, and, after the weld metal solidifies, unfused flux is removed by a vacuum pickup system, to be screened and reused. In automatic welding, flux recovery may be an integral function of the equipment, with a flux-recovery tube following directly behind the contact tube (see Fig. 2).

Submerged-arc welding is adaptable to both semiautomatic and fully automatic operation, although the latter, because of inherent advantages, is more widely used. In semiautomatic welding, the welder manually guides a welding gun (with flux hopper attached) that feeds the flux and the electrode to the joint, and he controls the rate of travel. In fully automatic welding, the equipment automatically feeds and guides the electrode and the flux along the joint and controls the rate of deposition. A typical machine for automatic submerged-arc welding is shown schematically in Fig. 2.

In some applications of automatic submerged-arc welding, two or more electrodes are fed simultaneously to the same joint. The electrodes can be side-by-side and fed into the same weld puddle, or they can be spaced just far enough apart to permit two weld puddles to solidify independently. The latter technique, sometimes referred to as tandem-arc welding, produces a multiple-pass weld in a single traverse of the joint, thereby increasing rate of deposition and welding speed.

Advantages and Limitations

Submerged-arc welding, either semiautomatic or fully automatic, offers the following advantages over some other welding processes:

1. Joints can be prepared with a shallow V-groove, resulting in less filler metal being used. (In some applications, no groove is required in joints between plates 1¼ in. or less thick.)
2. Shielding is not required to protect the operator from the arc, although eye protection is recommended. The arc operates under the flux cover, thus eliminating weld spatter.
3. The process can be used at high welding speeds and deposition rates to weld cylindrical or flat plate, or pipe, of virtually any size or thickness, and can be used for hard facing.
4. The flux acts as a scavenger and deoxidizer to remove undesirable contaminants from the weld puddle and to produce sound welds with good mechanical properties. The flux may, if required, supply alloying elements to the weld metal.
5. For welding unalloyed low-carbon steels, inexpensive electrode wires can be used — usually carbon steel wire, either bare or flash plated with copper, the latter to improve electrical contact and protect against rusting.
6. The submerged-arc process can be used for welding in exposed areas with relatively high winds; the granular flux shielding provides protection superior to that obtained from the electrode covering in shielded metal-arc welding.

Limitations of submerged-arc welding, some of which are also applicable to other welding processes, include the following:

1. Flux, flux-handling equipment, and workholding fixtures are required. Many joints also require the use of backing plates, strips or rings.
2. Flux is subject to contamination that may cause weld porosity.
3. To obtain welds of good quality, the base metal must be homogeneous and essentially free of scale, rust, oil and other contaminants.
4. Slag (solidified residue from the fused flux) must be removed from the weld bead, and this is sometimes a difficult operation. In multiple-pass welding, slag must be removed after each pass, to avoid entrapment in the weld metal.
5. The process usually is not suitable for use on metal less than 3⁄16 in. thick, because burn-through is likely.
6. Except for special applications, welding is largely restricted to the flat position for groove welds, and to the flat and horizontal positions for fillet welds, to avoid runoff of flux.

Suitable Work Metals

Submerged-arc welding is not adaptable to all metals and alloys. For convenience, metals and alloys may be divided into three groups with respect to their suitability to the process: most suitable, less suitable, and unsuitable.

Most Suitable Work Metals. Submerged-arc welding is used most widely in the production welding of unalloyed (plain) low-carbon steels containing not more than 0.30% carbon, nor more than 0.05% phosphorus and 0.05% sulfur. Most of the examples in this article deal with these steels, which range in tensile strength from about 45,000 to 85,000 psi and which usually are welded with a combination of flux and electrode wire included in AWS A5.17-69 (Specification for Bare Mild Steel Electrodes and Fluxes for Submerged-Arc Welding). Medium-carbon and low-alloy structural steels are equally well-

Some of the examples presented in this article were contributed by members of other Metals Handbook welding committees. A total of 24 examples of applications of submerged-arc welding appear in other articles in this volume, as recorded and briefly described in the table at the end of the Appendix to the present article, on page 77.

suited to submerged-arc welding, although they more often require preheating, postheating, and special electrode wires and fluxes.

Stainless steel, hardenable carbon steel, hardenable high-strength low-alloy steel, and hardenable high-strength structural steel are also welded by the submerged-arc process. Procedures for welding these steels are described in articles in this volume that deal individually with the welding of hardenable carbon steels, alloy steels, and stainless steels.

Submerged-arc welding is also used to deposit buildup and abrasion-resistant coatings on steel surfaces that are subjected to wear (see the article on Hard Facing by Arc Welding, which begins on page 152).

Less Suitable Work Metals. Some metals and alloys that can be submerged-arc welded are more often welded by processes that give a narrower heated zone. Some low-carbon, high-strength structural steels are included in this group, because of special notch-toughness and strength requirements that are difficult to meet by submerged-arc welding. Included also are high-carbon steels, maraging steels, and copper and copper alloys.

Unsuitable Work Metals. Cast iron usually cannot be submerged-arc welded, because it cannot withstand the thermal stress resulting from high heat input. However, Example 241 in the article on Arc Welding of Cast Irons describes an application in which malleable iron was submerged-arc welded to low-carbon steel. Problems are encountered with austenitic manganese steel and high-carbon tool steel, which are difficult to weld by any conventional welding process.

Aluminum alloys and magnesium alloys cannot be submerged-arc welded, because suitable fluxes are not available. Lead and zinc are unsuitable because of their low melting points. Titanium has been submerged-arc welded on an experimental basis, but no satisfactory flux for production welding has so far been developed.

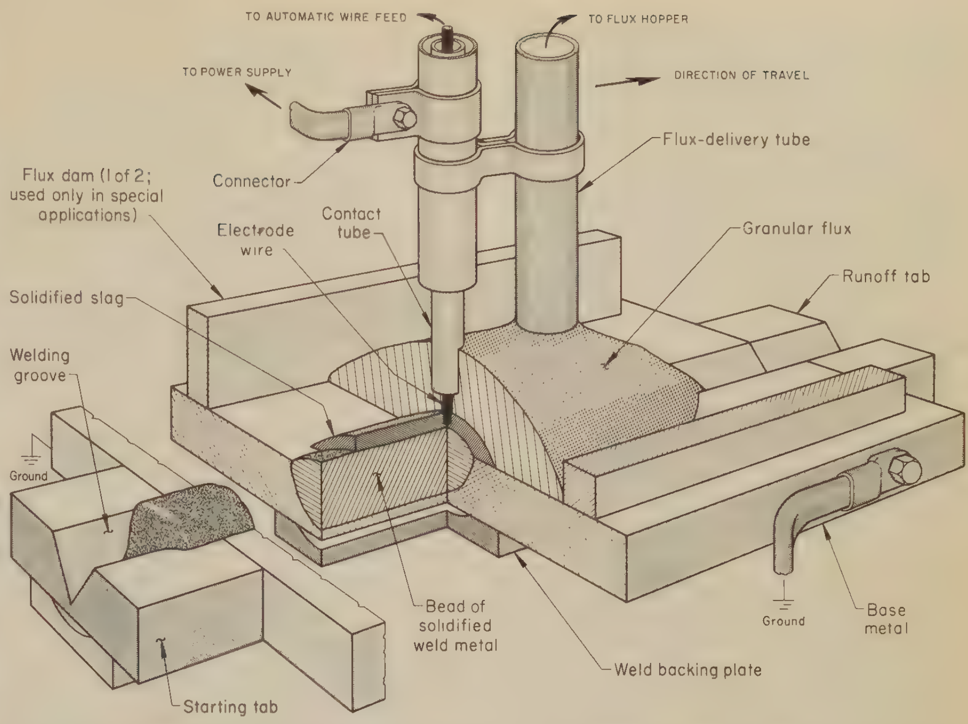

Fig. 1. Cutaway view of a single-V-groove weld in a butt joint, showing elements of an automatic submerged-arc welding operation

Metallurgical Considerations

Three characteristics of submerged-arc welding at high currents require special consideration: (*a*) the high percentage of base metal in the weld deposit when reverse-polarity direct current is used; (*b*) the large amount of slag that results from the operation; and (*c*) the large heat input, which affects microstructure.

When the percentage of base metal in the weld deposit is high, it is important that harmful impurities in the base metal, such as sulfur and phosphorus, be held to a minimum.

The large amount of slag generally constitutes a source of silicon or manganese, some of which may be transferred to the weld deposit. Consequently, a low-silicon electrode wire (one containing 0.05% Si max) is generally used with high-silica fluxes, to prevent the weld metal from picking up excessive silicon. A low-manganese electrode wire, containing 0.50% manganese or less, is generally used with high-manganese fluxes. A high-manganese electrode wire, containing 2% manganese, is generally used with fluxes that contain little or no manganese (see the section "Effect of Flux Composition on Weld-Metal Composition", on page 74 in the Appendix to this article).

The large heat input that results from welding at high current (such as 1500 amp) at low travel speeds may coarsen the structure of the heat-affected zone and decrease its notch-toughness (raise its impact transition temperature).

Microstructural Changes. The extent of change in the structure of the base metal depends on four factors: the maximum temperature to which the metal is subjected, the time at that temperature, the chemical composition of the base metal, and the cooling rate.

The microstructure of the weld metal is columnar, because the grains start to form at the solid boundary and can grow in one direction only. In a hardenable carbon steel, the base-metal zone immediately adjacent to the weld metal may be coarse grained, because temperatures in the range of 2800 to 2200 F have been reached. Metal that has been heated to 2200 to 1700 F has a band of finer grain. Although this zone has been heated above the transformation range, the maximum temperature and the time at temperature have not been sufficient to cause grain coarsening. The next zone, 1700 to 1400

F, is one in which the steel has been annealed and is considerably softer than in the adjoining zones. From here out to the unchanged base metal, there may be carbide spheroidization, due to prolonged holding near 1330 F.

Preheating and Postheating. The principles of preheating and postheating are the same for submerged-arc welding as for other arc welding processes. Preheating and postheating are applied to hardenable steels, particularly steels whose carbon content exceeds about 0.30%, in thicknesses greater than ¾ in.

The reduction in cooling rate that results from preheating increases the time during which the heat-affected zone is in the temperature range above the start of martensite formation, and therefore promotes transformation of austenite to a softer pearlite instead of to hard martensite. A preheated weld is less likely to have hard zones than a weld that was not preheated. Also, because of the low cooling rate associated with preheated steel, thermal stresses are lower, decreasing the risk of weld cracking.

Postheating is used when needed to provide stress relieving, annealing, normalizing or tempering.

Power Supplies

Power supplies for submerged-arc welding are: (*a*) motor-generators and transformer-rectifiers, for direct-current (dc) output; (*b*) transformers, for alternating-current (ac) output. Either alternating current or direct current produces acceptable results in submerged-arc welding, although each has distinct advantages in specific applications — depending on the amperage range, diameter of the electrode wire, and travel speed — as outlined in the following list:

1. Semiautomatic welding done with electrode wire 5/64 or 3/32 in. in diameter, at input current of 300 to 550 amp: use of direct current predominates.
2. Automatic welding with a single electrode at low current (300 to 500 amp) and high travel speed (40 to 200 ipm): use of direct current predominates.
3. Automatic welding, single electrode, medium current (600 to 900 amp), travel speed of 15 to 30 ipm: either alternating or direct current is used.
4. Automatic welding, single electrode, high current (1200 to 2500 amp), travel speed of 5 to 15 ipm: use of alternating current predominates.
5. Automatic welding with two or more electrodes in the tandem position at 500 to 1000 amp per electrode; alternating current on all electrodes (or direct current on the lead electrode) is used.
6. Automatic welding with two electrodes in the transverse position: either alternating or direct current is used.

Direct Current. The characteristics of the power supply for submerged-arc welding with direct current are essentially continuous current and continuous voltage, uninterrupted by short circuits, as shown in the superimposed oscillograms in Fig. 3(a). At the start of welding there is a surge of current as the arc is initiated. The current should drop to the desired value within a small fraction of a second.

Direct current may be supplied by a motor-generator or a transformer-rectifier. A motor-generator consists of an alternating-current motor connected by a common shaft to a direct-current generator; the generator field may be separately excited or self-excited. A transformer-rectifier is a transformer with selenium or silicon rectifiers to convert alternating current from the main power line to direct current. As they relate to submerged-arc welding, the important features of generators and transformer-rectifiers are the rated and maximum current outputs (see Table 1) and the volt-ampere characteristic curves.

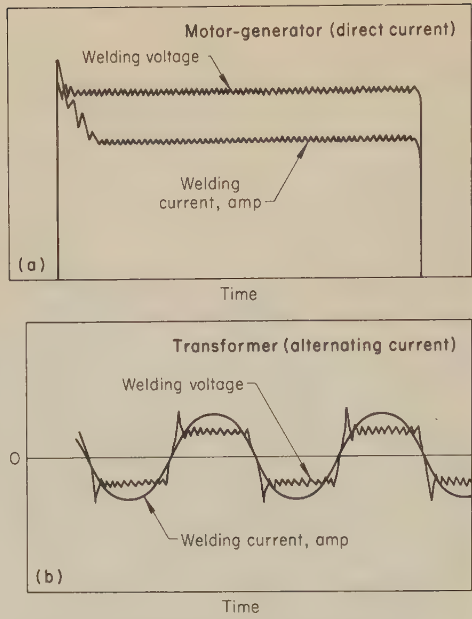

Fig. 3. Oscillograms (superimposed) for welding current and voltage for a motor-generator and a transformer

Volt-ampere characteristic curves are curves that show the voltage at which every value of current is provided under steady conditions. The curves are obtained by loading the welding machine with variable resistance and plotting the voltage at the electrode and work terminals for each ampere output.

(a) Rated current can be delivered continuously for 6 min out of every 10 min. (b) Rated current can be delivered continuously as long as required. (c) Rated current can be delivered continuously for 1 hr, and then for 45 min out of every hour for the next 3 hr.

In terms of equipment, two types of characteristic curves are available for submerged-arc welding — drooping and flat; these are illustrated by curves D and F, respectively, in Fig. 4. Curve D is called a drooping-characteristic curve because the voltage at the terminals of the motor-generator or transformer-rectifier decreases sharply as the current is increased. It is associated with a constant-current power supply providing either direct or alternating current. Curve F is called a flat-characteristic curve because the voltage remains almost constant as the current is increased. This curve is associated with a constant-voltage power supply providing direct current only.

The difference in welding action between flat-characteristic and drooping-characteristic motor-generators or transformer-rectifiers is shown by plotting the volt-ampere characteristics of two submerged welding arcs (arcs 1 and 2) on the same graph with curves D and F (see Fig. 4). Arc 2 has higher voltage than arc 1, and therefore is a longer arc. It is assumed that the electrode wire is advancing at constant speed. If, because of a sudden change in level of the workpiece, the arc voltage increases from that of arc 1 to that of arc 2, the current will shift to a slightly lower value on the drooping-characteristic power supply, but on the flat-characteristic supply, there is a larger decrease in current. The flat-characteristic power supply will return the arc to arc 1 voltage more rapidly than will the drooping-characteristic supply. Thus, a motor-generator or transformer-rectifier with flat characteristic has an advantage when used with a constant-speed wire-feeding system of control. This system is applicable to welding with small-diameter wire, such as 1/16 in., which is fed at rates that make the current response of the flat characteristic almost instantaneous. With larger-diameter wire (5/32 in. and over), the wire feed is so slow that the fast current response of the flat characteristic is of little or no consequence. The drooping-characteristic power supply with a voltage-controlled wire feeder then becomes more advantageous.

Alternating Current. The power demand for submerged-arc welding with alternating current from a transformer approximates a sine wave of amperage and a rectangular wave of voltage (see Fig. 3b). There is a reversal of polarity at every half-cycle with an associated peak voltage to reignite the arc. The power is supplied by a transformer with a drooping characteristic — that is, a constant-current transformer. Alternators have never been used for submerged-arc welding. Table 1 shows rated amperage for transformers at various duty cycles.

Most transformers are provided with reactance, to stabilize the arc. High-current-capacity transformers for submerged-arc welding have an open-circuit voltage of 80 to 100 volts to accommodate the high arc voltage needed to start and stabilize the ac arc. For transformers with lower current capacities, the open-circuit voltage usually is 65 to 75 volts. Transformers with open-circuit voltage of less than 65 volts are not suitable for submerged-arc welding. There are several satisfactory systems for changing the transformer setting; one of these, the saturable-reactor control, is most convenient for remote control.

As previously noted, alternating current is preferred in both automatic welding with a single electrode at a

high current level and in automatic, multiple-electrode tandem-arc welding. For high-current applications, transformers are more economical than motor-generators. Furthermore, the high current facilitates arc starting, and alternating current reduces the severe arc blow encountered with direct current at high amperage. For lower-current applications, direct current is better than alternating current for sharp-wire and scratch starts. At high travel speed, constant-voltage direct current provides more-uniform weld beads than does alternating current.

Wire-Feeding Systems

Equipment for feeding the electrode wire in submerged-arc welding employs either of two types of system for control of wire-feed rate — voltage-sensitive systems and constant-speed systems. Voltage-sensitive control systems are used with constant-current power supplies, whereas constant-speed control systems are used with constant-voltage power supplies.

Voltage-sensitive systems are those in which the power supply maintains an essentially constant welding current, and the electrode feeder varies the feed rate of the electrode wire to maintain a constant arc voltage. This is accomplished by monitoring the arc voltage and having the voltage control momentarily increase the wire-feed rate when the voltage increases beyond a preset level, or decrease the feed rate when the voltage drops. A voltage-sensitive control system is preferred for high-current welding, particularly when the current density is more than 35,000 amp per square inch of the cross-sectional area of the electrode wire.

Constant-speed systems are essentially the same as voltage-sensitive systems, except for the substitution of a constant-speed control for the voltage control. In a constant-speed system, the arc voltage is preselected at the power supply, which is designed to maintain this preselected voltage irrespective of the current demand. (This system is also known as a constant-potential system.) The wire is fed at a predetermined rate, and arc length is held constant through automatic adjustment of the current by the power supply to maintain fixed resistance across the arc. Compared with a voltage-sensitive control system, a constant-speed control system provides increased voltage stability, consistent scratch starting, and more convenient adjustment of voltage and current. Constant-speed systems are particularly suitable for the high-speed welding of thin metal. Best results are obtained when the current density is in excess of 35,000 amp per square inch of the cross-sectional area of the electrode wire.

Electrode Wire

Electrode wire for submerged-arc welding of steel is available commercially in sizes from 0.045 to ⅜ in. in diameter (although the 0.045-in.-diam wire is not listed in AWS specification A5.17-69). Electrode wire ⅜ in. in diameter is seldom used. The electrodes are produced in various ferrous alloy compositions, ranging from unalloyed low-carbon steel to special high-alloy steel.

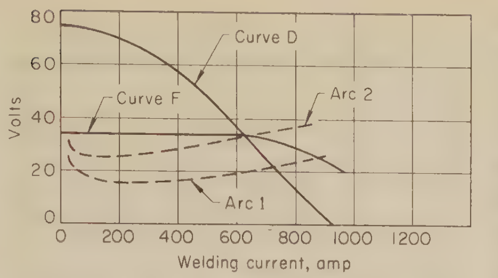

Fig. 4. Static volt-ampere curves of motor-generators or transformer-rectifiers with drooping (curve D) and flat (curve F) characteristics. See text for a discussion of the relation of curves D and F to curves for arcs 1 and 2.

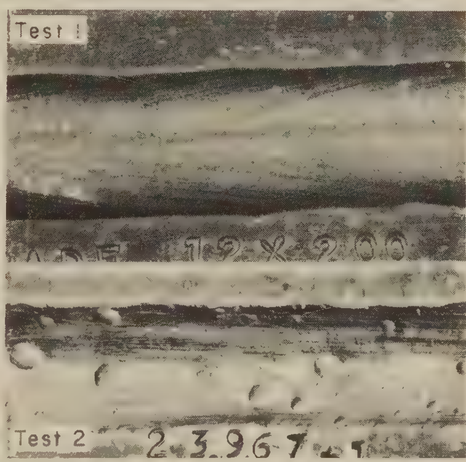
Packaging. The continuous unalloyed low-carbon steel electrode wire is either coiled, or wound into drums. (Straight lengths of wire can be used for laboratory work, but are rarely used commercially.) The weights of electrode coils vary slightly from manufacturer to manufacturer. Typically, electrode wire ⅛ in. in diameter or smaller is available in coils weighing 25 or 60 lb. Electrode wire $\frac{5}{32}$ in. in diameter or larger is available in coils weighing 150 or 200 lb. The weight tolerance for all coils is ±10%. The smaller coils are used where weight reduction and compactness are essential — as in semiautomatic welding.



Item	Test 1	Test 2
Mechanical Properties of Weld Metal		
Yield strength, psi	65,000	58,000
Tensile strength, psi	85,000	77,000
Elongation in 2 in., %	28	26
Reduction in area, %	56	59
Charpy impact, ft-lb:		
Room temperature	25	50
−20 C (−4 F)	10	18

Welding Conditions for Both Tests

Base metal	ASTM A515, gr 70, steel, ½ in. thick
Joint type	Butt
Weld type	Single-V-groove; copper backing
Joint preparation	Machined
Flux	F61
Electrode-wire diameter	$\frac{5}{32}$ in.
Welding position	Flat
Power supply	1200-amp transformer
Current	500 amp
Voltage	30 v
Welding speed	30 ipm
Number of passes	One
Preheat and postheat	None

The test 2 weld bead, made with electrode wire containing 0.50% manganese, is deeply cratered, contrasting with the smooth, sound weld bead made in test 1 with electrode wire containing 2% manganese.

Fig. 5. Two weld beads made by submerged-arc welding under similar conditions but using electrode wires of different compositions (Example 47)

Table 2. AWS Classifications and Composition Limits for Electrodes for Submerged-Arc Welding (AWS A5.17-69)

AWS classification	Composition, %(a) C	Mn	Si
Carbon Steel (Low Manganese) Electrodes			
EL8	0.10 max	0.30-0.55	0.05 max
EL8K	0.10 max	0.30-0.55	0.10-0.20
EL12	0.07-0.15	0.35-0.60	0.05 max
Carbon Steel (Medium Manganese) Electrodes			
EM5K(b)	0.06 max	0.90-1.40	0.40-0.70
EM12	0.07-0.15	0.85-1.25	0.05 max
EM12K	0.07-0.15	0.85-1.25	0.15-0.35
EM13K	0.07-0.19	0.90-1.40	0.45-0.70
EM15K	0.12-0.20	0.85-1.25	0.15-0.35
2% Manganese Steel Electrode			
EH14	0.10-0.18	1.75-2.25	0.05 max

(a) Electrodes of all classes also contain maximums of 0.035 S, 0.03 P, 0.15 Cu (independent of coating), 0.50 total other elements. (b) Also contains 0.05 to 0.15 Ti, 0.02 to 0.12 Zr, 0.05 to 0.15 Al — exclusive of the 0.50% content of "total other elements".

Drums of electrode wire are used primarily in high-production applications, where a large volume of wire is consumed and where the welding equipment has been designed to support and channel the electrode wire from the drum into the welding head. Electrode wire 0.045 to ¼ in. in diameter is available in drums weighing 250 to 300, 500, 700 to 750, and 1000 lb net.

Composition. The composition of steel electrode wire, including that used in welding low-carbon steel, is a factor in the establishment and control of the composition of the weld metal. Other important factors are the composition of the flux and of the base metal, and the welding procedure.

Table 2 lists AWS classifications and composition limits for nine different types of electrode wires that are widely used for submerged-arc welding of low-carbon steels. These electrodes may be used in suitable combination with ten AWS classes of flux to produce weld metal with specified mechanical properties (see Table 5). Many carbon and alloy steel electrodes of compositions different from those shown in Table 2 are available. The compositions of six low-alloy steel electrodes commonly used in submerged-arc welding are given in Table 3.

As shown in Table 2, the standard steel electrode wires contain controlled amounts of carbon, manganese and silicon, with residual amounts of sulfur and phosphorus. When all other significant variables remain constant, appreciable variation in the amounts of these elements contained in the electrode wire may significantly affect weld quality, as demonstrated in the following example.

Example 47. Effect of Electrode Composition on Quality of Weld Bead (Fig. 5)

Variations in the quality of submerged-arc butt welds made in ½-in.-thick ASTM A515, grade 70, steel plate were attributed to differences in electrode-wire composition. Test joints were welded under identical conditions, including use of the same flux (composition of which was not identifiable) but using two different electrode wires of the following compositions:

Table 3. Compositions of Low-Alloy Steel Electrodes Commonly Used in Submerged-Arc Welding

Common designation	C	Mn	Si	P	S	Cr	Ni	Mo
	Composition, %(a)							
½ Mo	0.13	1.95	0.04	0.010	0.020	...	...	0.53
½ Mo – 1 Ni	0.14	1.85	0.04	0.010	0.015	...	1.00	0.51
1¼ Cr – ½ Mo	0.10	0.65	0.15	...	...	1.53	...	0.56
2¼ Cr – 1 Mo	0.10	0.62	0.20	...	...	2.47	...	0.95
4130	0.30	0.50	0.31	0.024	0.021	0.90	...	0.21
8620	0.21	0.78	0.32	0.020	0.023	0.50	0.60	0.22

(a) Although the compositions listed apply to electrode wire, similar compositions of deposited weld metal can be obtained when an unalloyed low-carbon steel electrode wire is used in conjunction with a suitable alloy-containing flux.

	C	Mn	Si	S	P
Test 1	0.14	2.00	0.03	0.024	0.017
Test 2	0.09	0.50	0.03	...	0.017

As shown in Fig. 5, weld beads made in test 1 were smooth and sound and would be expected to pass radiographic examination, whereas those made in test 2 had craters and ripples and probably would not pass radiographic examination even after dressing or grinding to remove the surface roughness. Results of mechanical testing of the weld metal deposited in the tests are shown in the table accompanying Fig. 5.

Analysis of the weld metal in the two beads showed:

Test 1 .... 0.14 C, 0.74 Mn, 0.25 Si
Test 2 .... 0.11 C, 0.50 Mn, 0.22 Si

Because manganese serves both as a deoxidizing agent and as a strengthening element, the cratered surface, irregular outline of the weld, and lower strength of the weld metal in test 2 were attributed to the lower manganese content. If this deficiency had been known in advance of welding, it might have been overcome by using a flux capable of adding an adequate amount of manganese to the weld metal.

Surface Condition. Most unalloyed, low-carbon steel electrode wire is lightly coated with copper during manufacture. The copper coating provides some protection from rust and ensures good electrical contact between the electrode and the contact tube (nozzle) of the welding head. Good electrical contact is essential to the maintenance of satisfactory arc characteristics.

Electrode wire should have a smooth, clean surface. Rust and other surface contaminants can produce weld porosity, cause excessive wear of contact tubes, and adversely affect arc characteristics. Some small-diameter electrode wire is coated with a small amount of a special hydrogen-free lubricant. This lubricant helps to feed the wire through the welding-cable conduit that carries the wire from the semiautomatic wire feeder to the welding-gun contact tip.

Table 4. Current Ranges for Electrode Wires Used in Submerged-Arc Welding

Wire diameter, in.	Current range, amp(a)	Wire diameter, in.	Current range, amp(a)
0.045	100 to 350	5⁄32	340 to 1100
1⁄16	115 to 500	3⁄16	400 to 1300
5⁄64	125 to 600	7⁄32	500 to 1400
3⁄32	150 to 700	¼	600 to 1600
⅛	220 to 1000	5⁄16	1000 to 2500
		⅜	1500 to 4000

(a) Upper and lower limits of ranges are extremes and are rarely used.

Table 5. Mechanical-Property Requirements for Flux Classification (AWS A5.17-69) (a)

Tensile strength:
- Classes F60 thru F64 ...62,000 to 80,000 psi
- Classes F70 thru F74 ...72,000 to 95,000 psi

Yield strength (0.2% offset), min:
- Classes F60 thru F64 ....50,000 psi
- Classes F70 thru F74 ....60,000 psi

Elongation in 2 in., min (all classes) ..22%(b)

Charpy V-notch impact strength:
- Classes F60 and F70 ....Not required
- Classes F61 and F71 ....20 ft-lb at 0 F
- Classes F62 and F72 .....20 ft-lb at −20 F
- Classes F63 and F73 .....20 ft-lb at −40 F
- Classes F64 and F74 .....20 ft-lb at −60 F

(a) Mechanical properties are those of the weld metal, produced by one of the classes of flux in combination with an electrode of one of the classes shown in Table 2. A flux designation consists of the class number, as shown in the present table, followed by the designation of the electrode used in combination with it (for example, F60-EL8). (b) For each increase of one percentage point, the tensile strength or the yield strength, or both, may decrease 1000 psi to minimums as follows: tensile strength, 60,000 psi (F60 through F64) and 70,000 psi (F70 through F74); yield strength, 48,000 psi (F60 through F64) and 58,000 psi (F70 through F74).

Table 6. Conditions and Results of Tests To Determine Effect of Silicon Content of Flux on Silicon Content of Weld Metal (Example 48) (a)

Flux type, test 1 ....Special low-silicon
Flux consumption, test 1 .....0.15 lb per min
Flux type, test 2 ....General purpose(b)
Flux consumption, test 2 .....0.20 lb per min

Welding Conditions for Both Tests

Joint type ....Butt
Weld type ....U-groove (side 1), V-groove (side 2)
Joint preparation ....Machining
Welding position ....Flat
Power supply ....40-v, 600-amp transformer-rectifier
Preheat and postheat ....None
Electrode ....3⁄32-in.-diam EH14
Electrode stickout ....1 in.
Deposition rate ..0.5 lb per min per 1000 amp
Number of passes 18
Sequence and conditions of the 18 passes:

Side	Pass No.	Current (dcrp), amp	Voltage	Travel speed, ipm
1	1	320	27	20
	2	320	28	18
	3	320	28	18
2	4	350	26	15

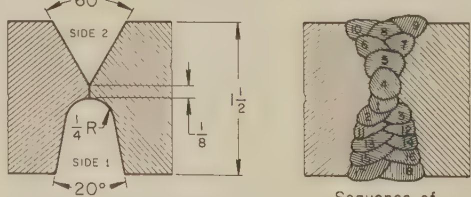
	6	330	30	8
	7-10	320	30	8
1	11-18	320	30	8

Chemical Compositions

Base metal ..... 0.20 C, 0.60 Mn, 0.008 Si
Electrode ...... 0.14 C, 2.00 Mn, 0.024 Si
Weld metal, passes 6 and 7:
Test 1 .... 0.09 C, 1.00 Mn, 0.014 Si
Test 2 .... 0.09 C, 0.95 Mn, 0.400 Si

Low-carbon steel (ASTM A285, grade C); 2% Mn steel filler metal (EH14)



Joint detail before welding

Sequence of weld passes

(a) Test welds were made in butt joints as illustrated above, which were between plates of a pulp digester that required weld metal with a silicon content of less than 0.015% to ensure corrosion resistance. (b) Contained a significant amount of silicon dioxide (silica) and no ferrosilicon or other deoxidizer.

Selection of wire size (diameter) depends on equipment requirements and application. Small-diameter electrode wire (0.045 through 5⁄64 in.) is used almost exclusively with semiautomatic welding equipment. The 3⁄32-in.-diam electrode wire is used with either semiautomatic or fully automatic equipment. Larger sizes (⅛-in. diameter and above) are used only with fully automatic equipment, because their use with semiautomatic equipment would make the welding cable leading to the semiautomatic welding gun too stiff and difficult to handle.

Small-diameter electrode wires (0.045 through 5⁄64 in.) are more flexible and perform better at low currents than large-diameter wires of the same composition and type. Flexibility is essential to the use of semiautomatic submerged-arc welding equipment. If the electrode wire is too stiff, the welder will find the welding gun and cable too difficult to manipulate into positions necessary to produce sound welds. A stiff welding cable also increases welder fatigue, thereby reducing arc time and efficiency.

Most semiautomatic submerged-arc welding is done with electrode wire 5⁄64 or 3⁄32 in. in diameter. The use of wire less than 5⁄64 in. in diameter is usually limited to applications requiring stable arc characteristics at low current — for example, for joining thin metal, for making circumferential welds on small-diameter assemblies, and for multiple-arc welding. In addition to their ability to develop stable arc characteristics, small-diameter wires provide better control of the molten weld puddle and of bead size and shape, and provide a more uniform weld appearance.

Large-diameter electrode wires (5⁄32 to ⅜ in.) are used to take advantage of higher current capacity and increased deposition rate (see Example 49). They are occasionally used to reduce depth of penetration and to increase bead width. Also, the large sizes make tightness of fit-up at the root of a joint less critical.

For large-diameter wire, the components of the wire-feeding mechanism, including the drive rolls, gearbox, electric motor, and wire straightener, must be larger and more ruggedly constructed than for small-diameter wire. This is essential to ensure uniform operating characteristics and to maintain weld quality.

Current Range. In submerged-arc welding, an electrode of a specific diameter can operate within an unusually wide current range, as shown in Table 4. The overlap of current ranges makes it possible to use any of several wire sizes at a particular welding-current setting. Changing to a smaller-diameter electrode wire at a given current may serve to increase depth of fusion and reduce the width of the weld bead.

With small-diameter electrode wire, the arc is initiated more readily than with a wire of large diameter, and small-diameter wires are particularly well-suited to hot starts and to high-frequency arc starting. When the welding current is at the low side of one of the current ranges given in Table 4, an electrode wire of the next-smaller diameter (resulting in a higher current density) will provide a more stable arc and a higher deposition rate.

Fluxes

Fluxes used in submerged-arc welding are granular, fusible, mineral materials containing oxides of manganese, silicon, titanium, aluminum, calcium, zirconium, and magnesium, and other

compounds. They are melted by the welding arc and, in the molten condition, blanket the weld metal and shield it from atmospheric contamination. Fluxes are generally chemically neutral with respect to the weld metal, must not evolve large amounts of gases during welding, and must have electrically stable welding characteristics.

Fluxes are classified by AWS on the basis of the mechanical properties of a weld deposit made with a particular combination of flux and electrode (see Table 5). A flux used in combination with an electrode of any of the classes shown in Table 2 must produce weld metal that conforms with the requirements in Table 5.

Additional information on fluxes is given in the Appendix to this article, beginning on page 73.

Low-silicon fluxes are used in applications where the silicon content of the steel base metal and of the weld deposit must be low to prevent excessive corrosion. A typical application is the welding of pulp digesters, which are subject to corrosive attack by digester liquids. The example that follows compares the compositions of the weld metal produced in such an application when using a special low-silicon flux and when using a general-purpose flux.

Example 48. Use of Low-Silicon Flux in Welding Joints for Service in Corrosive Environment (Table 6)

The plates of a pulp-digester tank were butt welded together by submerged-arc welding in 18 passes as shown in Table 6. The plates were made of 1½-in.-thick ASTM A285, grade C, low-carbon steel. It was important that the silicon content of the metal exposed to the digester fluids be below about 0.015% to minimize corrosion.

To determine the effect of the silicon content of the flux on the silicon content of the weld metal, test plates were welded using a special low-silicon flux (test 1), and other test plates were welded under the same conditions but using a general-purpose flux containing a significant amount of silicon dioxide (silica) and no ferrosilicon or other deoxidizer (test 2).

The carbon, manganese and silicon contents of weld beads made with the two fluxes are compared in Table 6. The weld bead that was made with the special low-silicon flux (test 1) contained only 0.014% Si, in contrast to the 0.40% Si contained in the bead made with the general-purpose flux (test 2). Welding conditions for the two tests are given in Table 6.

Particle Size. Fluxes for submerged-arc welding are available in a variety of sizes ranging from 8×48 to 48×325 mesh. These flux-size numbers indicate the sizes of the largest and smallest particles present; for example 8 × 48 indicates that 90 to 95% of the particles will pass through a screen having eight openings per inch and only 2 to 5% will pass through a screen having 48 openings per inch.

Flux particle sizes, therefore, correspond to the meshes per lineal inch on a screen-scale sieve table, such as that given in Table 7. Particle sizes of 250 and smaller are sometimes referred to as "dust" and may be represented by the letter "D", rather than by a specific particle size number. Thus, some manufacturers use the designation 48 × D instead of 48 × 250, since the "D" designation may represent several particle sizes that are 250 mesh and smaller.

Table 7. Tyler Screen-Scale Sieves

Meshes per lineal, In.	Meshes per lineal, Cm	Sieve opening, In.	Sieve opening, Mm	Wire diameter, In.	Wire diameter, Mm
8	3.15	0.093	2.36	0.032	0.813
9	3.54	0.078	1.98	0.033	0.838

250	98.43	0.0024	0.061	0.0016	0.041
270	106.3	0.0021	0.053	0.0016	0.041
325	128.0	0.0017	0.043	0.0014	0.036

The choice of flux particle size for a particular welding application depends on the current to be used, type of flux, travel speed, and type of weld being made. Table 8 gives ranges of welding current for a number of standard flux sizes. Finer sizes are desirable for high welding currents, and are also used at lower currents, because they give wider and flatter weld surfaces. For welding over rust or oily surfaces, coarse sizes are preferred because they are more permeable and liberate gases more freely.

Particle Size vs Current. The particle size of the flux affects the amount of current that can be used in submerged-arc welding. In general, a higher welding current can be employed with a fine flux than with a coarse one, while maintaining a stable arc and producing sound, uniform welds. Too high a current for a given flux particle size causes arc instability and results in ragged and uneven weld edges and surfaces.

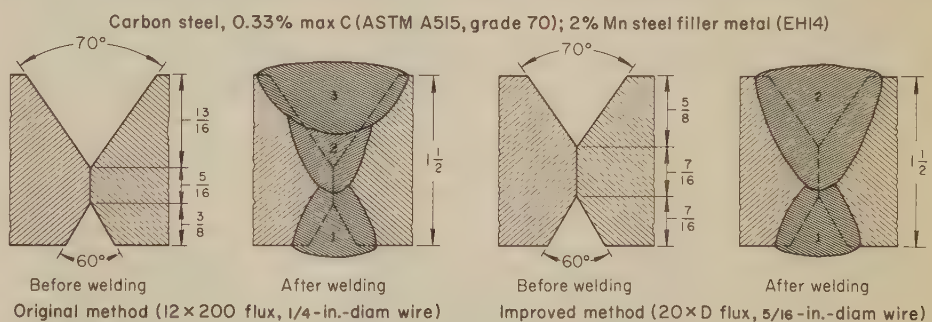
The higher current permissible and the more penetrating arc associated with a fine flux particle size and larger electrode-wire size may enable smaller grooves to be used in joining thick metal, with resultant savings, as in the application in the following example.

Example 49. Effect of Flux Particle Size and Electrode-Wire Size on Welding Current and Cost (Fig. 6)

The longitudinal seam in a 6-ft-diam by 24-ft-long unfired pressure vessel was originally butt welded in three passes, using size 12×200 flux. For full penetration in the 1½-in.-thick ASTM A515, grade 70, steel (0.33% max C), the joint design and double-V-groove weld were as shown at the left in Fig. 6.

Changing to a finer flux size (20 × D), and from a ¼-in. to a 5⁄16-in.-diam electrode wire, resulted in a substantial saving in labor and other costs by making it possible to complete the weld in two passes and reduce electrode and flux consumption. Because use of the finer flux particle size and larger electrode-wire size permitted welding at higher current, resulting in a more penetrating arc, total groove depth could be reduced by ⅛ in., with the same bevel angles, as shown at the right in Fig. 6.

Material and welding labor costs were reduced by 37% as a result of using 32% less filler metal, 20% less flux, and 46% less arc time. Other savings included less machining time for preparing the joint and a 29% reduction in the electrical power consumption for welding. Operating conditions and a detailed comparison of costs and cost factors for the original and the improved methods are given in the table



Welding Conditions for Both Methods

Joint type	Butt
Weld type	Double-V-groove
Joint preparation	Machining
Electrode stickout	1½ in.
Welding position	Flat
Deposition rate	0.5 lb per min per 1000 amp
Power supply	Transformer
Electrode class	EH14
Flux class	F72

Item	Original method	Improved method
Electrode diameter, in.	¼	5⁄16
Flux particle size	12×200	20×D
Cost per Foot of Weld		
Filler metal(a)	$0.503	$0.343
Flux(b)	0.332	0.264
Labor(c)	0.946	0.506
Total	$1.781	$1.113

Welding conditions	Original method, Pass 1	Original method, Pass 2	Original method, Pass 3	Original method, Total	Improved method, Pass 1	Improved method, Pass 2	Improved method, Total
Welding current (ac), amp	1050	1150	1250	...	1300	1600	...
Welding voltage	35	32	38	...	35	37	...
Travel speed, ipm	9	5	12	...	10	9	...
Flux consumption, lb per ft	0.86	1.65	0.81	3.32	1.10	1.54	2.64
Electrode consumption, lb per ft	0.75	1.46	0.66	2.87	0.83	1.13	1.96
Arc time, minutes	1.33	2.40	1.00	4.73	1.20	1.33	2.53
Power consumption, watt-hr(d)	814.6	1472	825	3111.6	910	1312	2222

(a) At $0.175 per pound. (b) At $0.10 per pound. (c) At $6 per hour; 50% arc time. (d) Net power consumption, neglecting efficiency and power factors.

Fig. 6. Reduction in groove depth of a longitudinal butt joint in a pressure vessel, and decrease in number of weld passes (which decreased welding cost), that were made possible by changing from a coarse flux to a small-particle-size flux and by using larger-diameter electrode wire (Example 49)

that accompanies Fig. 6. The major fraction of the cost saving was in labor charges.

To avoid excessive arc blow and to minimize power cost, alternating current was used. Arc initiation was by means of steel wool. Soundness of welds was checked by x-ray inspection. The welds were stress relieved at 1250 F for 4 hr.

Care of Fluxes. Commercial fluxes are thoroughly dry when shipped from the manufacturer, and are packaged in moisture-resistant containers to keep them dry. Fluxes should be stored in dry areas. If they become damp or wet, they can be dried by heating, usually at 750 F for about one hour. Moist or damp flux causes porosity and cracking in weld metal. Oil and rust contamination also cause porosity and should be avoided. When flux can be recycled after being used, care should be taken to avoid contamination with rust, mill scale, and other foreign substances.

Jigs, Fixtures and Booms

Because requirements vary with the shape, size and weight of individual workpieces, jigs and fixtures are subject to few firm rules of design and construction. However, the following design principles are generally applicable:

1. The fixture should serve to position the weld in the flat position.
2. Designs should be simple, to minimize cost.
3. Loose clamping should be avoided.
4. Fast-acting clamps (hand, air or hydraulic) are recommended.
5. Clamps should be adequately spaced from the joint being welded.
6. The ground connection, or connections, for the fixture should be located for most effective grounding and best control of arc blow.
7. The fixture should minimize or eliminate the need for tack welds in the weldment.

In addition to their primary function of holding and positioning the workpiece during welding, fixtures may also serve to control or minimize distortion due to thermal stress. Thus, fixtures should be rigid enough to ensure retention of alignment during welding. Although the movement of critical areas may be restricted, provision must be made for thermal expansion and contraction. Fixtures may be stationary or mobile in relation to the welding head.

Lathe fixturing is commonly used in welding plugs or caps to the ends of cylinders, and in joining cylindrical sections, because it combines a clamping action with centering and controlled rotation. A typical lathe fixture and setup for simultaneously welding two plugs to the ends of a cylinder is described in the following example.

Table 8. Recommended Current Ranges for Standard Sizes of Fluxes Used in Submerged-Arc Welding

Flux size(a)	Current range, amp
8×48, 14×48(b), 12×65, 10×150	Up to 1100
12×150	600 to 1100
12×200	600 to 1750
20×200, 35×200	600 to over 1750

(a) Size numbers indicate maximum and minimum particle sizes; for example, size 8×48 means most of the particles will pass through a screen with 8 openings per inch and almost none will pass through a screen with 48 openings per inch. Numbers are screen-scale sieve numbers given in Table 7 (see also ASTM E11). (b) Typical size for bonded flux.

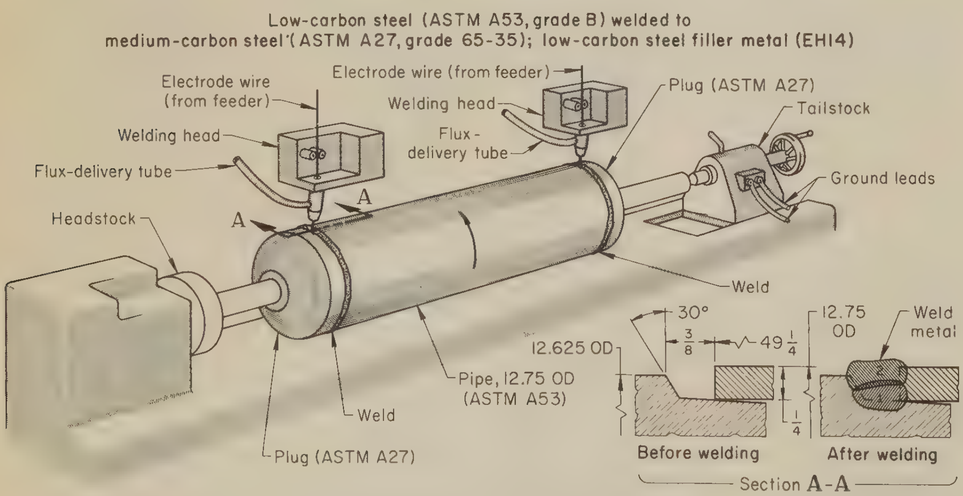
Example 50. Use of Lathe Fixturing in Welding Plug Ends of Cargo Cushions (Fig. 7)

Cargo cushions, used to control shock when coupling railroad freight cars, were assembled by welding a plug into each end of a 12.75-in.-OD pipe (¼-in. wall thickness), using automatic submerged-arc welding and the lathe setup shown in Fig. 7. The pipe, 49¼ in. long, was made of ASTM A53, grade B, steel. The beveled end plugs were cast from ASTM A27, grade 65-35, steel, and were tack welded into place before being submerged-arc welded to the tube. The welded joints had to withstand a hydrostatic test pressure of 430 psi.

The two plugs were welded simultaneously, using two welding heads mounted on separate carriages. Welding conditions are given in the table with Fig. 7.

The assembly was supported and rotated in a rework lathe. Each weld was made in two passes, as shown in section A-A in Fig. 7. No postweld finishing was done. Sample welds were macroetch-inspected.

Use of Booms. Booms and extensions of various types are used to support and guide the welding head, to enable it to reach locations that are not readily accessible, such as the inside surfaces of tubes and cavities. A typical use of a boom in the circumferential welding of internal and external surfaces of cylinders is described in Example 51, which follows. (See also Example 61,



Process	Automatic submerged-arc welding
Joint type	Butt
Joint preparation	Machining
Weld type	Single-bevel-groove
Electrodes (two)	3/32-in.-diam EH14
Flux	F70; size 12×65
Electrode stickout	¾ in.
Welding position	Flat (horizontal-rolled pipe position)
Welding voltage	29 v
Welding current	350 amp, ac
Welding speed	14 ipm
Flux consumption per assembly	4.1 lb
Electrode consumption per assembly	2.88 lb
Number of passes per weld	Two
Power supplies	Two 48-v, 500-amp transformers
Preheat and postheat	None
Auxiliary equipment	Rework lathe
Production rate	Six assemblies per hour

Fig. 8. Joining of two rotated cylinders by deposition of inside, then outside, circumferential weld beads, using a welding head that was supported and guided by a boom (Example 51)

which describes the use of booms in longitudinal welding of cylinders.)

Example 51. Circumferential Butt Welding of Cylinders, Using a Boom and Motor-Driven Rolls (Fig. 8)

Two ASTM A515, grade 70, steel cylinders, each 36 in. in diameter, 36 in. long, and with 0.750-in. wall thickness, were joined end-to-end by automatic submerged-arc welding in two operations, as shown in Fig. 8. During welding, the assembly was rotated on drive rolls, and the welding head and flux feeder were supported and guided by a boom.

The two ends to be joined were machined to form a groove along the inside of the joint, and were aligned and butted to a maximum root opening of 1/32 in., as shown in the "Before welding" view in section A-A in Fig. 8. The two cylinders were held together for welding either by tack welds or by a continuous weld bead, around the outside of the joint. (The continuous bead was used to provide backing for the first pass of the inside weld when fit-up was not tight enough to prevent drop-through.)

Then the assembly was loaded onto four motor-driven rolls, and the automatic welder was set up for the first operation — welding the inside of the circumferential joint in two passes (see section A-A in Fig. 8). The boom-supported welding head was located on the circumference at a position such that the weld deposit would solidify before it could run downhill (see Fig. 8).

After the inside of the joint had been welded, the groove on the outside of the joint was back gouged by grinding to sound weld metal (see "Before welding" view in section B-B in Fig. 8), to prepare for welding of the outside. The groove was liquid-penetrant or magnetic-particle inspected to ensure complete removal of unsound metal.

The weld on the outside of the joint was made in one or more passes — the number depending on the extent of grinding in making the groove. Again, the welding head was positioned so as to keep the weld metal from running off.

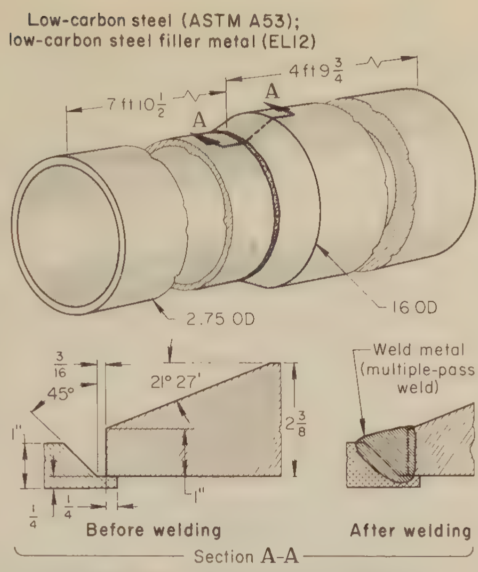
Both operations were done with the same welding head, with wire fed from the spool through the boom conduit to the welding head. Welding conditions are given in the table with Fig. 8. The welding was done with reverse-polarity direct current to obtain the desired control of bead shape and appearance, and consistent full penetration. All welds and welding procedures met requirements of the ASME Boiler and Pressure Vessel Code.

The completed weld was ground to within 1/8 in. above the cylinder surface on both sides. After 100% radiographic inspection, the cylinder weldment was given a postweld heat treatment at 1650 F for 1 hr.

Joint Design

Recommended designs of joints for use in submerged-arc welding are presented on pages 148 to 151 in this volume. These joint designs take into consideration the deep penetration that is characteristic of submerged-arc welding, and the difficulty of slag removal that attends deep-groove, multiple-pass welding. It will be noted that backing bars are used when needed to prevent burn-through and loss of flux. It is possible to obtain welds with 100% penetration in plates up to 5/8 in. thick without joint preparation, but a buildup of weld deposit will be produced on both surfaces. However, through the use of proper design that utilizes edges beveled by gas cutting, excessive reinforcement can be avoided.

Example 59 (and Fig. 25) in this article shows the effect of welding position on joint design.



Joint type	Butt
Weld type	Single-bevel-groove with integral backing
Electrode wire	1/8-in.-diam EL12
Flux	F71
Welding position	Flat (horizontal-rolled pipe position)
Welding voltage	28 v
Welding current	600 amp, dcrp
Travel speed	3 ipm
Preheat	250 F
Postheat	None
Number of passes	Six to eight
Production per 8-hr shift	Three assemblies

Fig. 9. Two pipes of different diameters joined by submerged-arc welding, with a land on the smaller pipe serving as a backing ring (Example 52)

Methods of Avoiding the Use of Backing Rings and Strips

The use of a solid backing ring or strip, to start a joint, or to obtain complete penetration while avoiding burn-through, can sometimes be avoided by redesigning the joint, or by the use of a flux bed as backing for the first pass (see Examples 57 and 61). This is desirable in applications that would require removal of the backing strip after welding is completed.

Joint Design. In the submerged-arc welding of pipes and other tubular workpieces, it is sometimes feasible to adopt a joint design that incorporates a backing lip, thereby eliminating the need for a backing ring or bar, which ordinarily would be required for preventing melt-through. Joint designs of this type are described in the following two examples.

Example 52. Incorporation of a Machine-Turned Land on Pipe To Serve as a Backing Ring (Fig. 9)

Sections of low-carbon steel pipes 12 3/4 and 16 in. in outside diameter, with wall thicknesses of 1 in. and 2 3/8 in., respectively, were joined as shown in Fig. 9. To facilitate and control fit-up of the two sections, the joint edges were machined so that the larger pipe would slip over a 1/4-in.-thick cylindrical land machined on the smaller pipe, as shown in section A-A in Fig. 9. In addition to aligning the pipe sections, the land served as a backing ring, and it completely contained the molten metal and flux.

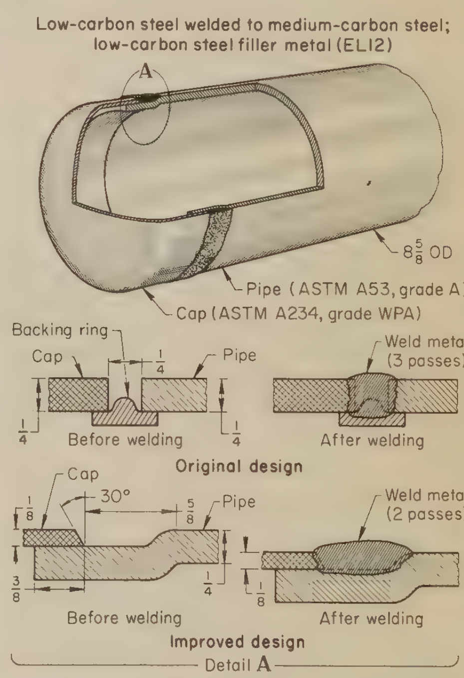
The joint was submerged-arc welded in six to eight passes with the pipe sections in the horizontal-rolled position, and with the welding head fixed in the 12 o'clock position. Welding conditions are given in the table that accompanies Fig. 9. The completed weld, after removal of flux, was inspected visually and by the magnetic-particle method.

Example 53. Use of an Offset in a Pipe To Eliminate Backing Rings (Fig. 10)

A component of a heat-exchanger shell assembly was initially made by submerged-arc welding a 1/4-in.-wall cap drawn from medium-carbon steel to a low-carbon steel pipe of the same wall thickness, by means of a circumferential butt joint supported and aligned by a backing ring, as shown in the "Original design" view in Fig. 10. The cap was made of ASTM A234, grade WPA, steel; the pipe was made of ASTM A53, grade A, steel.

When it became apparent that the wall thickness of the pipe cap could be less than that of the pipe without adversely affecting service performance, the joint was redesigned as a joggled lap joint (see "Improved design", Fig. 10). The offset incorporated in the pipe for the redesigned joint took the place of the backing ring previously used and furnished a locating surface for the cap. The redesigned joint was submerged-arc welded under the same conditions as those for the original joint (see table with Fig. 10), except that only two passes were required, rather than three.

Cost reduction was realized from elimination of the backing ring, from the saving in material resulting from the use of



Joint type	Joggled lap
Weld type, original design	Square-groove, with backing ring
Weld type, improved design	Modified single-V-groove, with integral backing
Joint preparation:	
Original design	Backing ring machined
Improved design	Cap end machined, pipe end reduced
Electrode wire	1/8-in.-diam EL12
Flux	F62
Welding position	Flat (horizontal-rolled pipe)
Welding voltage	25 to 26 v
Welding current	350 to 410 amp, dcsp
Welding speed	18 to 20 ipm
Number of passes, original design	Three
Number of passes, improved design	Two
Power supply	40-v, 600-amp transformer-rectifier (constant-voltage)
Fixturing	Chuck-type turning rolls; alignment clamps for tack welding

Fig. 10. Cap-to-pipe weldment for which over-all cost was reduced 35% by joint redesign that replaced a backing ring by an offset in the pipe (Example 53)

thinner pipe caps, and from the elimination of one circumferential welding pass. The change in joint design led to a saving of approximately 35% in total factory cost.

All joints were inspected visually and radiographically to check for full penetration and absence of slag inclusions. The rejection rate was less than 1%.

In multiple-pass welding of thick sections of steel, substantial savings in both material and labor can be realized by redesign of a joint to eliminate a backing strip, as in the application described in the following example.

Example 54. Change From a Single-V-Groove Weld With a Backing Strip to a Double-V-Groove Weld With a Welded-in Center Spacer Rod, That Reduced Costs and Distortion (Fig. 11)

Figure 11 shows a 120-in.-long steam-drum shell course, roll formed from 5-in.-thick ASTM A515, grade 70, steel (0.35% max C), with a welded longitudinal seam.

Originally, the butt joint for this seam was of single-V-groove design, and was welded with the use of a backing strip (see "Original design" in section A-A in Fig. 11). This joint design was unsatisfactory. Fit-up and removal of the backing strip were time-consuming operations, and welding from one side distorted the weldment.

The joint was changed to the double-V-groove design shown as "Improved design" in section A-A in Fig. 11. This change resulted in the need for much less weld metal; the need for a backing strip was eliminated; and distortion was reduced by sequential deposition of weld beads on the inside and outside of the joint. The amount of back gouging needed was less than that required to remove the backing strip from the single-V-groove weld. As a result of these improvements, electrode, flux and labor costs were reduced by 46%, and total cost of welding was reduced by 62%.

Operating conditions and costs for welding joints of the original and improved designs are given in the table with Fig. 11. Welding procedures and postweld operations for the two designs are described below. For both designs, the shell courses were hot roll formed into a cylinder and descaled, and the joint grooves flame cut.

Original Design. The single-V-groove joint was preheated to 175 F with a propane torch, the backing strip was installed, and the temperature of the joint was raised to 250 F. At least two root passes were made, using shielded metal-arc welding. This operation was followed by depositing six single-pass layers, each ⅛ in. thick, by single-electrode submerged-arc welding. Tandem submerged-arc welding was used to complete the weld, single-pass layers ⅛ in. thick being deposited to a weld level of 1½ in., followed by two-pass (split) layers ⅛ in. thick. Then the backing strip was removed by air carbon-arc gouging and grinding, and back welding was done, as required, to provide a flush joint.

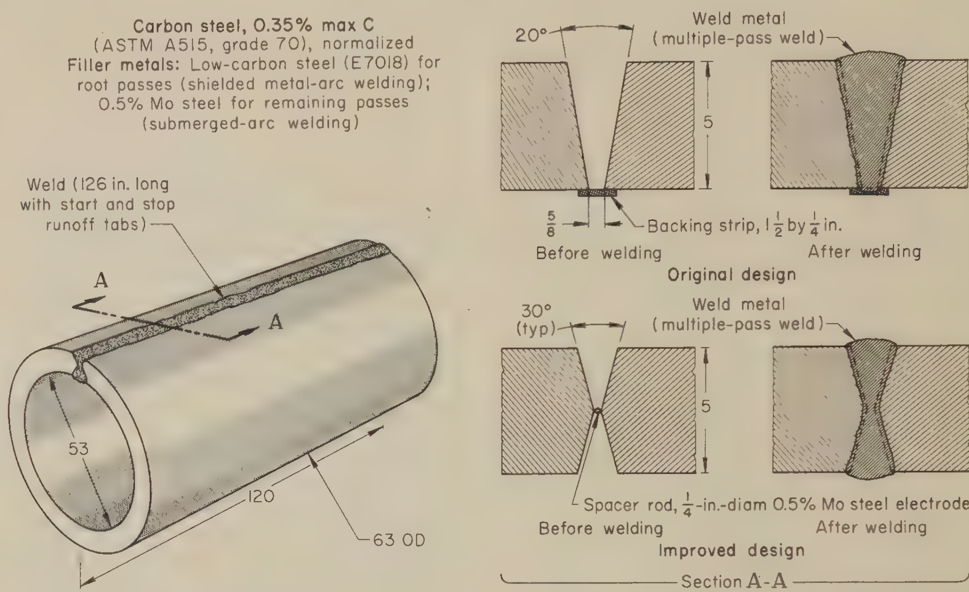
Improved Design. The double-V-groove joint was also preheated in two stages (175 F and 250 F) with a propane torch, except that instead of a backing strip being installed between stages, a spacer rod of ¼-in.-diam 0.5% Mo steel electrode material was tacked in place and seal welded by the shielded metal-arc process. Shielded metal-arc welding was used also for root passes. The first increment of single-electrode submerged-arc welds consisted of eight ⅛-in.-thick single-pass welds on the outside of the weldment. The workpiece was rotated 180°, and the joint was back gouged by air carbon-arc gouging and ground to a radius of ¼ to ⅜ in. The first increment of welding on the inside of the joint consisted of ⅛-in.-thick single-pass welds to a 1½-in. level, using single-electrode submerged-arc welding. Then the workpiece was again rotated 180°, and the remainder of the outside welding was completed using tandem submerged-arc welding to deposit two-pass (split) layers of ⅛-in. thickness.

After a final 180° rotation of the workpiece, the inside welding was completed using the same sequence of two-pass tandem submerged-arc welds of ⅛-in. thickness.

Postweld Operations. After having been welded, the shell courses incorporating both joint designs were examined radiographically. This was followed by stress relieving at 1150 ± 25 F for 1 hr per inch of thickness. Finally, welds were ground smooth.

Shell courses of both designs were welded in conformity with qualifications set forth in Section IX of the ASME Boiler and Pressure Vessel Code.

The example that follows describes an application in which both the workpiece and the joint were redesigned, and the welding process was changed,



Cost item	Joint design: Original	Joint design: Improved
Comparison of Costs per Weldment		
Electrode and flux per foot of weld(a)	$ 7.69	$ 4.14
Welding labor and overhead per foot of weld(b)	13.28	7.18
Total cost per foot of weld	$ 20.97	$ 11.32
Length of weld (including runoff tabs at ends), ft	10½	10½
Total welding cost per weld	$220.19	$118.86
Labor and overhead for installing and removing backing strip(c)	96.00	.....
Total cost per weldment	$316.19	$118.86

Cost Factors for Both Joint Designs

Weight of electrode and flux deposited per hour	15.6 lb
Weight of electrode and flux deposited per foot of weld:	
Original design (single-V-groove)	26 lb
Improved design (double-V-groove)	14 lb
Deposition efficiency	98%
Electrode and flux cost per pound	$0.29
Labor and overhead cost per hour	$8.00
Time for installing and removing backing strip (original design)	12 hr

Welding Conditions for Both Joint Designs

Joint type	Butt
Weld types	Single-V-groove (original); double-V-groove (improved)
Welding position	Flat(d)
Arc starting	Touch and retract
Preheat	175 F, then 250 F (propane torch)
Interpass temperature	500 F
Postheat	1150 ± 25 F (furnace), 1 hr per inch of section
Root passes (shielded metal-arc welding):	
Power supply	300-amp motor-generator
Electrode	3/16-in. E7018
Current and voltage	250 amp, dcrp; 24 v
Intermediate passes (single-electrode submerged-arc welding):	
Power supply	900-amp motor-generator
Electrode wire	7/32-in.-diam 0.5% Mo steel(e)
Current and voltage	700 amp, dcrp; 30 v
Travel speed	20 ipm
Final passes (tandem submerged-arc welding)(f):	
Leading head:	
Power supply	900-amp motor-generator
Electrode wire	7/32-in.-diam 0.5% Mo steel(e)
Current and voltage	800 amp, dcrp; 30 v
Trailing head:	
Power supply	1000-amp transformer
Electrode wire	5/32-in.-diam 0.5% Mo steel(e)
Current and voltage	700 amp, ac; 35 v
Travel speed	30 ipm

(a) Pounds of electrode and flux deposited per foot, multiplied by cost per pound of electrode and flux, divided by deposition efficiency. (b) Pounds deposited per foot, divided by pounds deposited per hour, multiplied by labor and overhead cost per hour. (c) 12 hr at $8 per hour. (d) Workpiece supported on one power roll and one idler roll. (e) Electrode wire contained 0.11 C, 0.50 Mo, 0.85 Mn, and was used at a 1-to-1 ratio of wire to flux. (f) Tandem welding head was mounted on a boom-type manipulator.

Fig. 11. Steam-drum shell course for which redesign of the longitudinal butt joint, from one for a single-V-groove weld to one for a double-V-groove weld, eliminated the need for a backing strip and reduced cost and distortion (Example 54)

to eliminate the need for backing bars, which unavoidably entrapped slag.

Example 55. Elimination of Backing Bars To Avoid Entrapment of Slag (Fig. 12)

A 12-ft-long header assembly for a large high-pressure heat exchanger was manufactured to Section VIII, Division 1, of the ASME Boiler and Pressure Vessel Code, under the rules for spot radiography (paragraph UW-52). These rules provide that one spot (with a minimum length of 6 in.) shall be examined in the first 50 ft of welding in each vessel, and one spot shall be examined for each additional 50 ft of welding or fraction thereof.

As originally designed (see view at upper left in Fig. 12), for manual flux-cored arc welding from the outside, the assembly consisted of four ASTM A515, grade 70, steel components and was welded at corner joints that incorporated backing bars, as shown in section A-A in Fig. 12. It was difficult to ensure a uniformly tight fit of the backing in the joint. Under radiographic inspection, slag, which ran between the backing bars and the adjacent 1½-in.-thick components, was revealed.

The problem was eliminated by redesigning the header assembly for automatic submerged-arc welding without backing bars. The redesigned assembly, shown in the upper right view in Fig. 12, consisted of two 1½-in.-thick ASTM A515, grade 70, channels formed in a press brake. The two components were welded at two longitudinal butt joints of the double-V-groove design shown in section B-B in Fig. 12.

For this improved design, the welding was done by use of a boom-mounted automatic welding head. The formed channels were held stationary while the welding head was advanced along the joints. First, root passes were made along the inside grooves of the two joints, then filler passes were made along the outside grooves. After the root passes, the outside grooves were machined-out to sound metal before the filler passes were begun.

Welding conditions for both designs and processes are compared in the table that accompanies Fig. 12. As this comparison shows, a major benefit of the change to two-piece design was that only about one-third as many filler passes were required for the entire weldment (ten passes, as compared with 28 to 32 passes for the original, four-piece design).

In the manufacture of horizontal shell-and-tube liquid coolers, as described in the following example, the use of backing rings was permissible under code requirements, but was avoided because the space occupied by the rings would necessitate a reduction in the number of tubes in the tube bundle, thereby impairing the efficiency of the unit. Backing rings were eliminated and melt-through was avoided by a combination of joint design, welding procedure, and special training of the welder.

Example 56. Joint Design and Welding Procedure That Gave Complete Penetration of a Joint Accessible Only From the Outside, Without the Use of a Backing Ring (Fig. 13)

Fabrication of heat exchangers for condensing or evaporating the refrigerant used in refrigeration equipment involved welding the heat-transfer chamber directly to the tube sheet. The chamber consisted of a cylindrical open-top shell and, when welded to the tube sheet, formed a pressure vessel completely enclosing the tube bundle, as shown in Fig. 13.

Because the inside of the vessel was inaccessible both for welding and for weld inspection, a major problem was that positive assurance could not be obtained that complete joint penetration had been effected, as required by Section VIII of the ASME Boiler and Pressure Vessel Code. When the entire weld was made by the submerged-arc process, complete penetration without melt-through was not obtained consistently when the joint was prepared by grooving the tube sheet for a single-V-groove and fillet weld (not shown in Fig. 13). The use of a backing ring was considered, but was ruled out because it would necessitate a reduction in the number of tubes in the bundle.

After experiments with several joint designs, a two-step welding procedure, using the joint shown in detail A in Fig. 13, was adopted. This design called for a single-bevel-groove weld with a fillet-weld reinforcement equal to the shell thickness.

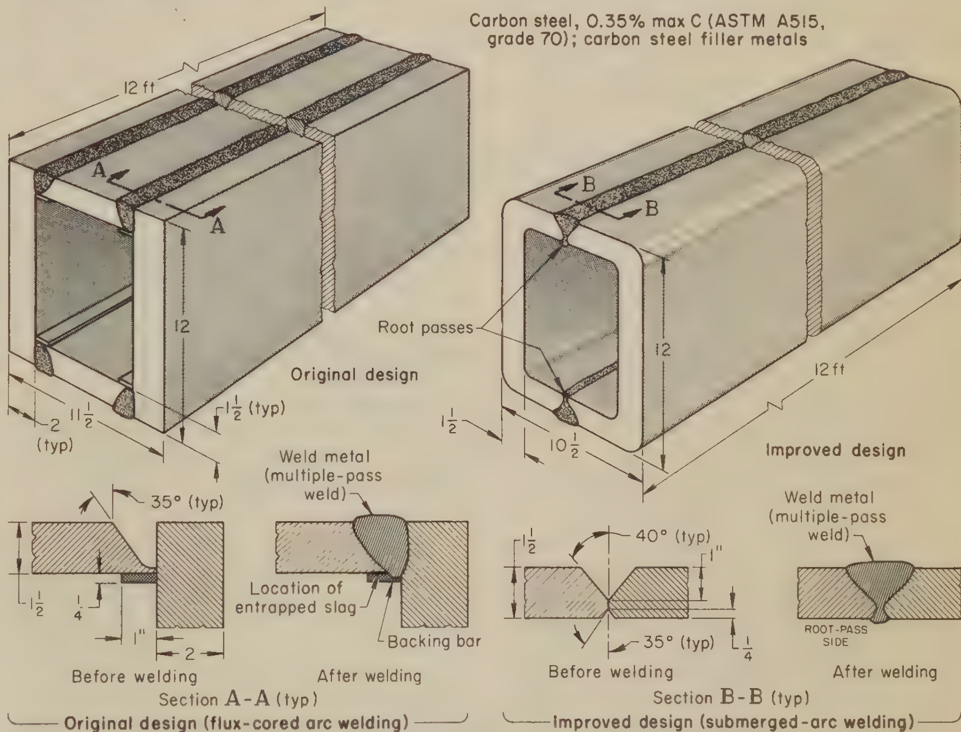
The two-step procedure consisted in the deposition of a root bead by shielded metal-arc welding, followed by a single filler pass by automatic submerged-arc welding. Welding conditions are given in the table with Fig. 13. The welding procedure, as well as the manual welder and the submerged-arc welding operator, had to be qualified in accordance with the rules of Sections VIII and IX of the ASME Boiler and Pressure Vessel Code. Melt-through and effective penetration were brought under control only by carefully following the welding procedures. Welders had to be specially trained to make the root pass satisfactorily. During submerged-arc welding, the electrode had to be carefully positioned to obtain proper sidewall fusion and to avoid undercutting.

Before welding, the joint areas were cleaned of scale and oil. Shell sheets had been sheared to size and beveled by oxyacetylene cutting before forming. In assembling the shell on the tube sheet, spacers were used to obtain the desired root opening and were removed after tack welding. No preheat or postheat treatment was used, normal room temperature (70 F) being the only requirement. The assembly was mounted on a conventional welding positioner for flat-position welding. After the root pass had been deposited, slag was removed by a needle gun, which consisted of a bundle of impact-driven steel quills capable of conforming to and abrading uneven surfaces. Surfaces were ground where necessary.

Automatic submerged-arc welding was performed from the carriage of a conventional manipulator on the same positioner and in the same position as the manual welding. Interpass temperature for this weld was 400 to 500 F.

After welding, the weld surface was cleaned by a needle gun, and the vessel was then tested for leaks by pressurizing it with dry air at 300 psig while submerged in water. Dry air was used because the interior of the vessel had to be dry for operation with refrigerants.

Flux-bed backing is provided by a separate backing flux or by the same flux used in welding. This eliminates



Item	Original design	Improved design
Welding process	Manual flux-cored arc	Automatic submerged-arc

Fig. 13. Refrigerant heat exchanger, and details of the tube-sheet-to-shell T-joint that required a manual root pass to ensure complete joint penetration without the use of a backing ring (Example 56)

the backing strip that is required for some types of complete-penetration welds. Beads deposited with flux backing require very little grinding or trimming to expose sound metal for deposition of the bead on the opposite (root) side of the joint. The resulting welds are of a quality that will pass radiographic inspection, as in the following example of this technique.

Example 57. Use of a Flux Bed as Backing for an Internal Bead in a Longitudinal Seam Weld (Fig. 14)

In submerged-arc welding of a longitudinal seam in a pressure vessel that was roll formed from 1 9⁄16-in.-thick carbon steel plate (ASTM A515, grade 70; 0.33% max C), a bed of welding flux was used as the backing for the internal weld bead, which was deposited first (see Fig. 14).

With the flux backing, there was no need to apply or remove a backing strip, and full penetration of the joint was obtained. Only minimum grinding was needed on the opposite (root) side to reach sound metal for deposition of the outside bead to complete the weld. The welding cost was less and production was faster than would have been possible by hand welding, semiautomatic welding, or submerged-arc welding with a removable backing strip.

The plate was laid out and gas cut to size before being roll formed. The edges of the double-V-groove butt joint (see detail at lower left in Fig. 14) were held in alignment for welding with either fitting blocks or tack welds applied to the outside of the joint. Maximum permissible misalignment was 1⁄16 in., and root opening varied from 0 to 1⁄16 in.

The workpiece was preheated, and then the first weld pass was made on the inside with the joint horizontal and on the bottom (6 o'clock position), as shown in Fig. 14. The welding head was on a long ram inside the shell. The flux was pressed against the back of the joint by the use of an air-inflated hose, as shown in Fig. 14.

After deposition of the inside weld bead, the opposite side of the joint was ground to sound metal, and the outside bead was deposited. Unfused flux was picked up by vacuum. Additional welding conditions are given in the table with Fig. 14.

Another application in which a flux bed was used as backing for the inside (first) weld pass in a longitudinal double-V-groove joint is described in Example 61 and illustrated in Fig. 28.

Flux Retention

In submerged-arc welding in the flat position, the layer of granular flux is maintained at a suitable thickness over the weld puddle. When a weld bead is to be deposited at or very close to the edge of one of the members, it is sometimes necessary to use flux retainers to provide mechanical means to contain the loose flux.

When using other positions in submerged-arc welding, a flux trough is used, or other means are provided, to prevent the loose flux from spilling away from the joint area.

In the following example, sheet edges were joined by welding in the horizontal position, using a flux trough that was part of the clamping fixture.

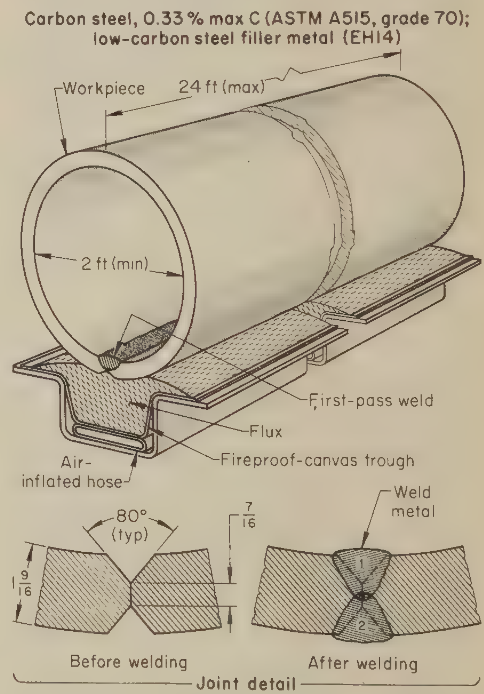
Example 58. Use of a Special Clamping Fixture With an Integral Flux Trough for Making a Horizontal Edge-Flange Weld (Fig. 15)

The two 1008 steel components of a warm-air-furnace combustion chamber were joined by a submerged-arc peripheral edge-flange weld while being held in the horizontal position between upper and lower rings of a special clamping fixture. As shown in Fig. 15, the lower clamping ring incorporated a flux-retaining trough to ensure flux coverage of the arc and the weld metal while the joint was being welded. The sheet-metal components of the chamber were aligned and located between the clamping rings, which were made of copper.

The welding-head carrier moved along the outside of a geared rack mounted on the underside of the table supporting the lower clamping ring (Fig. 15). The gear that engaged the rack was driven by a motor mounted on the welding-head support arm, and the geared rack served as a template to guide the welding head. The flux was introduced into the flux trough ahead of the arc, and unfused flux was removed by a trailing vacuum pickup. In addition to salvaging the unfused flux for reuse, the vacuum pickup cleaned the lower clamping ring well enough to receive the next chamber to be welded. The flux-delivery tube, the welding head, and the flux-recovery tube were guided from the same geared rack and were part of a single welding-head assembly.

An approximately round weld bead was produced along the flange edges, as shown in the joint detail for submerged-arc welding in Fig. 15. A 3⁄32-in.-diam electrode wire was used, to make alignment of the electrode tip with the flange edges less critical for maintaining a stable arc.

The welded joint was scraped clean and visually inspected by the welding operator. Later, the assembly was air-pressure tested under a waterhead of 6 in. When heated in service, the welded flange flexed to open slightly (see view at the right in the joint detail for submerged-arc welding in Fig.



Joint type	Butt seam
Weld type	Double-V-groove
Power supply	Two 100-volt (max), 1000-amp transformers, in parallel
Electrode wire	¼-in.-diam EH14
Electrode stickout	1 in.
Flux	F72 (20×D or 40×D)
Welding current and voltage:	
Inside bead	1200 amp, ac; 35 v
Outside bead	1550 amp, ac; 39 v
Number of passes	Two
Welding speed, both passes	7 ipm
Preheat	200 F, inside; 300 F, outside
Arc time (for 25-ft-long weld)	1½ hr, approx
Setup time (for 25-ft-long weld)	2½ hr, approx

Fig. 14. Use of a flux bed as backing in deposition of the internal weld bead in a longitudinal seam in a pressure-vessel shell (Example 57)

15), and expansion and contraction in heating and cooling were noiseless. There were no weld-related failures during prolonged use of the chambers. Conditions for submerged-arc welding are given in the table accompanying Fig. 15.

Experience With Other Welding Processes. The combustion chambers had previously been satisfactorily manufactured with the use of shielded metal-arc welding, but the rate of production was low. Welding speed was only 36 in. per minute, and direct-labor cost for welding each chamber was 20¢ — in comparison with 180 in. per minute and 5¢ per chamber by submerged-arc welding.

Before submerged-arc welding was adopted, alternative welding processes were evaluated. Gas metal-arc and gas tungsten-arc welding were not feasible, because there was no practical way to confine the shielding gas.

Resistance seam welding was tried, but the weldments were unacceptable because the electrode wheel indented the 0.036-in.-thick joint members, causing early service failures due to cracking. During flexing of the flanges while heating and cooling, cracks developed at the location shown in the view at the right in the joint detail for resistance seam welding in Fig. 15, a point of severe stress concentration. Unacceptable expansion and contraction noises, caused by the rubbing together of defectively welded sections of the seam, occurred during service. These defectively welded sections, which were up to ⅛ in. long, resulted from imperfect firing of the seam welder. They gradually became longer as adjacent sections of the weld failed from the expansion and contraction stresses in service.

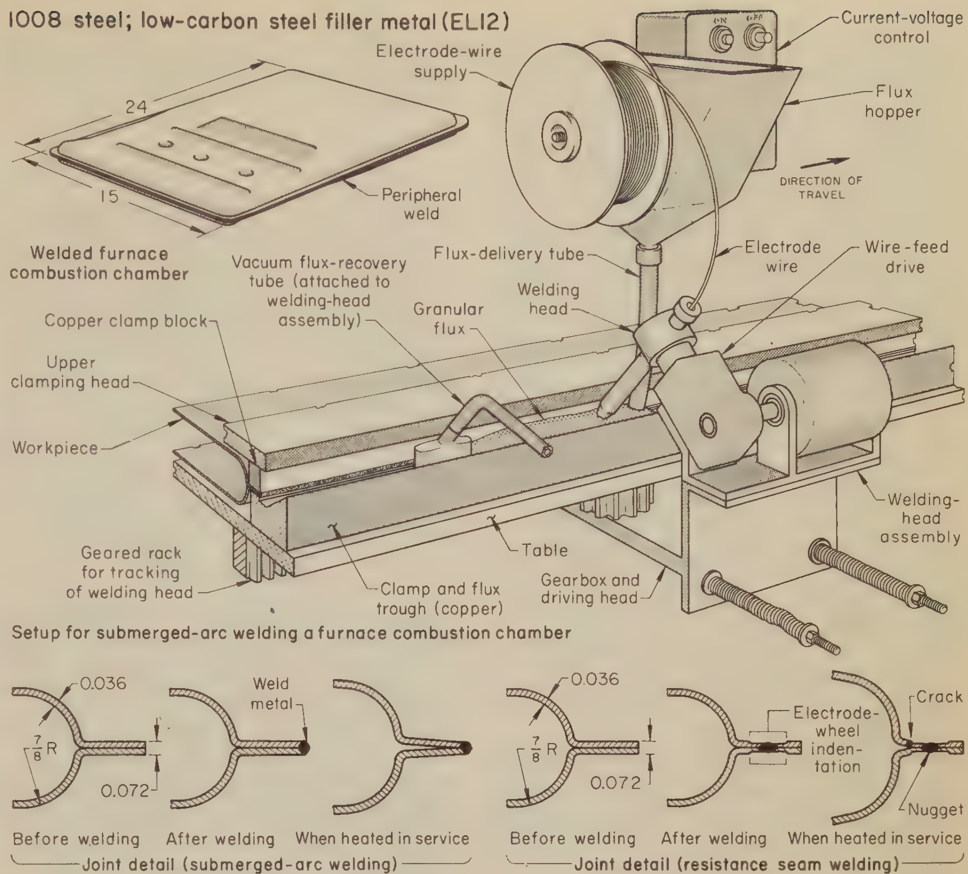
Circumferential welds (girth welds) present different problems in flux retention, depending on the orientation of the axis of the cylinder or other shape of workpiece being welded.

When the workpiece axis is horizontal, several techniques are effective in welding on small diameters. The normal electrode position, a few degrees from the vertical, to ensure proper solidification of flux and weld metal, helps to prevent spillage of loose flux. A nozzle assembly can be arranged to pour the flux directly on the arc, affording the flux less chance to spill. Also, a flexible strip of metallic or nonmetallic heat-resisting material may be attached to the nozzle assembly and positioned to ride over the workpiece ahead of the arc so as to retain the flux. Such an arrangement, incorporating a flexible dam, is shown in Fig. 16.

Figure 17 shows a flux dam that retained flux for two circumferential welds that were made simultaneously as the workpiece was rotated in a fixture. The portion of the dam that made contact with the flux was made of stainless steel for heat resistance, whereas the supporting arm was made of copper for good electrical conductivity. To prevent arcing between the workpiece and the dam, the copper arm contacting the workpiece was grounded, as shown in Fig. 17. (Submerged-arc welding with this flux dam was replaced by gas metal-arc welding, as described in Example 105, on page 102.)

Flux support may also be needed at the extreme ends of a cylindrical workpiece. This may be accomplished by either tack welding sheet-metal rings to the edges or providing flexible retainers that will ride along the edges. Both of these methods will permit welding close to the ends of the workpiece.

When making circumferential groove welds in the 3 o'clock position on work oriented with its axis vertical (horizontal welding position for large tanks or cylinders, or vertical pipe position), a flux trough is used, as described in Example 59 and illustrated in Fig. 25.



Conditions for Submerged-Arc Welding

Joint type .... Edge	Welding voltage .... 22 v
Weld type .... Edge-flange	Welding current .... 400 amp, dcrp
Joint preparation .. Die trimmed to square edge	Wire feed .... Automatic
Electrode wire .... 3/32-in.-diam EL12(a)	Welding speed .... 180 ipm(b)
Flux F62	Number of passes .... One
Welding position .... Horizontal	Direct-labor cost per chamber .... 5¢(b)

(a) Copper plated. (b) In shielded metal-arc welding, welding speed had been 36 in. per minute, and direct-labor cost per chamber had been 20¢.

Originally, chamber had been shielded metal-arc welded, but at lower speed and higher cost as shown in footnote (b), above. Resistance seam welding was unsatisfactory because cracking occurred when chamber was heated in service (see bottom right views, above).

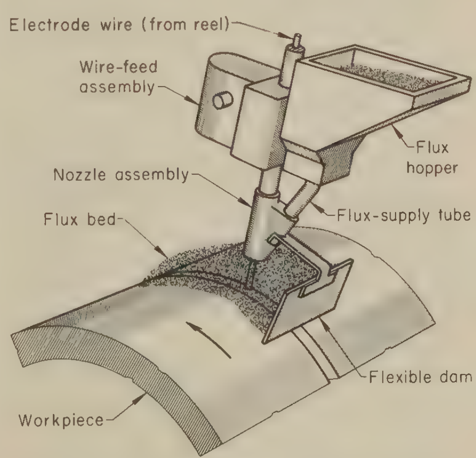

Fig. 16. Use of a flexible dam, attached to a nozzle assembly, for retention of flux in circumferential welding

Slag Removal

The size and shape of the weld bead can facilitate or hinder slag removal. Small beads cool more rapidly than large beads, thereby reducing the likelihood that slag will adhere to them. If the electrode melting rates are the same, the deposition of small beads is more economical than the deposition of large beads, because of the slag-removal factor. First-pass weld beads that are slightly concave (Fig. 18a) are much easier to remove slag from than are convex beads (Fig. 18b), which provide crevices for slag entrapment.

In general, slag removal is a function of groove width; if the slag bridges across the groove, removal is difficult. If split-weave technique is used, time for slag removal is minimal.

Because a circumferential weld on a small-diameter workpiece develops a large amount of local heat, slag removal can be made easier by training an air jet on the completed weld. When welding in the horizontal-rolled pipe position, the jet should strike the weld between the 2 and 3 o'clock positions.

Arc Starting

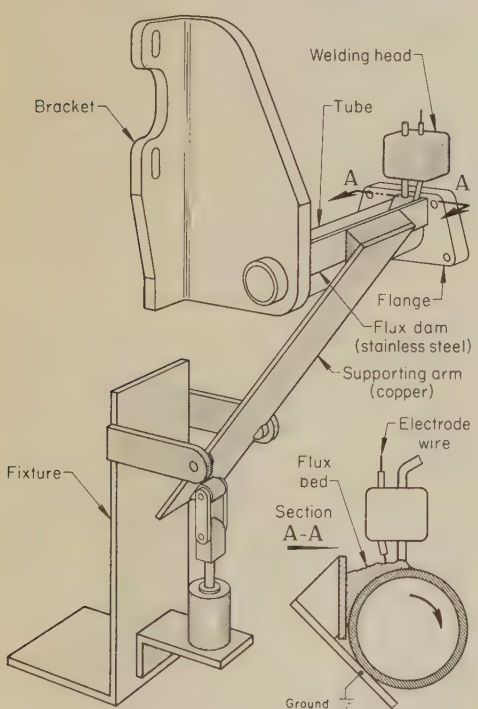
In submerged-arc welding, considering both semiautomatic and automatic methods, there are six methods of starting the arc: (*a*) high frequency, (*b*) wire retract, (*c*) fuse ball, (*d*) scratch, (*e*) pointed wire, and (*f*) carbon rod. Of these, the first three are used most frequently, employing either an alternating-current power supply or direct current with drooping voltage. The carbon rod is almost never used.

High-frequency starting requires the use of an accessory high-frequency, high-voltage unit. When the electrode wire is positioned about 1/16 in. away from the workpiece, the unit generates a spark that crosses from the wire to the workpiece and produces an ionized path through which the welding current can flow to establish the arc.

In wire-retract starting, the electrode wire is positioned to make electrical contact with the workpiece. When the welding current is applied, the wire is retracted by means of special equipment that reverses the wire-feed motor, drawing an arc of proper voltage. As soon as the arc is established, the motor reverses and feeds the wire at the desired speed.

In fuse-ball starting, a tightly rolled ball of steel wool is placed between the end of the electrode wire and the metal to be welded. When the welding current is applied, the ball melts instantaneously, and the arc is established between the wire and the workpiece.

Scratch, pointed-wire and carbon-rod arc starting depend on the light contact between the electrode wire and the workpiece, or between a carbon rod and the workpiece, to develop an arc before the wire fuses to the workpiece. These methods of arc starting are generally not required when a constant-voltage power supply is used.



To increase production rate and reduce costs, submerged-arc welding, using this flux dam, was replaced by gas metal-arc welding, as described in Example 105, on page 102. Figure 39 on page 103 shows details of the welded joints, and the table with that illustration gives conditions for submerged-arc welding.

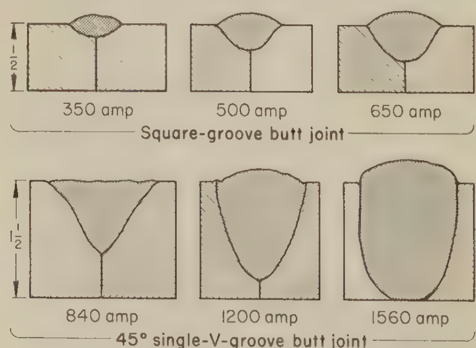
Current, Voltage, Speed and Other Operating Variables That Affect Weld Size and Quality*

Among the variables of submerged-arc welding that must be closely controlled to give welds of good quality, the most critical — in order of their importance — are welding amperage, current type (and, if direct current is used, polarity), welding voltage, and welding speed (travel speed). The combined effect of these factors on the base metal, the electrode wire, and the flux largely determines the nature and quality of the weld puddle and, ultimately, of the weld.

Other operating variables that affect weld size and quality are depth of flux layer, electrode stickout, electrode size, and the angle between the base metal and the electrode.

Welding current controls the rate at which the electrode is melted, the depth of fusion, and the amount of base metal melted. If the current is too high for a given travel speed, the depth of fusion or penetration will be too great, the weld may melt through the joint, and the weld heat-affected zone will be larger. Costs will be high because excessive power and filler metal will be consumed. On the other hand, too low a current will lead to inadequate penetration and inadequate reinforcement. The effect of current (amperage) on penetration and shape of butt welds in carbon steel plates ½ and 1½ in. thick is shown in Fig. 19.

*See also Fig. 51 to 59, in the Appendix to this article, beginning on page 73.



Welds were made in carbon steel plates ½ and 1½ in. thick, with 5/32-in.-diam electrode wire. For the ½-in. plate, voltage was 29 volts and travel speed was 30 in. per minute; the 1½-in. plate was welded at 40 volts and a travel speed of 12.5 in. per minute.

Fig. 19. Effect of welding current on penetration and configuration of two types of submerged-arc butt welds in two thicknesses of steel plate

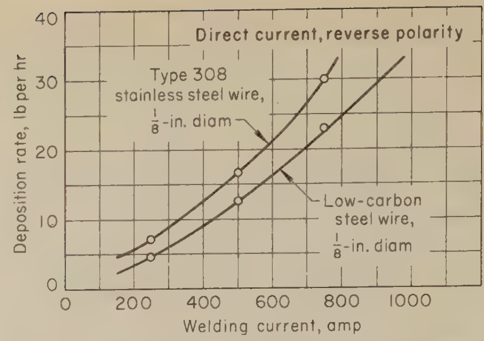


Fig. 20. Effect of current on deposition rates of stainless steel and low-carbon steel electrode wires, in welding with reverse-polarity direct current. (With straight polarity, deposition rates increase about 30 to 50%.)

The amount of weld metal deposited per unit of time is almost directly proportional to amperage. This is illustrated in Fig. 20, which shows the effect of amperage on deposition rates of ⅛-in.-diam low-carbon steel and type 308 stainless steel electrode wires. As Fig. 20 shows, about 2 to 3 lb of low-carbon steel wire is deposited per hour for each 100 amp of reverse-polarity direct current, whereas stainless steel wire is deposited at approximately a 30% higher rate because of its higher electrical resistance and lower heat capacity and melting temperature. (Deposition rate per 100 amp can be increased by increasing the stickout of the electrode wire beyond the contact tip, but this decreases penetration.)

In welding with direct current, deposition rate is 30 to 50% higher and penetration is shallower with straight polarity (electrode negative) than with reverse polarity (electrode positive). Thus, straight polarity may be preferred for surfacing and to prevent cracking of base metals that contain elements that promote hot cracking.

Alternating current is intermediate between straight-polarity and reverse-polarity direct current with respect to deposition rate and penetration, and is preferred where arc blow is troublesome. In multiple-wire, multiple-power welding, two arcs in close proximity are affected by each other's magnetic field. Arcs of like polarity flare together, and arcs of unlike polarity flare apart.

Welding voltage principally determines the shape of the fusion zone and reinforcement. As welding voltage is increased, the weld bead becomes flatter and wider, more flux is exposed to the arc, and flux consumption increases. With excessively high voltage, however, the arc breaks out from under its cover of liquid flux, air contacts the molten weld metal, and porosity results. The effects of increasing levels of voltage on the configurations of submerged-arc butt welds are shown in Fig. 21.

If the arc current is held constant and the arc voltage is low in relation to current, the base metal will not melt enough to give a good weld. The molten globules of metal passing from the elec-

trode to the workpiece cause continual short circuiting, which results in spattering and a high bead. As the arc voltage is increased, an optimum point is reached at which the arc no longer sputters but has a steady, sharp crackling sound. At this stage, good penetration will be obtained. If the arc voltage is further increased, the arc length will increase. The arc will be unstable and will make a wide, flat bead, usually with an undercut.

Increasing stickout will have essentially the same effect on bead shape as decreasing voltage.

Welding speed (travel speed) is an important variable governing the production rate and metallurgical quality of welds. Increasing the welding speed decreases the production time per unit on fillet welds, but has little influence on production time per unit length of groove welds for a given current and wire size. Welding speed also affects the rate of heat input. Increasing welding speed and decreasing current are two practical ways to lower heat-input rate.

Welding speed helps to determine the width and depth of the weld, as shown in Fig. 22. A weld bead consists partly of molten filler metal and partly of base metal melted by the arc. Base metal can constitute 15 to 60% of a submerged-arc weld, the percentage decreasing with welding speed. Excessively high welding speed decreases wetting action and increases the probability of undercutting, arc blow, weld porosity, and uneven bead shapes. Excessively low speed produces hat-shape beads that are subject to cracking; causes excessive melt-through; and produces a large weld puddle that flows around the arc, resulting in a rough bead, spatter, and slag inclusions.

Electrode-Wire Diameter. Decreasing the diameter of the electrode wire increases the pressure of the arc, thus increasing penetration and decreasing the width-to-depth ratio of the weld bead (see Fig. 23).

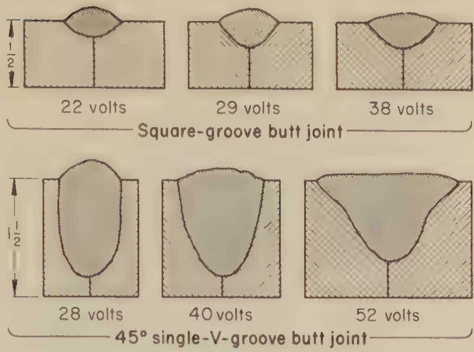
Depth of flux layer affects the shape and penetration of welds, as shown in Fig. 24. When the flux layer is too shallow (Fig. 24a), the arc is exposed and a cracked or porous weld results. When the flux is too deep (Fig. 24c), the result is peaked weld beads with above-average penetration. When the flux is neither too shallow nor too deep, very faint flashes appear around the interface between the electrode wire and the flux, and the weld bead appears as shown in Fig. 24(b).

Effect of Welding Position on Joint Design and Welding Conditions

Welding position during submerged-arc welding affects current, voltage, speed, joint design, and flux retention. As compared to the preferred flat-position groove welding, horizontal (or 3 o'clock) groove welding is done with lower current, higher voltage, and higher welding speed, as well as a different groove design. A flux trough is needed to retain the loose flux.

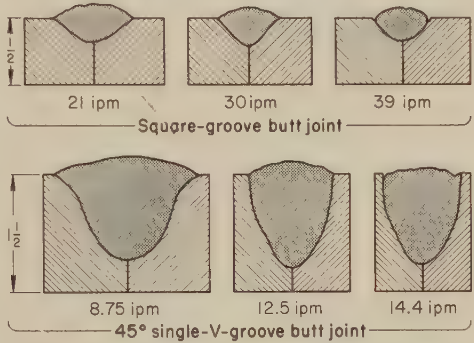
To compensate for the greater effect of gravity on the weld puddle and the molten flux, smaller beads are deposited in a weld groove that has its lower surface beveled at only a few degrees from the horizontal. Narrow, stringer beads are used. For the same thickness of work metal, at least twice as many passes are needed as for flat-position groove welding.

The effect of welding position on procedure is shown in the following example, in which it was not possible to do the welding in the preferred flat position.



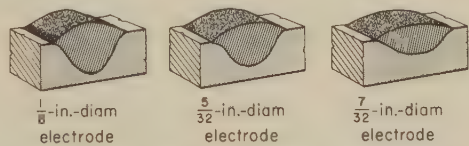
Welds were made in carbon steel plates ½ and 1½ in. thick, with 5⁄32-in.-diam electrode wire. For the ½-in. plate, welding current was 500 amp and travel speed was 30 in. per minute; the 1½-in. plate was welded at 1200 amp and a travel speed of 12.5 in. per minute.

Fig. 21. Effect of welding voltage on penetration and configuration of two types of submerged-arc butt welds in two thicknesses of steel plate



Welds were made in carbon steel plates ½ and 1½ in. thick, with 5⁄32-in.-diam electrode wire. For the ½-in. plate, welding current was 500 amp and voltage was 29 volts; the 1½-in. plate was welded at 1200 amp and 40 volts.

Fig. 22. Effect of welding speed (travel speed) on width and configuration of two types of submerged-arc butt welds in two thicknesses of steel plate



Welds were made on carbon steel plate by fully automatic submerged-arc welding, at 30 volts, 600 amp, and 30 in. per minute.

Fig. 23. Effect of electrode-wire diameter on width and penetration of surface welds

Example 59. Submerged-Arc Groove Welding in the Horizontal (Vertical Pipe) Position (Fig. 25)

A pipe nipple was submerged-arc welded to a forged steam chest oriented with the work axis vertical, so that the welding had to be done in the horizontal (vertical pipe) position. The nipple was made of 6-in.-ID forged Cr-Mo steel pipe with a 1-in.-thick wall. The two members were held in position by tack welding them to a machined backing ring, and a sheet-metal trough was clamped in place with a metal band to retain the loose flux, as shown in Fig. 25. The flux trough was wide enough to retain flux for the entire welding operation, so repositioning was not necessary. The backing ring was removed in a later operation. During welding, the workpiece remained stationary and the welding head was advanced. Welding conditions are given in the table with Fig. 25.

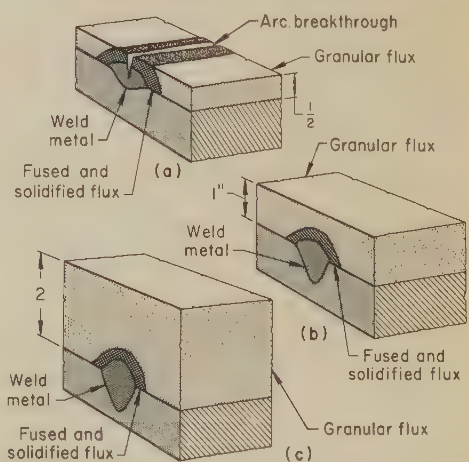
Although many of the welding conditions were the same as they would have been for welding in the flat (horizontal-rolled pipe) position, there were differences:

1 Electrode wire of smaller diameter (⅛ in. instead of 5⁄32 in.) was used.
2 Current was about 30% lower.
3 Voltage was about 1 to 2 volts higher, to flatten the bead.
4 Travel speed was about twice as high.
5 Flux depth was increased to maintain 1-in. minimum flux coverage as each bead was deposited (see detail of buildup sequence in Fig. 25).
6 A special joint design with a very small bevel angle at the bottom and a generous bevel angle at the top was used. (See Fig. 25 for joint designs and typical buildup sequences for welding in both the horizontal and the flat positions.)
7 The position of the electrode in relation to previously deposited weld beads was particularly important.
8 Closer control over current and welding speed was required.

Because of its drawbacks, submerged-arc welding in the horizontal position was used only on small-diameter assemblies, and then only when production schedules could be met in no other way. It was subsequently replaced on similar work by gas-shielded flux-cored arc welding.

Distortion

Because submerged-arc welding is characteristically well adapted to the joining of heavy sections at high current densities and correspondingly high heat inputs, it is more likely to cause distortion than are welding methods that employ lower heat input, depending, in part, on the number of weld layers deposited. However, the ability of submerged-arc welding to deposit large beads may be an advantage in reducing angular (transverse) distortion.



(a) Flux layer too shallow, resulting in arc breakthrough (from loss of shielding), shallow penetration, and weld porosity or cracking. (b) Flux layer at correct depth for good weld-bead shape and penetration. (c) Flux layer too deep, resulting in peaked weld bead with above-average penetration.

Fig. 24. Effect of depth of flux layer on shape and penetration of submerged-arc surface welds made at 800 amp

Longitudinal distortion, an important factor in the camber of welded girders, is greater for a single, large weld bead than for a series of small beads. Because reverse precambering is not difficult to apply, longitudinal distortion resulting from large weld beads can be readily controlled. In addition, torch straightening can be used after welding.

Angular distortion of a fillet-welded member increases with the number of weld layers. Thus, a ½-in. fillet weld deposited as a single layer by submerged-arc welding may exhibit only 1° distortion, whereas a four-layer deposit may be distorted as much as 3°.

Causes and Prevention of Weld Porosity

With few exceptions, the composition of the steels commonly welded by the submerged-arc process is not a major contributor to porosity. Exceptions are very high carbon contents, very low carbon contents (which can be corrected by using a silicon-killed electrode), and an excess of sulfur or sulfide inclusions. The last are particularly troublesome, because they generate gases that, when trapped in the molten metal, result in porosity.

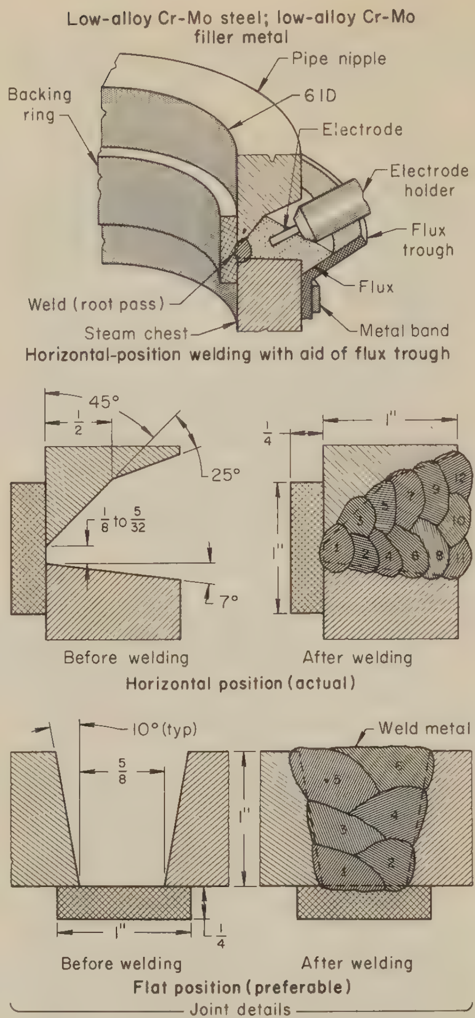
Sulfur-Rich Segregates. Even when the sulfur content of steels being welded does not exceed permissible limits, sulfur-rich segregates and inclusions may cause considerable hot cracking. Laminations of segregates in the base metal may cause porosity in the weld.

When it is necessary to weld steels containing sulfur-rich segregates, special procedures must be adopted. To minimize intermixing of base and filler metals, such steels usually are welded using low straight-polarity direct current, and large-diameter electrode wire. The use of high-manganese electrode wire will promote the formation of manganese sulfides — some of which, in turn, will be removed as part of the slag covering. Welding speed should be low enough to permit entrapped gases to escape through the molten puddle. Butt joints that normally would have square edges should be prepared as beveled joints, and on joints that are normally beveled, the bevel angle should be increased. Multiple-pass welding procedures should be used.

Hydrogen. To avoid porosity in the weld metal and cracking of the heat-affected zone of hardenable steel, submerged-arc weld metal should be deposited under low-hydrogen conditions. To obtain low-hydrogen conditions, the base metal, flux and electrode wire must be free of moisture, oil, rust and paint. Complete removal of all mill scale from the weld zone is imperative.

Joint Contaminants. Carbonaceous and other gas-producing contaminants in the joint are the most common cause of porosity. Joints must be cleaned of all contaminants, including moisture, rust, oil, paint and soil. Above all, the abutting edges of joints must be clean; cleaning only the outer surfaces of the joint is of little benefit.

Joint surfaces that have been prepared by machining or gas cutting can be welded satisfactorily provided they are not rusty or oil coated. Unprepared edges with normal "blue mill scale" generally can be welded without further preparation if the scale is not loose or flaky.



Conditions for Horizontal-Position Welding(a)

Joint type	Circumferential butt
Weld type	Modified J-groove
Joint preparation	Machining
Electrode wire	⅛-in. diam (b)
Flux	Neutral; size, 20×200
Electrode stickout	¾ to 1 in.
Welding position	Horizontal (vertical pipe)
Voltage	28 to 30 v
Current	325 to 350 amp, dcrp
Travel speed	20 to 25 ipm
Flux consumption per hour	10 to 15 lb
Deposition rate	10 to 12 lb per hr
Number of passes	12 to 14
Power supply	45-volt, 600-amp transformer-rectifier (constant-voltage type)
Preheat	400 to 450 F
Postheat(c)	600 F, 2 hr; 1250 F, 2 hr

(a) See text of Example 59 for details of conditions that would have been different for flat-position welding. (b) Same composition as base metal (low-alloy Cr-Mo steel). (c) Stress relief.

The horizontal welding position was used instead of the preferable flat position in order to meet production schedules. Joint designs and buildup sequences for the two positions are compared in the illustration.

Fig. 25. Pipe nipple joined to steam chest by submerged-arc groove welding in the horizontal (vertical pipe) position, with the use of a flux trough (Example 59)

Although blue mill scale will not adversely affect weld quality, "red mill scale" (which is reddish-brown in color) has the same detrimental effect as rust. For best results, red mill scale should be removed from joint surfaces by a combination of power wire brushing and torch heating. The wire brush should be used for preliminary removal of scale, and, during welding, the torch should be directed at the joint ahead of the arc to provide a reducing flame and drive off all residual moisture. To be effective, the torch should heat the surface of the base metal to the range of 400 to 600 F.

Flux and Electrode Wire. Contaminants in the flux, notably moisture, dirt and mill scale, also contribute to weld porosity. These contaminants are more likely to be found in flux that is reused. Moisture can be removed by heating the flux for about one hour at 750 F.

Electrode wire also must be free of contaminants, although a very light coating of special lubricant that has been used to facilitate feeding will not result in weld porosity.

Flux coverage is of the correct depth when the light of the arc reflects on the electrode. When flux coverage is insufficient, the arc flashes through and may cause porosity. Insufficient flux cover is more likely to occur on circumferential welds than on flat welds. On small circumferential welds, it is often necessary to provide mechanical support to the flux around the arc [see discussion under "Circumferential welds (girth welds)", page 57]. Similarly, if slag spills off a weld that has not yet solidified, the weld may exhibit surface porosity. Corner welds and multiple-pass horizontal fillet welds are especially susceptible to surface porosity caused by flux spillage.

Tack Welds. For shielded metal-arc tack welds that will be covered with a submerged-arc weld bead, electrodes of class E6010, E6011 or E7016 should be used (the choice depending on the application), because they give adequate penetration and produce porosity-free deposits. With these electrodes, slag removal is easy. Defective tack welds must be removed before proceeding with submerged-arc welding.

Backward arc blow is a cause of porosity that is most often encountered in the high-speed welding of thin sheets, using direct current, although thicker work metal can be similarly affected. In sheet-metal welds, porosity from backward arc blow usually occurs in the last few inches of a weld, becoming progressively more severe as the end of the weld is approached.

Although arc blow can occur in any direction, backward arc blow is a most common cause of porosity. Backward arc blow can result from a variety of causes, including improper placement of the electrical ground, poor electrical contact at the ground due to mill scale, and the development of a secondary magnetic field caused by the welding cable being partially wrapped around the joint being welded and thereby diverting the arc.

Backward arc blow can be prevented by welding away from the location of the ground, by depositing a heavy tack weld at the finish end of a joint, by angling the electrode forward, by using alternating-current welding power, or by clamping the ground firmly to the workpiece and welding toward the closed end of the fixture. Fixtures for welding thin metal preferably should

be made either of copper or of some other suitable nonmagnetic material.

Poor joint fit-up can promote porosity and slag inclusions by allowing flux to become trapped between the bottom of the weld bead being deposited and the side of the joint opposite the bead. These defects may be subsurface, occurring in the root of the weld, or they may come through to the lower surface.

Slag inclusions due to poor joint fit-up occur most often in butt welds. In a butt weld, the joint may be backed by a backing strip, by backing flux, or by another weld. If the gap between the plate edges is 1/32 in. or more, flux will spill into the gap ahead of the arc. Therefore, to avoid inclusions, either the weld bead must penetrate the backing, or penetration must be reduced to allow the weld bead to clear the backing by at least 5/32 in.

Press-fitted joints are sometimes coated with white lead (basic lead carbonate) before the parts are pressed together. White lead (as do most other lubricants) becomes a gas-producing contaminant that may cause porosity, generally in the form of large holes at or near the end of the weld, or weld cracking. It is best to avoid press fits and to allow a gap of 10% of the plate thickness, not to exceed 1/32 in., or to knurl the edge of one workpiece, thereby providing a path for the escape of gas.

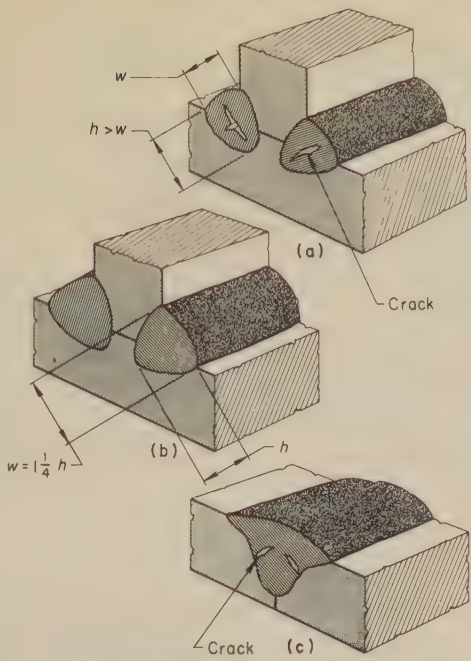
Porosity can also result from failure to remove scale or rust from lands of butt-joint groove welds.

Causes and Prevention of Weld Cracking

In submerged-arc welding of low-carbon steel less than 3/8 in. thick, weld cracking is seldom encountered. However, when thicker sections are welded — particularly those 2 in. or more in thickness — welds are subjected to more rapid cooling, accompanied with more severe cooling stresses. These stresses promote cracking, but precautionary measures can be taken to prevent cracking due to thermal stresses and thereby produce sound welds.

Causes of Cracking. Steel composition can be a cause of cracking, especially when the steel being welded is quench hardenable or exhibits hot shortness. Other factors that promote cracking include: (*a*) failure to preheat, or preheating at too low or too high a temperature; (*b*) heavy sections, which rapidly draw heat from the weld zone and thereby intensify thermal stress; (*c*) workpiece designs that impose a high degree of mechanical restraint on the weld area; (*d*) the presence of hydrogen-producing contaminants, such as moisture, in the weld zone; and (*e*) failure to postheat or adequately stress relieve the weldment.

Base-Metal Composition. The steels that are most suitable for welding by other major welding processes are equally well suited to welding by the submerged-arc process. Among the more weldable compositions are those of the carbon steels containing from 0.06 to 0.20% carbon, 0.35 to 0.80% manganese, and not more than 0.10% silicon, 0.035% sulfur, and 0.030% phosphorus. However, carbon may be increased to 0.25%, manganese to 1.10%, and silicon to 0.15% without affecting welding characteristics significantly. In contrast, special welding procedures are usually required when any one of the following elements exceeds the percentage indicated: 0.35% carbon, 1.40% manganese, 0.30% silicon, 0.05% sulfur, and 0.04% phosphorus. Further, the combination of a low manganese content, such as 0.25%, with a high sulfur content, such as 0.05%, will affect weldability adversely; manganese content must be increased to compensate for a high sulfur content.



(a) Fillet weld beads that have cracked internally because they are deeper than they are wide. (b) Fillet welds that are wider than they are deep, and hence are less susceptible to cracking. (c) Butt weld bead that has cracked because of its "hat" shape, caused by welding at too high a voltage or too low a speed.

Fig. 26. Effect of the shape of the weld bead on its susceptibility to cracking

Several structural steels, such as the grades covered by ASTM A36 and A283, are usually (although not always) welded without difficulty and without the use of special procedures, even though the specifications for these steels indicate upper limits of composition that exceed the optimum range. In practice, most steel sold to these specifications avoids the upper limits, particularly those for sulfur and phosphorus. However, when these steels are purchased to the ASTM specification, there is no guarantee that composition will invariably avoid the upper limits of those elements most likely to promote welding difficulties. Some ASTM specifications do not establish upper limits for certain elements (A283, for example, limits silicon and phosphorus contents only). Thus, the weldability of these steels cannot be predicted with assurance on the basis of specification, but depends on actual tests to qualify welding procedures.

In general, the importance of the chemical composition of the steel, as it affects welding quality, increases directly with increases in joint thickness and joint restraint.

Fillet Welds. To minimize internal-shrinkage stresses that could result in cracking, the fillet-weld bead should be at least 1¼ times as wide as it is deep. This is especially important for steels suceptible to cracking. Beads deeper than they are wide may crack internally, as shown in Fig. 26(a), and may present difficulties in slag removal. Bead contours and cross sections like those shown in Fig. 26(b) are satisfactory. These beads are 1¼ times as wide as they are deep, and the bead surface ranges from flat to slightly convex. The surface of the bead should not be concave; although concave welds present an attractive appearance, they can develop stresses that can result in cracks.

To avoid cracking in fillet welds joining steels of different compositions, the arc should be directed toward the steel with greater weldability, thereby minimizing interalloying of the less weldable steel.

Increasing stickout of the electrode wire (distance from tip of contact tube to workpiece) increases deposition rate and decreases penetration and interalloying. This helps to avoid cracking, but the shape of the weld bead is more difficult to control.

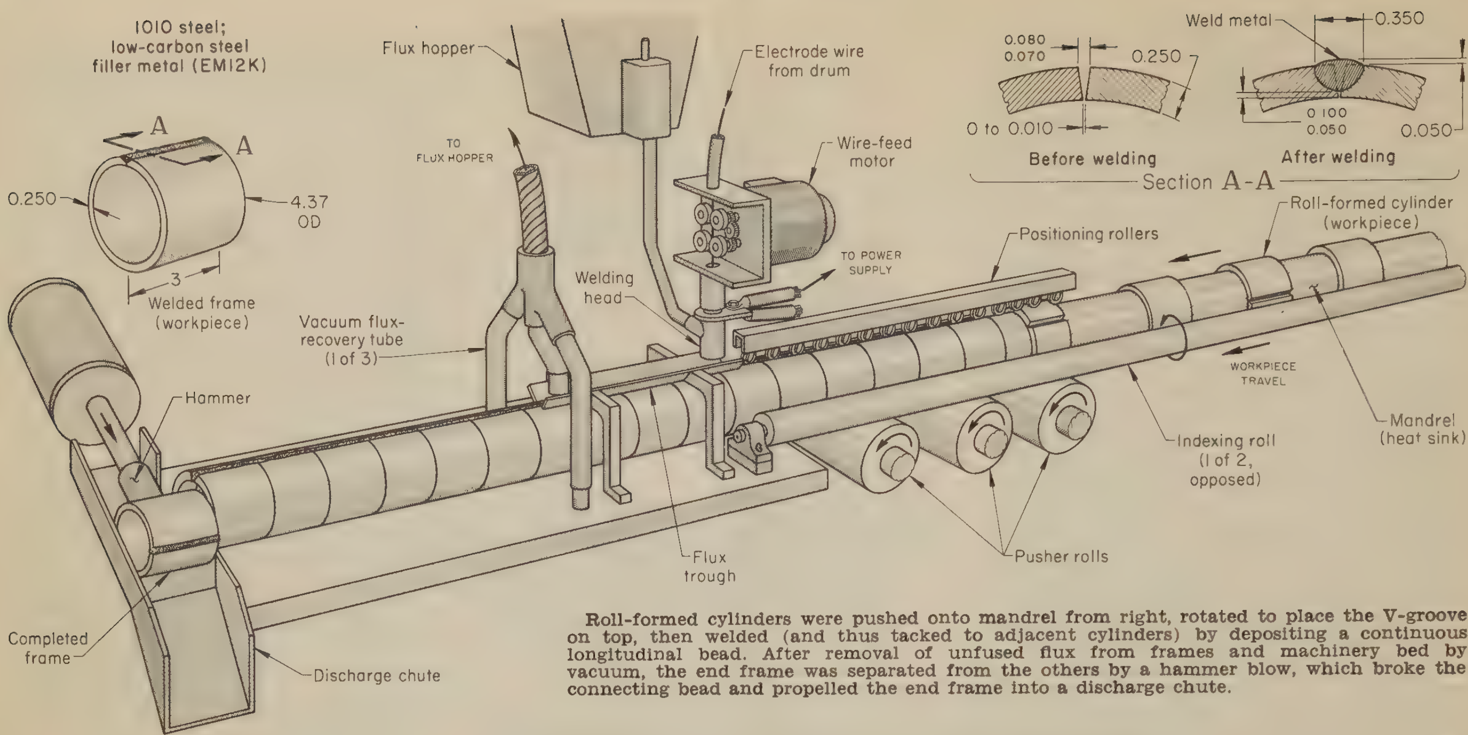
Butt Welds. Cracking in butt welds is less common than in fillet welds, because butt joints are usually less restrained. Under certain unfavorable conditions, however, cracking may occur. Internal cracking and slag inclusions are likely to occur when the butt joint has a groove angle that is too acute, especially for deep grooves that have zero root opening.

Recommended proportions of grooves for submerged-arc welding of steel are given on page 151. These groove proportions have been designed to ensure that the cross section of each weld bead can be at least as wide as it is deep.

For applications in which welds with 100% penetration are required in T-joints between thick plates, a low-hydrogen, shielded metal-arc electrode can be employed for the first pass on each side, to avoid an amount of penetration that will produce weld beads that are deeper than they are wide.

Hat-shape weld beads in butt joints, which result from welding at too high a voltage or too low a speed, may develop cracks at the locations shown in Fig. 26(c). Usually, the cracks can be prevented by reducing the voltage. Sometimes it is necessary to increase welding speed as well as to reduce voltage; this may require welding in two passes instead of one.

Another type of butt-joint weld bead that may crack is the one made during the first pass on the second side of a double-bevel-groove or double-V-groove joint. When the trough produced by back gouging the root-pass weld bead on the first side of the joint is deep and narrow, the first-pass weld bead on the second side of the joint will also be deep and narrow, and likely to crack. This can be prevented by making the back-gouged trough wide enough so that the first bead on the second side can be wider than it is deep. The depth of any one weld pass should not exceed its width. When necessary, a split-weave layer may be used.



Roll-formed cylinders were pushed onto mandrel from right, rotated to place the V-groove on top, then welded (and thus tacked to adjacent cylinders) by depositing a continuous longitudinal bead. After removal of unfused flux from frames and machinery bed by vacuum, the end frame was separated from the others by a hammer blow, which broke the connecting bead and propelled the end frame into a discharge chute.

Joint type	Butt	Flux	F72(c)	Welding position	Flat
Weld type	Single-V-groove	Number of passes	One	Arc length	¼ in.
Power supply	Motor-generator(a)	Current	420 amp, dcrp	Welding speed	51 ipm
Electrode wire	⅛-in.-diam EM12K(b)	Voltage	27 v	Preheat or postheat	None

(a) Output rating at 100% duty, 35 volts and 1000 amp. (b) This medium-manganese wire (0.85 to 1.25 Mn) was used to obtain weld metal with slightly higher manganese content than that of the base metal. (c) Containing manganese silicates.

Fig. 27. Automatic submerged-arc welding of automobile-starter frames, as a continuous process in a production-line station (Example 60)

Automatic Welding

In automatic submerged-arc welding, the welding equipment performs the entire operation (except for loading and unloading, which can be done manually or automatically) with little or no observation and adjustment of the controls by an operator. The electrode wire is fed automatically by means of an electric motor located in the welding head. The welding head also contains the necessary mounting and adjusting equipment for directing the arc at the work and maintaining proper arc length. The welding head is advanced by means of an automatic drive mechanism. It can travel over or alongside the workpiece, or be held stationary while the workpiece travels beneath or alongside it. Arc striking is also automatic. A flux-dispensing tube and hopper are usually attached to the welding head, together with the necessary conductors to provide the welding current. The equipment can deliver high welding currents.

Advantages. In automatic submerged-arc welding, precise control can be maintained on high-volume production, and more than one machine can be controlled by a single operator. Only periodic spot checking is required. The process is well suited to multiple-electrode welding, and also to the completely automatic handling of workpieces during loading and unloading. It also can provide higher welding speed than is controllable by a welder using semiautomatic equipment.

Limitations. Automatic submerged-arc welding requires the use of expensive equipment. In common with many automatic processes, justification for capital outlay for tooling and fixturing depends greatly on large production quantities and continuing demand. Automatic submerged-arc welding may be relatively cumbersome and inefficient when applied to small assemblies, because setup requirements, manipulation of additional equipment, and flux removal combine to offset the advantage of a high metal-deposition rate. Example 105, on page 102, discusses such a small assembly for which automatic submerged-arc welding was only marginally suitable.

Typical Applications. In terms of tonnage, steel line pipe used for transporting petroleum products represents a large application of automatic submerged-arc welding. In making the pipe, formed plate is fed into a cage of rollers that close the joint. The pipe travels through the welding station, where flux is automatically deposited on the joint, the weld is completed, and unused flux is returned to the flux-recovery system.

Although automation is the rule in submerged-arc welding, interruption of the arc between workpieces is ordinarily necessary. The completely mechanized operation described in the following example was unusual in that separate workpieces were welded continuously in sequence as if they were a single workpiece, without interruption of the arc and of deposition of the weld bead.

Example 60. Automated Continuous Welding of Roll-Formed Cylinders (Fig. 27)

Figure 27 shows essentials of the welding station in a continuous line for the production of automobile-starter frames from ¼-in.-thick 1010 steel flat stock by shearing, three-roll forming to cylindrical shape, and automatic submerged-arc welding. Welding conditions are given in the table that accompanies Fig. 27.

The V-groove of the longitudinal joint to be welded (see section A-A in Fig. 27) was that resulting from the roll forming of the sheared stock. After being washed, the roll-formed frames were transferred to a storage tower in the line, to assure continuity of supply for welding in the event of shear or forming-roll failure. From the storage tower, the frames were pushed, one after the other, onto a mandrel to form a tubelike arrangement for welding, as illustrated in Fig. 27.

The frames were oriented under the welding head by means of two parallel indexing rolls that rotated the frames until the joints were at the top, where a row of sharp-edge positioning rollers engaged and held the joints in alignment for continuous welding. Pushers advanced the aligned frames along the mandrel.

Through a single tube in the welding head, flux was fed to the joint from an overhead hopper while the electrode wire was motor-fed to the joint from a large cardboard drum. Just beyond the welding head were three vacuum tubes that picked up unfused flux for return to the overhead hopper. One tube was positioned directly above the weld; the other two were positioned on either side of the work to pick up flux that spilled off the frames onto the machinery bed.

The mandrel that supported the frames during welding also served as a heat sink. This, in combination with control of welding current and travel speed, resulted in weld penetration as shown in section A-A in Fig. 27, with no flash or melting on the inside wall of the frames.

Because the welded joint was continuous, the frames became automatically tacked together. They were separated by horizontal blows from a hammer, delivered as each welded frame moved beyond the mandrel, as shown in Fig. 27. The impact from the

hammer also served to break off much of the solidified flux adhering to the frames.

The separated frames passed through a cooler and then were expanded to finished size; the expanding action removed any remaining solidified flux and made internal machining unnecessary. Because the expanding operation was the most severe treatment the frames would receive, it served as a 100% check on weld quality. Failures were less than 2%. Weld-metal specimens had tensile strength of 75,000 psi.

Automatic submerged-arc welding can be used to produce high-quality internal and external longitudinal welds in cylinders and tanks that are roll-formed from plate, provided that the internal and external clearances permit the necessary manipulation of the welding head or heads. In some of these applications, including that described in the following example, it is advantageous to mount and transport the welding heads on booms to traverse the joint.

Example 61. Internal and External Longitudinal Welding of a Long Cylinder (Fig. 28)

The longitudinal double-V-groove butt joint in a 30-in.-OD cylinder 134 in. long, roll formed from 9/16-in.-thick steel plate, was welded by the automatic submerged-arc process in two operations, as illustrated in Fig. 28. The welded cylinder, which weighed about 1700 lb, had to undergo a fairly severe final forming operation, and for this reason, it was made from ASTM A515, grade 70, steel (0.31% max C), which has good formability and weldability.

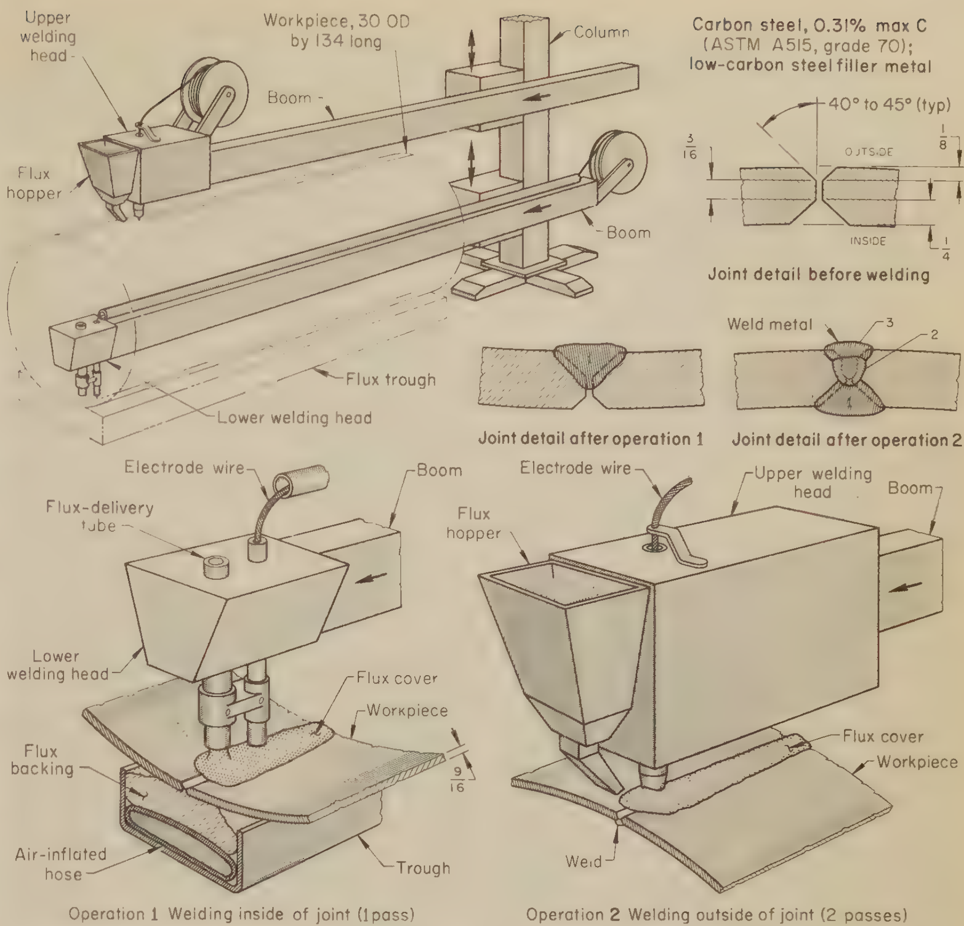
Submerged-arc welding was used because of its ability to yield sound welds with good penetration. An additional benefit of submerged-arc welding was that a flux-bed backing could be used in depositing the inside weld bead (the first operation), as shown in Fig. 28.

First, the plate was beveled on the edges to be joined, and roll formed to a cylinder, thus producing the double-V-groove butt joint shown in detail in Fig. 28. The outside of the joint was tack welded, and runout tabs (not shown in Fig. 28) were added to each end.

Two welding heads, mounted and transported on booms supported by the same column (see Fig. 28), were used for successively welding the inside and outside of the joint. The welding setup also included a trough in which an air-inflated hose was used to force granular flux against the outside joint groove, thus providing backing to contain the weld metal deposited on the inside of the joint, in the first operation. The flux trough also served as a workholding fixture.

The roll-formed cylinder was set on the flux bed with the joint at bottom center, the runout tabs were clamped down, and the air hose in the flux trough was inflated, forcing flux against the joint. Then the inside weld was deposited by the lower welding head in one pass. After the inside of the joint had been welded, the cylinder was removed from the flux trough and the outside of the joint was ground to sound weld metal. Then the cylinder was returned to the flux trough, with the joint at top center, for deposition of the external bead by the upper welding head, in two passes. The inside bead acted as the backing. Both operations required some observation by the welding operator to ensure alignment and to control welding speed and other operating variables (see table with Fig. 28).

The welding was done automatically with single electrode wires, using direct current with reverse polarity to control the bead shape and appearance and to produce consistent full penetration. Two 900-amp motor-generator sets connected in parallel supplied the welding current. The generators had a steep arc-voltage current characteristic. The electrode wire was low-carbon steel with copper coating to reduce



Joint type	Butt
Weld type	Double-V-groove
Joint preparation	Machining

Fig. 28. Use of boom-mounted welding heads for two-operation automatic submerged-arc welding of the inside and outside of a longitudinal seam in a roll-formed cylinder. Trough contained flux for backing of the inside weld, and served to support the cylinder and helped maintain alignment for both operations. (Example 61)

electrical resistance at the contacting surfaces and to resist corrosion. The electrode wire and the contact jaws were kept clean and close fitting to ensure the maintenance of good electrical contact.

For each operation, flux was fed by gravity from a hopper at the welding head. Unmelted flux was returned by vacuum to storage after passing through a screen to remove slag. The flux was selected for good bead shape with reasonable penetration. It produced easily removed slag without significantly altering the composition of the weld metal.

The inside bead was ground flush with the cylinder wall, as required for subsequent operations. The welds were given a 100% radiographic inspection, and all production conformed to Section VIII, Div. 1, of the ASME Boiler and Pressure Vessel Code.

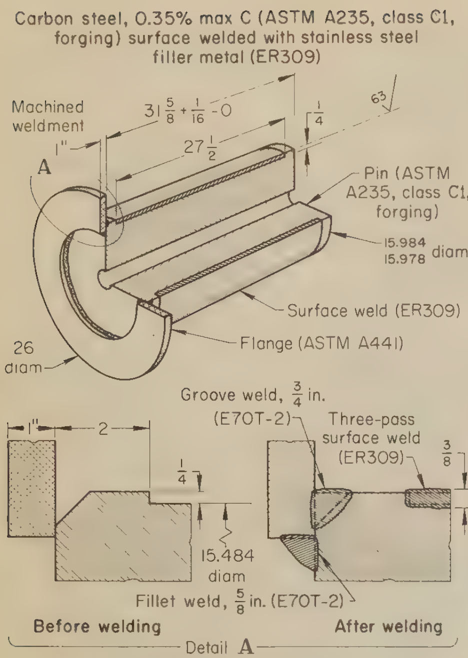
Surfacing Applications

The high deposition rates that are characteristic of submerged-arc welding can be adapted to various applications of surfacing — an operation in which weld metal is deposited on the surface of the workpiece to obtain resistance to wear or corrosion or to provide some other specific property or properties (also see the article on Hard Facing by Arc Welding, which begins on page 152 in this volume). The deposition of a corrosion-resistant overlay by submerged-arc welding is described in the example that follows.

Example 62. Surfacing a Low-Carbon Steel Trunnion Pin With Stainless Steel (Fig. 29)

The dam-gate trunnion pin shown in Fig. 29 was forged from ASTM A235, class C1, steel, which provided adequate strength for the application, but inadequate resistance to atmospheric corrosion. To provide protection from corrosion, a type 309 stainless steel overlay was deposited in an undercut section of the pin by three-pass submerged-arc welding, after a flange had been joined to the pin by flux-cored arc welding.

The undercut for surfacing was ¼ in. deep and extended nearly the full length of the pin, as shown in Fig. 29. To make the overlay, the pin was rotated in a 1000-lb welding positioner. The pin was supported by a shaft through its cored hole and by a mounting plate (not shown) that was tack welded to the end of the pin opposite the flange. A bridge over the positioner supported a carriage for the welding head. An improvised heater consisting of an insulated box and the burner from a floor furnace was used for preheating the pin and for interpass heating. In each pass, a bead ⅛ in.



Conditions for Surfacing

Weld type	Surfacing
Surface preparation	Machining ¼-in. undercut
Electrode wire	⅛-in.-diam ER309
Flux	Neutral; size, 48×100
Power supply	Two 35-volt, 350-amp transformers
Current	250 amp, ac
Voltage	25 v
Welding position	Flat(a)
Welding speed	17 ipm
Number of passes	Three
Preheat and interpass temperature	250 to 300 F
Arc time per pin	23¼ hr
Flux consumption per pin	40 lb
Weight of filler metal deposited per pin	40 lb

(a) Horizontal-rolled pipe position

Prior to surfacing, the groove weld and fillet weld joining the pin to the flange were deposited by semiautomatic flux-cored arc welding, using ³⁄₃₂-in.-diam E70T-2 electrode wire at 30 volts and 250 amp; welding time was 45 min.

Fig. 29. Dam-gate trunnion pin that was submerged-arc surface welded with stainless steel for protection against atmospheric corrosion (Example 62)

thick was deposited. Welding conditions are given in the table accompanying Fig. 29.

After the last pass, the pin was wrapped in 3-in.-thick fiber-glass and allowed to cool slowly for 12 to 14 hr. It was then machined to final dimensions, leaving a ¼-in.-thick coat of stainless steel on its shank.

Limited-Access Locations. When access to the area to be surfaced is limited, automatic submerged-arc welding is sometimes the most suitable and economical of the automatic welding processes, and gives more-uniform weld quality than does manual welding.

In the following example, two layers of weld deposit were applied to almost inaccessible sites in a steam chest, by automatic submerged-arc welding.

Example 63. Automatic Submerged-Arc Surface Welding of Internal Valve Seats (Fig. 30)

Four internal valve seats in a steam chest cast from low-alloy Cr-Mo steel were surface welded with stainless steel by the automatic submerged-arc process, as shown in Fig. 30 and detailed in the accompanying table. Manual welding was not feasible, because the only access to the valve seats was through holes 3½ to 5¼ in. in diameter, 15 to 22 in. above the seats (hole diameter and distance from the seats varied with the size of the chests, which varied in diameter and ranged from 8 to 12 ft in length).

The electrode wire was brought to the weld area through an electrically insulated copper guide tube (nozzle) with an angled head (see Fig. 30). The guide tube, lowered through and centered in the hole above each valve seat, was rotated at a fixed speed. During welding, flux, which was supplied manually or by gravity feed through the same hole in the steam chest, was retained by a carbon steel plug, which was machined out after welding. On each valve seat, a ⅜-in.-thick, two-layer surface weld was deposited in 10 to 14 passes. A typical 10-pass buildup sequence is shown in detail A in Fig. 30.

After each pass, a limit switch automatically stopped the welding and the rotation of the guide tube; then loose flux and slag were removed by a suction system, assisted by a pneumatic hammer that loosened the slag.

Gas burners were used to preheat the valve seats to at least 250 F before welding and to maintain this minimum temperature throughout the two-hour welding time required for completing each valve seat.

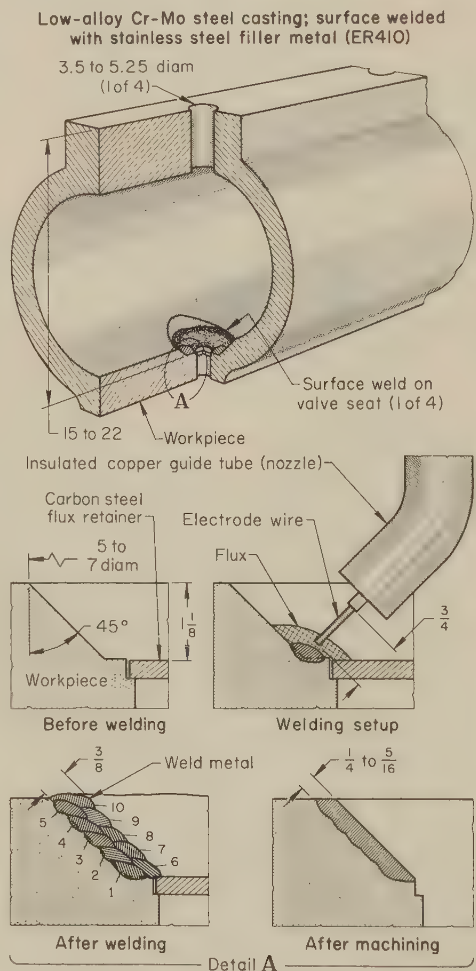
Electrode stickout was held constant at about ¾ in., and the guide tube was relocated upward ¼ in. and outward (horizontally) ⅛ in. for each pass. The arc for each pass was initiated by contacting the workpiece with the electrode and retracting the electrode automatically by means of the constant-voltage wire-feed system.

Because the valve seats were exposed to the erosive effects of high-temperature, high-speed steam flow, the weld deposit had to be sound, without voids, cracks, inclusions or oxides, and had to contain a minimum of 11% Cr. The electrode wire was ER410 (type 410 stainless steel), ⁵⁄₆₄ in. in diameter — the largest wire that could be fed through the guide tube.

By welding with straight-polarity direct current of 320 to 340 amp and an arc voltage of 34 volts, supplied by a constant-voltage transformer-rectifier, the small-diameter electrode wire provided a flat bead with good flow and clean overlaps.

The weld-surfaced parts were stress relieved by holding at 1250 F for about 10 hr. Then the flux retainers were machined out, and the weld deposit on each valve seat was machined to final dimensions (see "After machining" in detail A in Fig. 30). Inspection was carried out by visual examination and dye-penetrant testing. The rejection rate was less than 1%.

Two other automatic processes, gas tungsten-arc and gas metal-arc welding, had been evaluated for this application. Submerged-arc welding was chosen over the other processes because it required the least setup and cycle time, was easiest to apply through the limited-access hole, permitted greatest control of variables, and entailed the lowest initial and maintenance costs.



Process	Automatic submerged-arc welding
Weld type	Surfacing
Power supply	45-v, 600-amp constant-voltage rectifier
Voltage	34 to 35 v
Current	320 to 340 amp, dcsp
Electrode wire	⁵⁄₆₄-in.-diam ER410
Electrode stickout	¾ in.
Flux	Neutral
Welding speed	15 ipm
Number of passes	10 to 14
Preheat and interpass temperature	250 F min
Postheat (stress relief)	10 hr at 1250 F
Deposition rate	12 to 14 lb per hr
Flux consumption	12 to 15 lb per hr
Production time per valve seat	2 hr

Fig. 30. Portion of a steam chest in which four internal valve seats, accessible only through opposing holes, were surface welded as shown (Example 63)

Positioning the Welding Head in Relation to the Work. The deposition of surface welds often requires the use of complicated fixturing to position the workpiece and to guide the welding head over the surface contours that are to be overlaid. However, if the overlay is to be deposited on a surface of rotation, simpler fixturing may be required, as described in the following example.

Example 64. Surface Welding the Groove of a Large Sheave (Fig. 31)

The large low-carbon steel sheave (pulley) shown in Fig. 31 was used infrequently, and when not in use was exposed to the weather, which led to surface deterioration that caused the grooved rim to seize during operation of the sheave. To prevent this, the rim was surface welded with a three-layer deposit of stainless steel. Automatic submerged-arc welding, under the conditions listed with Fig. 31, was chosen, to obtain the best combination of deposition rate and soundness of deposit.

The sheave was gas cut from ASTM A36 steel plate 4½ in. thick, and the center hole was rough bored. The rim groove was then machined to the dimensions shown in the "Before welding" view in detail A in Fig. 31, and the sheave was mounted on a welding positioner.

So that the same welding conditions could be applied during the entire surfacing operation, the welding head was mounted on the frame of the positioner with fixturing that held the head in a fixed position with reference to the grooved rim. The sheave was rotated automatically on its axis to give a welding speed of 20 to 22 in. per minute. The overlay was deposited in three layers, each consisting of 36 passes; total thickness of the overlay was ¼ in. For the initial passes covering the central portion of the sheave groove, the sheave was in an upright position (with its axis horizontal). As the welding progressed toward the outside of the groove, the angle of the positioner was adjusted in increments to keep the work surface at the welding point within 30° of horizontal for each pass. The

same sequence of positioning was repeated to deposit the second and third layers of weld metal.

Initially, solid stainless steel electrode wire was used, but the overlay cracked severely on cooling. The cracking was caused by shrinkage stress in the first layer of the overlay, which was brittle because of dilution of its alloy content and increase in carbon content by diffusion from the carbon steel base metal. To increase the ductility of the first layer deposited, cored tubular electrode wire was used instead of solid wire. The cored wire consisted of a low-carbon steel tube filled with alloying and fluxing ingredients needed to deposit weld metal similar in composition to type 309 stainless steel. The cored wire gave a less penetrating arc, so that bead dilution and carbon diffusion were reduced, thereby eliminating the cracking during cooling.

The completed overlay was visually inspected, and then it was machined to final dimensions. The finished surface was dye-penetrant inspected; a few pinholes were the only flaws detected in the 40 sheaves processed. The pinholes were repaired by manual gas tungsten-arc welding and hand dressed.

Examples 153, 154, and 155 in the article on Hard Facing by Arc Welding describe the use of submerged-arc welding for deposition of wear-resistant alloys in surfacing oil-field drill collars, tractor rollers and idlers, and blades for shearing hot metal.

Multiple-Electrode Welding

In submerged-arc welding, deposition rate can be markedly increased by the use of a multiple-electrode welding system. These systems can be differentiated on the basis of three variables: number of electrodes, type of power connection used, and the position of the electrodes (tandem or transverse) with respect to direction of travel.

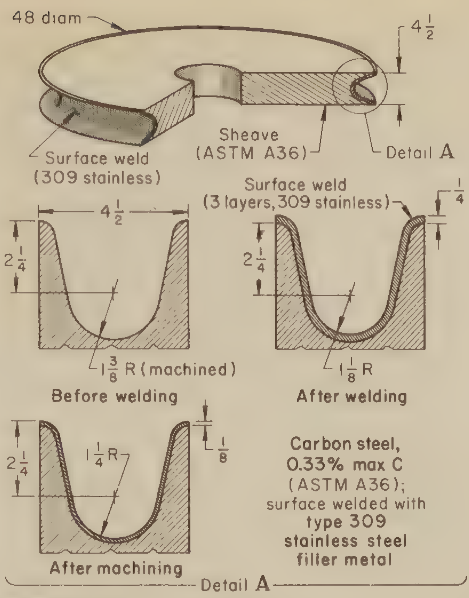
Number of Electrodes. Depending on the system selected, the number of electrodes in simultaneous operation can vary from two to four (see Example 67), or more.

Power connection may consist of a multipower connection, a parallel connection, or a series connection.

In a multipower connection, each electrode has its own power supply, welding head, voltage-control mechanism, and wire-contact assembly. Two-phase or three-phase power, and any combination of alternating and direct current, can be supplied to the electrodes. The welding ground is attached to the workpiece, and a voltage-control unit governs each welding head. With multipower connections, extra-high-speed welds can be made. With two-phase or three-phase power, magnetic effects permit better arc control and improved operation. The weld is narrow and deep-penetrating.

In a parallel connection, the electrodes are connected in parallel to the power supply, and attachment of the welding ground to the workpiece is conventional. One voltage-control unit governs the operation of a single welding head, which feeds both electrodes simultaneously. This is the only multiple-electrode welding system that requires only one welding head. Current densities are reduced, and penetration is less than that obtained with a multipower connection. A parallel connection is often used with electrodes in the transverse position to make extrawide welds for poorly fitted joints. With a parallel connection, the weld is much broader than it is deep.

In a series connection, two electrodes are connected in series, and two welding heads are used. Each electrode has a separate voltage-control unit and operates independently. One power-supply cable is connected to one welding head. The other



Process	Automatic submerged-arc welding
Weld type	Surfacing
Surface preparation	Machining
Power supply	750-amp, constant-voltage rectifier
Electrode wire	1/8-in.-diam cored 309 stainless
Flux	Proprietary
Welding position	Flat (within 30°)
Current	380 amp, dcrp
Voltage	30 v
Wire feed	Automatic
Welding speed	20 to 22 ipm
Number of weld layers	Three
Number of passes per layer	36
Total arc time per sheave	12 hr
Finishing	Machining to dimensions

During welding, the sheave was rotated in a three-ton variable-speed positioner, to the frame of which the welding head was mounted in such a way as to retain a fixed position relative to the groove being surface welded.

Fig. 31. Sheave with a rim groove that was surface welded with stainless steel, to prevent seizing in service (Example 64)

cable is connected to the second welding head, instead of to the workpiece, as in conventional welding. Welding current travels from one electrode to the other through the weld puddle and surrounding material. There is no connection between the power supply and the workpiece. Almost all of the power is used to melt the electrode, with little power entering the workpiece. With the electrodes in the transverse position, series connection produces a broad, shallow weld bead, and thus is well suited to the deposition of a surfacing overlay on a base metal with very little dilution. Deposition rates of 25 lb per hour are readily obtainable.

Electrode Position. With any of the three types of power connections, different effects can be produced by altering the position of the electrodes with respect to the direction of travel. Electrodes may be arranged in either the tandem or the transverse position; with three or more electrodes, other patterns are possible.

Usually, electrodes are arranged in the tandem position — that is, with one electrode following *behind* the other as they move in the direction of travel. (Welding with electrodes in the tandem position is sometimes referred to as tandem-arc welding.) With electrodes in the transverse position, one is positioned *alongside* the other as they move in the direction of travel.

For more complete coverage of power-supply systems, electrode positioning, electrical circuitry, phase-angle relationships, and other variables in the application of welding with multiple-electrode systems, the reader may refer to the following articles: D. E. Knight, Multiple Electrode Welding by "Unionmelt" Process, *Welding Journal,* Apr 1954, p 303-312; R. A. Kubli and H. I. Shrubsall, Multipower Submerged-Arc Welding of Pressure Vessels and Pipe, *Welding Journal,* Nov 1956, p 1128-1135.

In the example that follows, welding in the tandem position was used to butt weld thick plate in a pressure vessel.

Example 65. Tandem-Arc Welding of Pressure-Vessel Plates up to 8 In. Thick (Fig. 32)

Figure 32 shows the design of a single-V-groove longitudinal butt joint used in submerged-arc welding of thick-wall pressure vessels made of carbon or low-alloy steel. The minimum inside diameter of these vessels was 24 in., and the wall or plate thickness did not exceed 8 in. — an upper limit imposed by the need to accommodate the welding head in the joint.

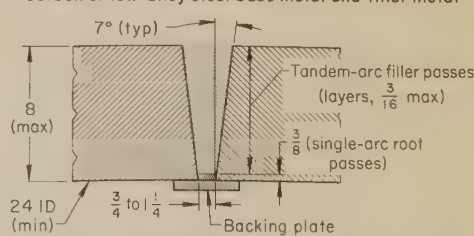
The edges that formed the joint groove were beveled by gas cutting to provide the 7° angle shown. Mismatch allowance after roll forming the plate was 1/16 in. max. Prior to welding, a backing plate was located at the base of the groove, as shown in Fig. 32. The root opening varied from 3/4 to 1 1/4 in., depending primarily on wall thickness and accessibility required by the welding head. Workpieces were preheated to 250 ± 50 F, to minimize distortion and prevent cracking.

For root passes to a depth of 3/8 in., a single electrode was used, and power input was reduced to a level that would avoid burning through the backing plate. The remainder of the joint was filled by two-electrode (tandem-arc) welding, using alternating current in both electrodes. The current input was increased to provide maximum speed of metal deposition.

Additional welding conditions are given in the table with Fig. 32.

Deposition rate can be further increased by preheating the electrode wire by electrical resistance to passage of the welding current. Resistance is increased by lengthening the path the current has to travel — that is, by lengthening the stickout (also called electrical stickout), which is the distance from the end of the contact tube to the weld puddle. In the next example, both the tandem-arc and the long-stickout heating methods for increasing deposition rate were used.

Carbon or low-alloy steel base metal and filler metal



Process	Automatic submerged-arc welding
Joint type	Butt
Weld type	Single-V-groove
Electrode wire	3/16-in.-diam carbon or low-alloy steel
Power supply	Transformers
Preheat	250 ± 50 F

	Single-arc root passes	Tandem-arc filler passes(a)
Current (ac), amp	500	750
Voltage	33	35
Welding speed, ipm	12	20

(a) Values shown are for each electrode.

Fig. 32. Longitudinal butt joint in a thick-wall pressure vessel that was tandem-arc welded after single-arc root passes had been made (Example 65)

Example 66. Deposition Rates in Welding With a Single Electrode, and With Tandem Electrodes Using 1-In. and 5-In. Stickouts (Fig. 33)

A cylindrical, high-pressure steam vessel 10 ft long, shown at upper left in Fig. 33, was roll formed from ASTM A515, grade 70, steel plate, 2½ in. thick. The joint edges were then machined or torch cut to make a 60° groove (see section A-A in Fig. 33), the joint was fitted up, and the sealing root pass was shielded metal-arc welded.

Automatic submerged-arc welding was then used to complete the joint from the outside. The joint was turned over and the root-pass bead was air carbon-arc gouged from the inside to expose sound submerged-arc weld metal, and the resulting groove was then submerged-arc welded to produce a smooth inside joint.

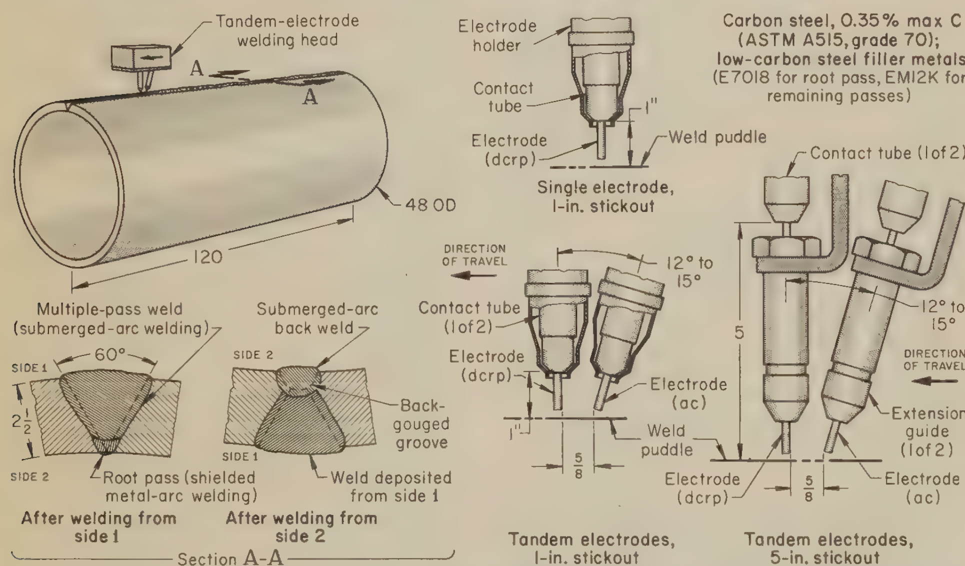
Twelve pounds of weld metal per linear foot was required to complete the longitudinal seam — 120 lb for the 10-ft length. When single-electrode submerged-arc welding was used, total arc time required per seam was 8.6 hr. To reduce this arc time, two other submerged-arc welding techniques were evaluated. In both techniques, following a single-electrode first filler pass, tandem-arc welding was employed for the first side of the joint, using a lead electrode with reverse-polarity direct current and a trailing electrode with alternating current. The difference lay in the length of the stickout of the electrodes: in one method it was 1 in. on both electrodes; in the other it was 5 in. on both electrodes, using extension guides (Fig. 33).

For the tandem-arc arrangement with 1-in. stickout, the total arc time for the joint was 4.6 hr, or about one half the time consumed by single-electrode welding. For tandem-arc welding with 5-in. stickout, arc time per joint was reduced to 2.8 hr, because of the increased resistance heating of the wire that resulted from the greater stickout. Operating details for the three welding procedures are given with Fig. 33.

Welding Position. When two or more electrodes are used to deposit filler metal, the flat welding position is usually preferred. In this position, the bead is least distorted by unsymmetrical pull of gravity, and loss of flux is minimized so that there is less need for using dams and restraints to keep the flux from spilling off the weld area.

When heavy assemblies that require fillet welds are difficult to manipulate into the flat welding position, the horizontal welding position (for fillet welds) may be used. To compensate for the lopsided flow of the filler metal in horizontal-position welding, the electrodes are spaced far enough apart to make separate weld puddles. The leading electrode deposits a layer that sags down to cover more of the flat surface than of the vertical surface. Trailing electrodes are angled to deposit most of the metal on the vertical wall of the joint. The composite of all the beads makes a relatively symmetrical fillet.

Submerged-arc welded bridge girders and other welded bridge structural components are designed and fabricated in accordance with code specifications (AWS D2.0) in order to attain prequalified status. Although welding in the flat position is generally preferred, the code states that fillet welds may be made in either the flat or horizontal position, except that the size of single-pass multiple-arc fillet welds made in the horizontal position shall not exceed ½ in. A change from flat to horizontal welding position in tandem-arc welding of girders is described in the following example.



Item	Single electrode, 1-in. stickout	Tandem electrodes, 1-in. stickout	Tandem electrodes, 5-in. stickout
Arc time, hr	8.6	4.6	2.8
Deposition rate, lb per hr	14	26	42

Side(a)	Pass(a)	Current, amp	Voltage	Welding speed, ipm
Submerged-Arc Welding With Single (1-In. Stickout) Electrode(a)				
1	First filler	400 to 450 (dcrp)	32 to 33	14 to 15
	Remaining	575 to 600 (dcrp)	33 to 34	13 to 14

(a) Joint was sealed from side 1 by a root pass made by shielded metal-arc welding, using a ⅛-in.-diam E7018 electrode at 110 to 140 amp, 18 to 20 volts. Filler passes were made by submerged-arc welding, using 5⁄32-in.-diam EM12K electrode wire and F61 flux. Welding was done in the flat position. Power supplies were an 800-amp motor-generator for the single electrodes and for the leading tandem electrodes, and a 1000-amp transformer for the trailing tandem electrodes. Preheating consisted in heating the vessel to 175 F minimum. Postweld heating consisted in holding the vessel at 1150 F minimum for 2½ hr, then furnace cooling it to 600 F. (b) After air carbon-arc back gouging approximately ⅜ in. deep to reach sound metal.

Fig. 33. Pressure vessel with a 10-ft longitudinal seam for which welding time was progressively reduced by changing from automatic submerged-arc welding entirely with a single electrode to first-side welding of all but the first filler pass with tandem electrodes having a 1-in. stickout and then a 5-in. stickout (Example 66)

Example 67. Change in Welding Position That Increased Welding Efficiency and Reduced Handling of Tandem Welded Bridge Girders (Fig. 34)

Originally, I-beam bridge girders were welded in the flat position with the web tilted at 45°, as shown in Fig. 34(a), after assembly by tack welding. The welding head was held in a vertical position during travel along each joint, and the girder was progressively repositioned to make the four welds in the numerical sequence shown in Fig. 34(a). The wires in the two-electrode welding head, each fed by a separate wire-feed motor, were spaced 1 in. apart, so that both fed the same weld puddle, developing a single bead (Fig. 34b). Although sound welds were made with this procedure, production rate was limited because the girders had to be repositioned and aligned for each weld, and only one weld could be made at a time.

To increase the production rate, the girder was oriented so that two welds could be made simultaneously in the two horizontal positions shown in Fig. 34(c) and (d). For horizontal-position welding, the positions of the electrodes were changed so that the fillet welds would be of proper shape. First, the two electrode wires were spaced 4½ in. apart, so that the bead from the leading wire solidified before the second bead was deposited; welding thus became a multiple-pass operation. This was necessary because gravity pulled the molten metal toward the horizontal member of the girder and the proper shape for the weld bead could not be developed from a single weld puddle. In addition, the trailing electrodes were positioned as shown in Fig. 34(c) and (d), to develop the upper portion of the fillet welds. The two-layer weld deposits built up in these horizontal positions are shown in Fig. 34(e).

With the reduction in handling time from that required when one weld at a time was deposited in flat-position welding, and with the increase in deposition rate obtained with the "two-pass" welding effected by the use of spaced electrodes, the time for welding each girder was reduced 65% by welding in the horizontal position.

Welding conditions for various fillet sizes, using the flat position and horizontal position, are given in the table with Fig. 34.

Improvements in equipment and technique have made it possible to use three, and sometimes four, electrodes in the horizontal position, depending on fillet size and code requirements; the table with Fig. 34 lists welding conditions for 5⁄16 and 3⁄8-in. fillets, using three electrodes and the horizontal position, and for ½-in. fillets, using four electrodes and the horizontal position. All of the welding data in the table are applicable to a series of carbon steels and high-strength low-alloy steels covered by the specifications in AWS D2.0 — including ASTM steels A36, A441, A500 (grade B), and A588. Filler metals and flux-electrode combinations are selected for compatibility with the base metal, in accordance with specifications in AWS D2.0.

Cost of Tandem-Arc vs Single-Arc Welding. The example that follows discusses the use of single-arc and tandem-arc welding of girth joints between various thicknesses of plates that comprised the cylindrical shells of large field-erected storage tanks, and presents the results of a ten-year cost study made to determine which of the two methods was more economical in relation to specific plate thickness.

Example 68. Tandem-Arc vs Single-Arc Welding of Large Field-Erected Storage Tanks (Fig. 35)

Cylindrical shells of large field-erected storage tanks were constructed by welding successive shell-ring courses, as shown schematically in Fig. 35. Although various processes were used for welding the vertical butt joints, the horizontal girth joints were submerged-arc welded, using either the single-arc or the tandem-arc method. Both methods employed a special traveling cab, containing the welding operator and the welding equipment, driven along the upper edge of a shell ring. Tandem-arc welding was limited to plates ½ in. or more in thickness, because the tandem equipment would deposit excess reinforcement with plates less than ½ in. thick.

Although the tanks were of various sizes, the one shown in Fig. 35 indicates typical construction. This tank, 180 ft in diameter and 48 ft high, had six shell-ring courses, with the thickest plate (1¼ in.) at the bottom and the thinnest (5⁄16 in.) at the top. The two joints at the top of the tank, between plates 5⁄16, 13⁄32, and 5⁄8 in. thick, were welded from both sides by the single-arc method (see detail A in Fig. 35). The three joints between the four lower courses of plates (5⁄8, 0.82, 11⁄32, and 1¼ in. thick, top to bottom) were welded from both sides by the tandem-arc method (joint design is shown in detail B in Fig. 35).

A comparison of labor and material costs for the use of single-arc and tandem-arc welding over a ten-year period for tanks up to 260 ft in diameter and 64 ft high, with shell courses ranging in thickness from 3⁄16 to 1½ in., is presented in the graph of Fig. 35. Labor costs were based on a labor-plus-overhead rate of $14 per hour. Material costs were based on a flux consumption of 1.7 pounds of flux per pound of weld metal deposited. The amounts of deposited metal and the material costs were the same for single-arc as for tandem-arc welding, for plates ranging in thickness up to 1⅛ in.

Summary of Cost-Comparison Data. On plate thicknesses of ½ to 1⅛ in., tandem-arc welding cost $0.55 to $0.43 less per foot than single-arc welding (the difference in labor cost). On plate more than 1⅛ in. thick, the per-foot cost of tandem-arc welding was $2.08 to $2.40 less for labor and $0.15 to $0.17 less for material, or $2.23 to $2.57 less for both items, depending on the plate thickness (see graph in Fig. 35).

The large increase in labor cost occurred because, for plate more than 1⅛ in. thick, a shielded metal-arc root pass was required before single-arc welding, to avoid cracking in the first submerged-arc weld bead.

(a) L = leading electrode, T = trailing electrode. (b) As shown in illustration. (c) Not shown in illustration.

Because of decreased workhandling and increased deposition rate in horizontal-position welding, production time was reduced 65%. Techniques illustrated were used for girders of various lengths and section thicknesses. Table above gives conditions for single-pass tandem-arc deposition of different sizes of fillet welds in both welding positions.

Fig. 34. Tandem-electrode submerged-arc fillet welding of bridge girders in the flat and horizontal positions (Example 67)

Submerged-Arc Welding vs Other Arc Welding Processes

Submerged-arc welding often is selected in preference to other processes because it is faster. In the example that follows, submerged-arc welding was not as fast as flux-cored arc welding, one of several processes with which it was compared, but it was preferred on the basis of lower cost and other production advantages.

Example 69. Cost of Welding a Planetary-Gear Carrier by Submerged-Arc Welding vs Three Other Arc Welding Processes (Table 9)

The six 3⁄8-in. fillet welds that joined three spacers to the backing plate of a planetary-gear carrier (see illustration in Table 9) had to be free of particles that could flake off into system oil and clog oil holes and lines, and to have enough strength and notch toughness to withstand shocks of sudden load changes in service.

To evaluate suitability and costs, gear carriers were arc welded by four different processes — shielded metal-arc (with ¼-in. and 5⁄16-in. electrodes), gas metal-arc, flux-cored arc, and submerged-arc welding. All proved capable of providing welds that would satisfy service requirements. A time-and-cost comparison of the processes is presented in Table 9. As this comparison shows, flux-cored arc welding required the least welding time per assembly. Submerged-arc welding was the second-fastest process, as well as the least expensive. Unlike the three other processes, submerged-arc welding left no weld spatter to be cleaned off the workpiece (at additional expense). Accordingly, submerged-arc welding was adopted for regular production. No postheating was employed after any of the welding processes evaluated.

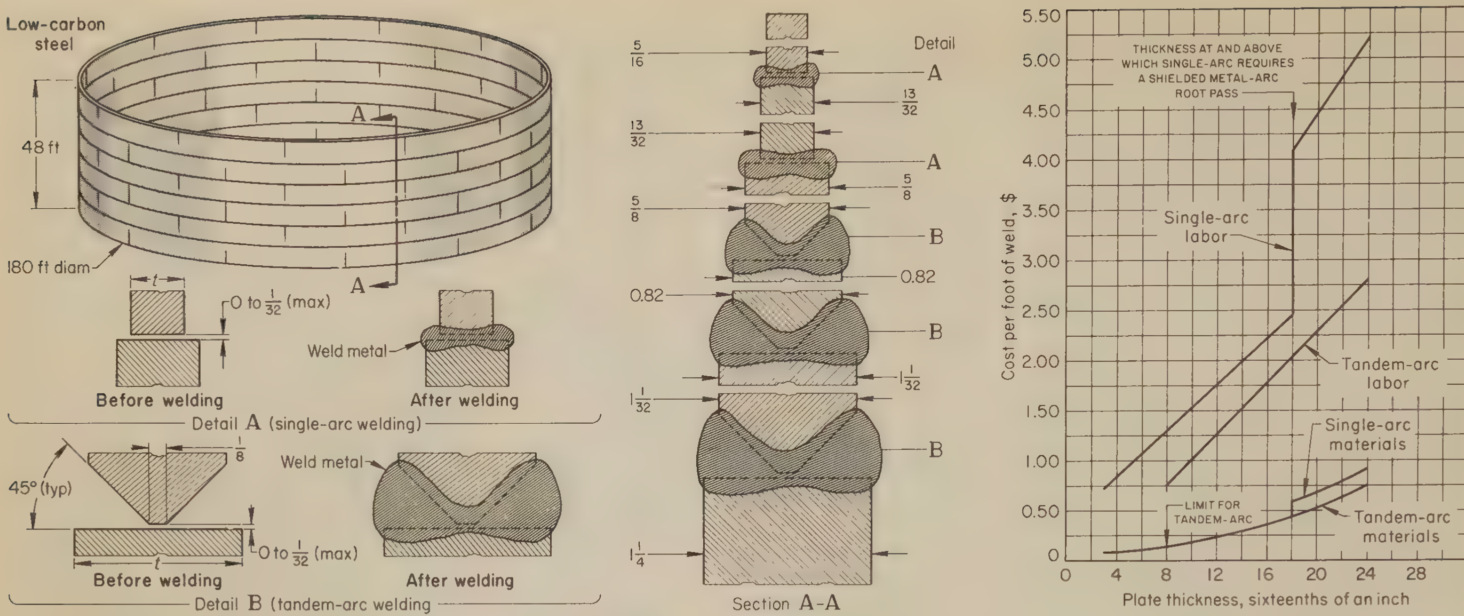
As shown in section A-A in the illustration in Table 9, the spacers overlapped the backing plate, and were welded to it by fillet welds on both sides of the joints. First, the assembly was loaded spacers-down into a positioner tilted at 45°; it was rotated to maintain flat position under the electrode throughout the deposition of each weld. After the welds on the lower sides of the joints had been completed, the assembly was reversed and reloaded into the positioner with the spacers up, and the welds on the upper sides were made.

Submerged-Arc Welding vs Shielded Metal-Arc Welding

Submerged-arc welding is faster than shielded metal-arc welding, because more current can be applied to the submerged arc and because it does not involve the interruptions or changes in speed that are characteristic of shielded metal-arc welding, and that impede steady production. The advantages can be realized in welding both large and small workpieces, as illustrated by the next five examples, in which the productivity of submerged-arc welding is compared with that of shielded metal-arc welding (see also Examples 58, 69 and 75, for similar applications).

Examples 70 to 74. Changes From Shielded Metal-Arc Welding to Submerged-Arc Welding That Increased Production

Example 70 — Collar-Ring Assembly (Fig. 36). The low-carbon steel collar-ring assembly shown in Fig. 36 was produced by fillet welding a roll-formed and welded cylinder to a gas-cut ring. The weld was required to have a good appearance. Originally, because production quantity was low, and it was desirable to keep investment in equip-



The joint design shown in detail A was used for single-arc welding of plates 3/16 to 7/16 in. thick. The joint design shown in detail B was used for tandem-arc welding of plates ½ to 1½ in. thick, and for single-arc welding of plates 7/16 to 1 in. thick. For single-arc welding of plates 1 to 1½ in. thick, the joint design shown in detail B was used, but with the 0-to-1/32-in. root opening increased to 3/16 in.

Fig. 35. Typical field-erected storage tank (upper left) in which horizontal girth joints between shell-course plates were butt welded by single-arc and tandem-arc methods, using the joint designs shown. Graph at right compares costs of the two methods for welding different plate thicknesses in the construction of various sizes of tanks over a ten-year period. (Example 68)

ment to a minimum, shielded metal-arc welding was used. For this welding process, the cylinder and ring were tack welded in four places, the assembly was inclined at 45° on a welding positioner, and the joint was welded in the flat position in three passes as the assembly was rotated. Time to produce one weldment was about 46 min.

When production demand increased, it was decided to replace shielded metal-arc welding by automatic submerged-arc welding. The submerged-arc welding head was modified by installing a switch in the wire-feed motor circuit, which enabled the operator to stop the electrode-wire drive before he turned off the generator, in order to prevent the electrode from sticking in the weld puddle at the end of the welding cycle. The assembly was tack welded and mounted on a fixture that allowed the assembly to be rotated on an axis at 45° from vertical, so that it could be welded in the flat position. Time required to produce one weldment was 16 min — about one-third the time required by the shielded metal-arc process.

Additional processing data for shielded metal-arc and submerged-arc welding of the collar-ring assembly are given in the table that accompanies Fig. 36.

Table 9. Times and Costs for Welding a Gear Carrier by Four Processes (Example 69) (a)

Item	Shielded metal-arc welding: 1/4-in. E7024 electrode	Shielded metal-arc welding: 5/16-in. E6013 electrode	Gas metal-arc welding; 1/16-in. E70S-5 electrode	Flux-cored arc welding; 3/32-in. E70T-2 electrode	Submerged-arc welding; 5/64-in. EM12K electrode

(a) Length of welds, 60 in.; fillet size, ⅜ in.; volume per inch of weld, 0.0825 cu in. Both manual and semiautomatic processes were employed. (b) Settings were based on attaining equal quality of weld. (c) Flux (F71) cost for depositing 1 lb of weld metal was $0.197. (d) 60% argon – 40% carbon dioxide, at 30-35 cfh. (e) Carbon dioxide, at 30-35 cfh.

Example 71 — Steam-Boiler Header (Fig. 37). In welding radial stub tubes to a steam-boiler header (see Fig. 37), production rate using automatic submerged-arc welding was 2¾ times that obtained by shielded metal-arc welding. For both methods, stub tubes were held in place for welding by two tack welds 180° apart, made manually. When the shielded metal-arc process was used, the operator welded 180° on all stub tubes while standing on one side of the header; after removing the slag, he completed the welds from the other side of the header.

Submerged-arc welding was done by a rotating welding head that was supported by an overhead-trolley crane. The welding head was located by a pin that was inserted into the stub tube before welding was begun. The arc was started, and the four beads shown in Fig. 37 were deposited without stopping. Unfused flux was removed continuously by a vacuum hose attached to the welding head, and slag was removed manually by the operator.

Additional welding details are given in the table that accompanies Fig. 37.

Example 72 — Large Piston (Fig. 38). The large hydraulic-jack piston shown in Fig. 38 was assembled by welding three low-carbon steel castings (head, piston body, and seat) at girth joints. When similar smaller pistons with wall thicknesses of 3 to 5 in. had been assembled by shielded metal-arc welding, about one welded joint in eight was found to be defective and had to be reworked.

Because of the experience with the pistons with 3 to 5-in. wall, it was decided to use submerged-arc welding to assemble four large pistons, in which an 8-in. wall was to be joined to a 6⅝-in. wall, using the joint design shown in detail A in Fig. 38. The

(a) A 5/32-in. E7018 electrode was used for shielded metal-arc welding. (b) Supplied by a 300-amp constant-voltage rectifier. Current for shielded metal-arc welding was 195 amp, supplied by a 300-amp constant-current rectifier.

Fig. 37. Steam-boiler header for which production using automatic submerged-arc welding was 2¾ times that for shielded metal-arc welding (Example 71)

magnetic-particle inspection and stress relief. The welded pistons were stress relieved at 1115 F for 7 hr and furnace cooled to 600 F. They were then machined to the size required for application of a bronze overlay (see Example 93, in the article on Gas Metal-Arc Welding, for a description of this surfacing operation). Each welded joint was ultrasonically inspected for a distance of 3 in. on each side of the weld. After inspection, the pistons were hydrostatically tested at 3000 psi. There were no rejections. Additional welding data are given in the table with Fig. 38.

Production time for welding the large piston was 101 hr, which was a considerable improvement over the production time of 212 hr for the smaller pistons assembled by shielded metal-arc welding.

Example 73 — Press-Gear Blank (Fig. 39). The blank for a large press gear was made by welding a forged medium-carbon steel rim to a web and crank arm made of low-carbon steel plate, as shown in Fig. 39. Semiautomatic submerged-arc welding was used (under the conditions given in the table with Fig. 39), because the production lot for any one size was too small to justify the cost of more expensive equipment for automatic welding.

Before welding, the web and crank arm were cut to shape with an oxy-natural gas torch, guided by a template, and the crank arm was beveled (by gas cutting) to make the groove shown in detail B of Fig. 39. The rim, web and crank arm were positioned for welding, and the rim was preheated by torch to 150 F. With the exception of the one groove weld shown in Fig. 39, detail B, the welds were fillet welds.

Depending on the size of the blank, the production time varied from 5 to 8 hr per piece. This was 50 to 70% faster than the rate obtainable using shielded metal-arc welding (with low-hydrogen electrodes).

Example 74 — Double-Wall Bearing Mold (Fig. 40). The joint between the sleeve and the shell in the low-carbon steel bearing mold shown in Fig. 40 was welded originally by the shielded metal-arc process. The sleeve was positioned in the bearing shell by use of fixtures and its flange was tack welded in four places. The fixtures were then removed, and the joint was shielded metal-arc welded. To meet production requirements, six welders were needed.

When automatic submerged-arc welding replaced shielded metal-arc welding, one operator and one machine produced as many molds as had previously been produced by six welders, and operators that had less basic knowledge of welding could be assigned to the job.

For automatic submerged-arc welding, the sleeve was positioned on the shell on a rotating variable-speed turntable; distortion during welding was prevented by an overarm rotating-disk hold-down. The welding operation was conventional. Electrode wire was fed to the welding head from a 25-lb coil mounted in an overhead spool holder, and flux was fed from an overhead hopper. A contoured flux-retaining shoe placed on the outside of the shell, at the top edge, ensured provision of a protective layer of granular flux for the weld puddle. Excess flux was picked up by vacuum and, after screening, was returned to the overhead hopper.

Bearing molds of various sizes were made. When the shell of a mold was ¼ in. thick or less, automatic submerged-arc welding was not practical and gas tungsten-arc welding was used (see Example 129 in the article on Gas Tungsten-Arc Welding).

A comparison of welding conditions for shielded metal-arc and submerged-arc

Fig. 38. Large piston assembled by submerged-arc welding. Production time was 101 hr, but production time for similar smaller pistons assembled by shielded metal-arc welding was 212 hr. (Example 72)

welding of the bearing molds is given in the table that accompanies Fig. 40.

In some applications, the uniformity and freedom from spatter of submerged-arc welds, as compared with shielded metal-arc welds, can reduce or eliminate postweld finishing requirements. In the example that follows, changing to submerged-arc welding eliminated the need for grinding the weld, and gave increased welding speed and freedom from distortion and leaks. In addition, the greater welding speed and weld uniformity enabled the welding of joints having different curvatures.

Example 75. Change From Shielded Metal-Arc to Submerged-Arc Welding of a Hydraulic Cylinder (Fig. 41)

The hydraulic cylinder shown in Fig. 41 was produced by welding two spuds (1117 steel) and an end plug (1020 steel casting) containing a mounting eye to a cylinder (1015 steel). The joints at the spuds had to contain hydraulic pressure without leaking, and the joint at the end plug had to contain hydraulic pressure and also withstand the stresses developed during operation of the cylinder.

Originally, the joints were welded by the shielded metal-arc process, but production was slow and extensive grinding was necessary to remove unwanted weld metal. When standard spuds with flat ends were used, an exceptionally high level of welder skill was needed to produce good assemblies. If the bases of the spuds were machined for good joint fit-up, a better weld was obtained, but because the outside diameters of the cylinders ranged from 3 to 6 in., it was necessary to machine the same radii in the spuds, which then had to be classified and stored according to radius.

With the increased depth of fusion provided by submerged-arc welding, joint fit-up was adequate when spuds with a mean-radius contour on the base were used. Maximum misfits of the mean-radius contour are shown in Fig. 41, section A-A, submerged-arc welding. An improved design was developed for the cylinder-to-plug joint, as shown in Fig. 41, detail B. This provided a flat bottom for the weld groove and positive location of the plug on the cylinder; as a result, welds were more uniform and had fewer flaws and leaks than those made with the original design.

To weld the spuds (section A-A in Fig. 41), the cylinder was positioned on its side, spuds up, and the electrode, mounted on a rotating head, revolved 360° to make the weld. To make the cylinder-to-plug weld, shown in detail B in Fig. 41, the electrode was held stationary and the cylinder assembly was rotated under it. Times for attaching spuds and end plug and finish grinding of welds are given in the table with Fig. 41.

The cost of welding, per assembly (labor plus overhead), was reduced from $1.52 for shielded metal-arc welding to $0.57 for submerged-arc welding. In addition, electrode cost was reduced for submerged-arc welding, by eliminating loss from discard of short electrodes and ends of electrodes, and loss from spoilage by moisture absorption. The uniformity, appearance, and quality of the welds were improved, and there was better, and more even, penetration, and less distortion. Rework after leak testing was reduced from over 5% to less than 1%.

Welding conditions for the two processes are given in the table with Fig. 41.

Submerged-Arc Welding vs Casting

Weldments are sometimes used instead of castings to obtain improved quality or increased production. The example that follows describes an application in which a submerged-arc welded assembly replaced a casting when production requirements for the casting exceeded the capacity of the foundry.

Example 76. Submerged-Arc Welding of Brake Shoes Previously Produced as Castings (Fig. 42)

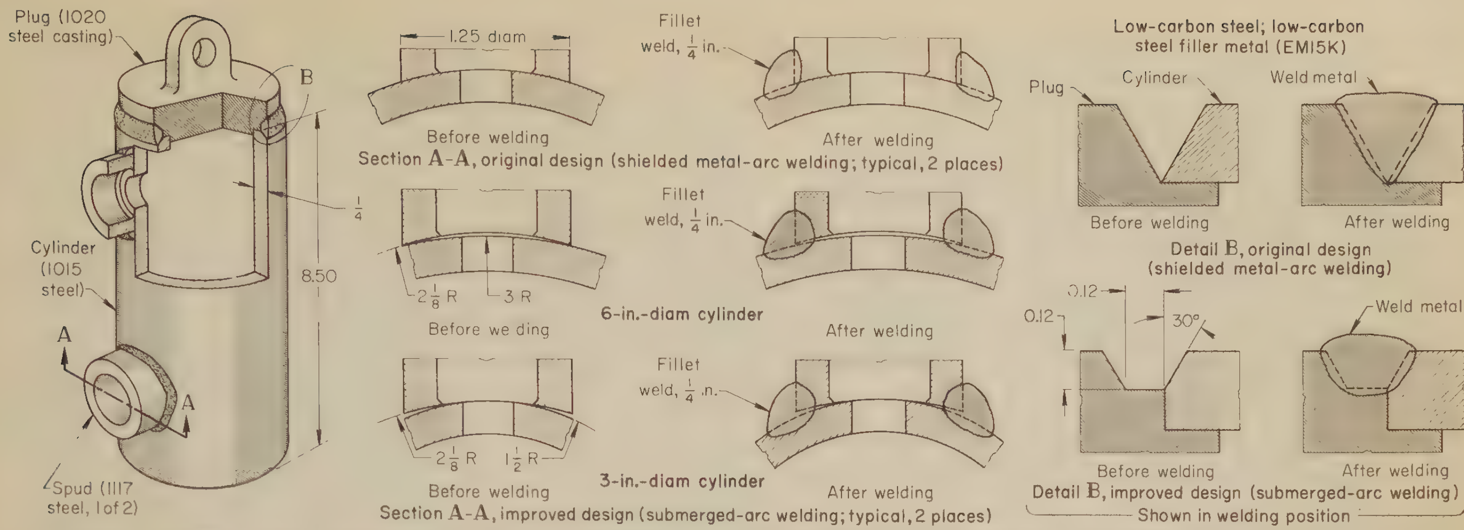
Originally, brake shoes like the one shown in Fig. 42 had been produced as castings, but when production requirements became more than the foundry could handle, they were produced as weldments. The welded assembly consisted of a web of 1035 steel bar and a table of 1010 steel plate. Both bar and plate were press formed to the curvature required, but springback of the formed sections caused difficulty in welding. The difficulty was overcome by assembling the parts in a hydraulic press and tack welding them together. Shoes with braking surfaces 4 to 10 in. wide were made in this way. The shoe shown in Fig. 42 has a braking surface 8 in. wide.

Special submerged-arc welding equipment was built to produce the two 25¼-in.-long ¼-in. fillet welds (one on each side of the web) simultaneously. The electrode holders were mounted on retractable arms and were stationary during the welding cycle. The workpiece was placed on a welding table that was curved to fit the part and that was moved by a rack-and-pinion drive. Welding details are given in the table that accompanies Fig. 42.

The components were degreased and washed before welding. After welding, the assembly was stress relieved at 1300 F for 1 hr to temper the heat-affected zone on the web and to stabilize the structure. After stress relieving, the shoe was sized in a 1700-ton mechanical press.

Welding costs per assembly are given in the table that accompanies Fig. 42.

In the next example, gear blanks that had formerly been cast were fabricated by submerged-arc welding to eliminate defects that had resulted in high rework charges and scrap losses.



Item	Shielded metal-arc	Submerged-arc
Welding Conditions		
Power supply	Rectifier	Rectifier
Electrode wire	7/32-in.-diam E7024	3/32-in.-diam EM15K
Flux	....	F70
Current and voltage, spuds	180 amp, dcsp; 27 v	360 to 375 amp, dcsp; 29 v
Current and voltage, plug	180 amp, dcsp; 27 v	380 amp, dcsp; 27 v

Example 77. Submerged-Arc Welding Large Bull-Gear Blanks Formerly Produced as Castings (Fig. 43)

A large bull gear for a steel-mill drive was machined from the welded blank shown in Fig. 43. Blanks had formerly been sand cast in alloy steel, but too many castings had contained defects, such as cracks, porosity and shrink cavities, that were found only during the final stages of machining, after thousands of dollars of machining time had been expended.

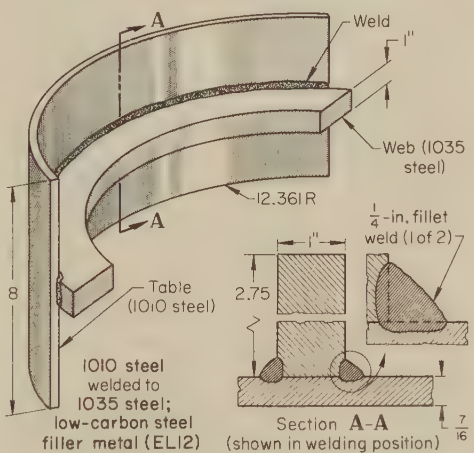
The welded blank was made up of the following components: a 4140 steel rim, which had been produced as a roll forging and rough machined; a hub, which had been gas cut from a 14-in.-thick slab of carbon steel (ASTM A36) and then rough machined on the outside diameter; 16 stiffeners, which had been sheared or gas cut from 1-by-3-in. 1020 steel bar stock, with one edge ground to facilitate fit-up; and a web, which had been gas cut from 2-in.-thick carbon steel (ASTM A36) plate. Double J-grooves were machined into the edges of the web where it was to be joined to the hub and the rim.

The sequence of operations for welding the bull-gear blanks was as follows:

A Tack weld.
1 Fit and tack web to hub.
2 Fit and tack web to rim (rim was preheated before welding).

B Join hub to web by automatic submerged-arc welding (see table with Fig. 43).
3 Preheat hub to 300 F.
4 Weld joint on side A half full (operation 1, detail E, Fig. 43).
5 Turn workpiece over and back gouge to sound metal.
6 Weld joint on side B full (operation 2, detail E, Fig. 43).
7 Turn workpiece over; complete weld on side A (operation 3, detail E, Fig. 43).

C Join rim to web, using shielded metal-arc welding for root passes and submerged-arc welding for filler passes (see table, Fig. 43).
8 Preheat the rim locally to 400 F.
9 Weld root pass on side A by shielded metal-arc welding (operation 4, detail F, Fig. 43).
10 Inspect root pass on side A (magnetic-particle inspection).
11 Weld joint on side A half full (operation 5, detail F, Fig. 43); follow with magnetic-particle inspection.



Conditions for Submerged-Arc Welding(a)

Joint type	T
Weld type	Double fillet
Power supplies (2)	Drooping-voltage, 40-v, 500-amp motor-generators
Welding heads (2)	600-amp, air cooled
Electrode wire	3/32-in.-diam EL12
Flux	F70
Welding position	Horizontal
Current	410 amp, dcrp
Voltage	23 v
Electrode stickout	1½ in.
Welding speed	14 ipm
Flux consumption	0.2 lb per ft
Number of passes	One
Preheat	None
Postheat (stress relief)	1 hr at 1300 F
Production rate	14 assemblies per hour
Production per month	500 assemblies

Welding Costs per Assembly

Electrode wire	$0.075
Flux	0.104
Labor and burden	1.130
Total	$1.309

(a) Welds were made simultaneously, using two welding heads.

Fig. 42. Brake shoe produced as a weldment instead of a casting, when demand exceeded foundry capacity (Example 76)

12 Turn the workpiece over and back gouge to sound metal.
13 Weld root pass on side B by shielded metal-arc welding (operation 6, detail F, Fig. 43).
14 Inspect root pass on side B (magnetic-particle inspection).
15 Weld side B half full (operation 7, detail F, Fig. 43); magnetic-particle inspect.
16 Weld side B full (operation 8, detail F, Fig. 43); magnetic-particle inspect.
17 Turn workpiece over; complete weld on side A (operation 9, detail F, Fig. 43); magnetic-particle inspect.

D Fit, tack and weld stiffeners to web, using flux-cored arc welding (see section B-B, Fig. 43, and the table with Fig. 43).

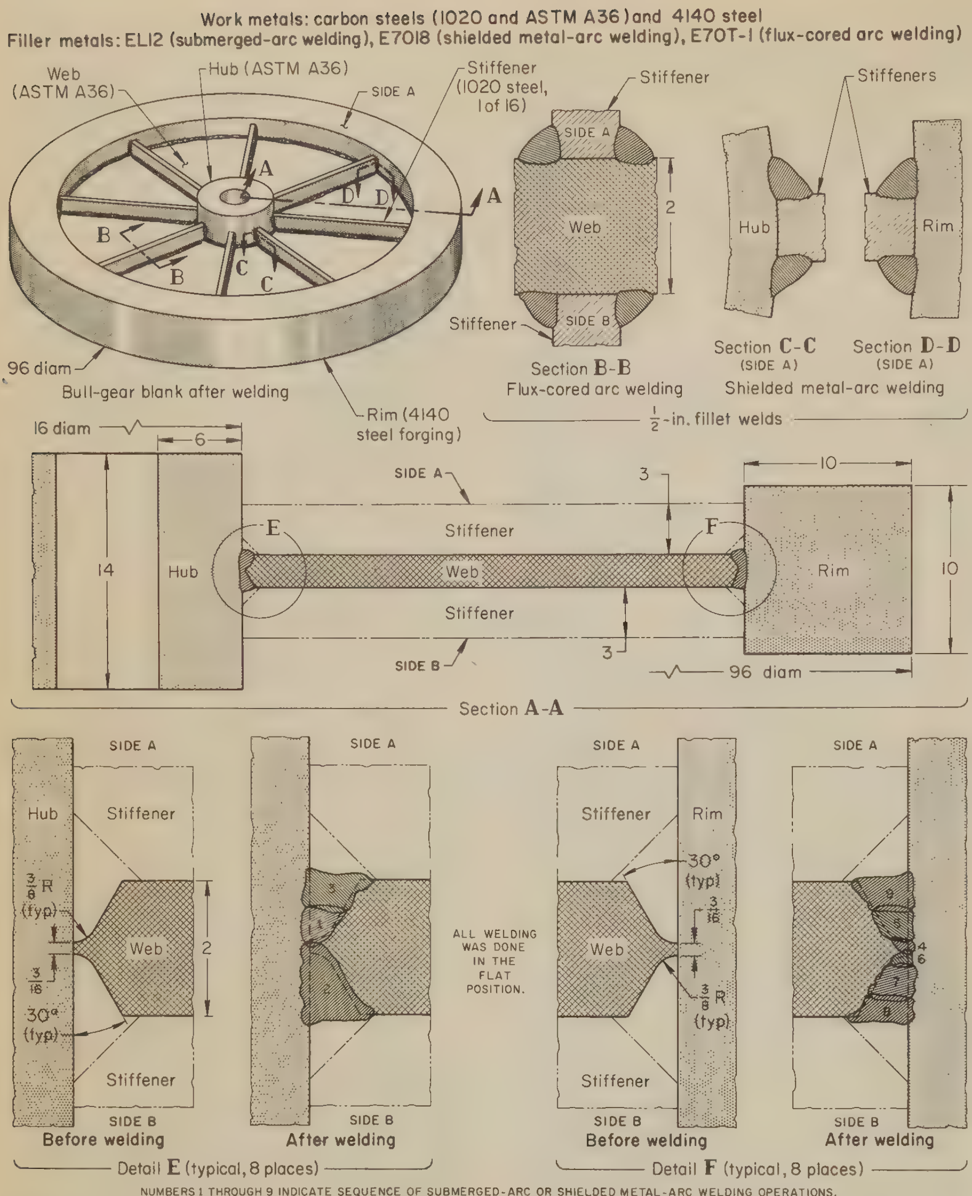
E Fit, tack and weld stiffeners to hub and rim, using shielded metal-arc welding (see sections C-C and D-D, Fig. 43, and the table that accompanies Fig. 43). Rim was preheated locally to 400 F.

The welded blank was covered with asbestos blankets, allowed to cool slowly, and then stress relieved at 1050 F for 6 hr. After cooling, the hub and rim joints were 100% ultrasonically inspected.

Welded gear blanks cost $1000 each to produce, exclusive of material cost. Cast blanks cost the same when only one or two were made from a pattern, but if six or more blanks of the same design were produced, the cost was less. The quality of the welded blanks was higher than that of the cast blanks, and no partly machined gears had to be discarded because of defects.

Safety

Submerged-arc welding presents many hazards that differ from those found in other arc welding processes, and that thus call for different precautions. There are, however, many areas where the same precautions may be required; among these are (a) care in selecting power supplies and auxiliary equipment of adequate capacity to provide the high current at the high duty cycles required by most submerged-arc welding installations; and (b) the installation, maintenance and operation of the equipment in accordance with safety



Welding condition	Submerged-arc(a)	Shielded metal-arc(b)	Flux-cored arc(c)
Power supply	40-v, 1200-amp rectifier(d)	400-amp rectifier	40-v, 500-amp rectifier(d)

Welding speed, ipm	16 to 24	...	12 to 14
Preheat temperature, rim	450 F	400 F	450 F
Preheat temperature, hub	300 F	...	...

NOTE: After welding, the gear blank was stress relieved at 1050 F for 6 hr.

(a) Used for all welding operations in joining the web to the hub (operations 1, 2 and 3; see detail E), and for filler passes in joining the web to the rim (operations 5, 7, 8 and 9; see detail F). (b) Used for root passes in joining the web to the rim (operations 4 and 6; see detail F), and for tacking and welding stiffeners to hub and rim (sections C-C and D-D). (c) Used for joining stiffeners to web (section B-B). (d) Constant-voltage type.

Fig. 43. Bull-gear blank that was welded by automatic submerged-arc, shielded metal-arc, and semiautomatic flux-cored arc welding to improve quality and reduce costs (Example 77)

standards and codes (see the list of references presented at the bottom of column three on this page).

Certain parts of the equipment used in submerged-arc welding that are exposed to contact by the operator are at the welding-voltage potential. Although these parts are never at a higher potential than the open-circuit voltage (which should be kept as low as possible consistent with satisfactory welding, but in any case does not exceed 100 volts), there are circumstances under which low voltage can cause serious injury when the resistance of the electrical path through the body is low. One example is when the skin of a person is wet (as from perspiration) and when the person's body is in contact with the ground or a grounded steel plate. In addition, other injuries can be caused by the uncontrolled physical reaction that results from an electric shock. Every welding operator should know which parts of the equipment are at welding-voltage potential, and electric shock should be avoided by the observance of the following safe practices:

1. When the welding-current switch is closed (on), never touch any of the parts of the equipment that will be at the welding voltage or the open-circuit voltage. Typical of such parts are connectors, electrode wire, contact jaw or nozzle assembly, wire-reel frames and supports, electrode-wire feed rolls and pressure rolls, gear housings, and motor frames.
2. When the machine is not welding, when the operator leaves his work, or when the machine is to be moved, the contactor switch should be open (off). Equipment should be disconnected from power supply when not in use.
3. All control and switch boxes should be effectively grounded, and a separate lead should be used for grounding the frame of the carriage.

Helmets or hand shields are not normally necessary in submerged-arc welding, because the flux completely covers the end of the electrode and the welding zone. To avoid harmful exposure, however, accidental striking of the arc should be prevented by observance of the following precautions:

1. Never use the "inching" button control when the welding-current contactor is closed, because an arc may be created if the electrode wire accidentally touches the work.
2. The electrode wire and contact point on the work should be covered with flux before starting a weld, because the wire might melt off rapidly and create an arc across the open space if it is not completely covered.
3. The path of travel of the welding machine should be clear, because a short circuit and arcing will result if a part of the machine at welding voltage or open-circuit voltage touches a grounded object, such as a steel building-support member.

Safety goggles should be worn to protect the eyes from flying objects; the goggles may be tinted for protection against flashes of light from adjacent arc welding operations.

Handling of granular flux sometimes creates a dust in the atmosphere; and during welding, fumes and gases are produced. These dusts, fumes and gases may be hazardous, and so adequate ventilation should be provided.

APPENDIX

Submerged-Arc Welding Fluxes and Relations Among Process Variables

By CLARENCE E. JACKSON*

SUBMERGED-ARC welding fluxes are produced in three forms: prefused, bonded, and agglomerated.

Prefused Fluxes. In the production of a prefused flux, the ingredients are dry mixed and then are melted in an electric furnace, by heat generated by passing large currents through the molten bath, rather than by the use of open arcs on the surface of the melt. The current can be regulated by changing the depth of immersion of the electrodes in the molten bath. After last-minute additions, the molten flux may either be water shotted or poured on chill plates to await crushing and sizing. Typical melting and pouring temperatures are between 2700 and 3100 F (1500 and 1700 C). With proper chilling, a glassy product is obtained (Fig. 44a). The product is passed over a series of screens that set upper and lower limits on the particle size — for example, through 12 mesh (0.055 in.) and on 200 mesh (0.0029 in.).

Advantages of prefused fluxes are:

1. They have extremely good chemical homogeneity.
2. Fines can be removed without changing the composition of the flux.
3. The product is not hygroscopic, thus simplifying storage problems.
4. Unfused portions can be reused several times without significant change in particle size or flux composition.
5. They are suitable for the highest travel speeds in welding operations.

The primary disadvantage of prefused fluxes is that deoxidizers and ferroalloys cannot be added to them without segregation or prohibitive losses during processing, because of the high temperatures involved.

Bonded Fluxes. In the production of a bonded flux, the raw materials are ground to approximately 100×D; they are dry mixed and then bonded together with an addition of potassium silicate or sodium silicate. The resulting mixture is pelletized, dried at a relatively low temperature, broken up by mechanical means, and screened (Fig. 44b).

Advantages of bonded fluxes are:

1. Because of the low temperatures involved in the bonding process, metallic deoxidizers and ferroalloys can be included in the flux.
2. The density of the flux is lower, which permits use of a thicker layer of flux in the weld zone.
3. The solidified slag is readily detachable after welding.

One disadvantage of a bonded flux is that fines cannot be removed without some alteration in the flux composition. Another disadvantage is that bonded fluxes are likely to absorb moisture.

Agglomerated fluxes are similar to bonded fluxes except that a ceramic binder is used. The high curing temperature of the binder (2550 F, or 1400 C) limits the use of deoxidizers and ferroalloys, as with fused fluxes.

Sizing of a submerged-arc welding flux is important because the size of the particles and the distribution of particle sizes determine the level of welding current at which a flux performs best. For currents greater than 1500 amp, the percentage of small particles must be increased, and that of coarser particles must be decreased. For bonded fluxes that are to be used at lower currents, sizing is less critical; these fluxes generally are available in only one sizing — for example, 12 × 150. The maximum welding current at which bonded fluxes can be used is generally 800 to 1000 amp. Some prefused fluxes of the modified calcium silicate type can be used at more than 2000 amp.

Table 10. Typical Compositions of Manganese Silicate Fluxes for Submerged-Arc Welding

Substance	Prefused flux	Bonded flux
MnO	42.0%	36.5%
MnO_2	...	5.2(a)
SiO_2	45.0	38.0
CaF_2	6.9	3.9
CaO	1.2	0.8
MgO	0.3	2.7
BaO	0.1	0.3
Al_2O_3	2.0	1.1
FeO	1.5	...
Fe_2O_3	...	2.7
TiO_2	0.1	0.1
K_2O	0.4	...
Na_2O	0.4	1.5
PbO	0.1	0.1
FeSi (50%)	...	7.1(b)
Ratio MnO/SiO_2	$\frac{42.0}{45.0} = 0.93$	$\frac{40.7}{45.6} = 0.89$

(a) At welding temperatures, MnO_2 reacts with silicon in ferrosilicon to yield additional MnO equal to 4.2% of the total flux (0.815 × 5.2% = 4.2%). (b) In reaction with MnO_2 at welding temperatures, silicon in ferrosilicon forms additional SiO_2 equal to 7.6% of the total flux (2.14 × 7.1% ÷ 2 = 7.6%).

Composition of Fluxes

In the development of the submerged-arc welding process in the middle 1930's, prefused fluxes consisting of complex silicates were used. The formulations were chiefly alumina silicates of manganese, calcium and magnesium. Manganese silicate compositions corresponding to the typical analyses shown in Table 10 have been used throughout the world. Composition is balanced using the MnO-SiO_2 phase diagram (Fig. 45; Ref 1) as a guide to melting range and structure. With a bonded flux, fusion is accomplished during the welding operation, and the final reaction between molten flux and weld metal is similar to that with prefused flux.

As explained in the footnotes in Table 10, the ferrosilicon in a bonded flux reacts in the weld zone with the manganese dioxide to generate additional manganous oxide and silica. In this manner, a ratio of MnO to SiO_2 that is suitable for submerged-arc welding is maintained in the weld zone.

Fluxes of the types defined in Table 10 are modified with metal silicates to produce more economical compositions that contain less manganese and to provide improved weld properties and welding performance. Other flux formulations of higher basicity (higher contents of CaO and CaF_2) have been suggested for greater impact strength and

Fig. 44. The two principal forms of submerged-arc welding flux — prefused and bonded. Both forms shown are of manganese silicate composition and crushed to 12 × 150 (through 0.055-in. opening and retained on screen with 0.0041-in. opening). Magnification, about 8×.

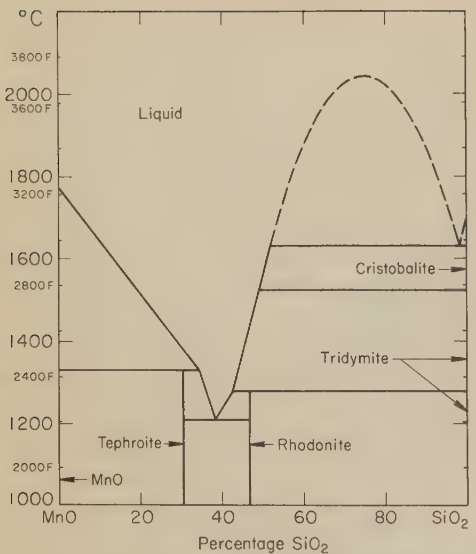

Fig. 45. Phase diagram for the MnO-SiO₂ system (Ref 1)

improved mechanical properties of the weld metal. Arc stability is improved by adding titania. Additions of selected metal oxides provide improved performance in the welding of alloy steels. High-speed performance in welding sheet metal is obtained by adjusting the viscosity – temperature characteristics of the flux. Special fluxes can be formulated to give adequate performance in many applications (Ref 2 and 3).

Comparison With Electrode Coverings. Submerged-arc welding fluxes differ in several important respects from the fluxes used as coverings on electrodes for shielded metal-arc welding. Fluxes for shielded metal-arc welding contain compounds, such as cellulose, that break down in the heat of the arc to provide a shielding gas; compounds with a low work function, such as sodium oxide and potassium oxide, are added to assist in initiating and sustaining the arc; and other substances may be added to facilitate control of penetration, melting rate, and polarity of operation. Submerged-arc welding fluxes do not require most of these additions. The protection afforded by the molten flux and granular burden eliminates the need for generation of shielding gases. The presence of silica and fluoride compounds generally assures satisfactory arc stability, and up to 10% (or more) calcium fluoride can be added to metal silicates to modify arc behavior and increase fluidity of molten flux.

Unlike the coatings used on covered electrodes, whose formulation is complicated by the necessity for the coating to be extrudable and by other production considerations, submerged-arc welding fluxes can be based on simple mineral compounds selected from binary, ternary or quaternary oxide systems. The most common fluxes are based on the $MnO-SiO_2$ system (Fig. 45) or the $CaO-SiO_2$ system, both of which may be combined with alumina, magnesia, zirconia, or titania to form fluxes for particular applications.

Fluxes for covered electrodes and those for submerged-arc welding are classified on a different basis. The most widely used specification for covered electrodes (AWS A5.1-69) classifies electrodes according to the type of material in the flux covering. The AWS specification for electrodes and fluxes for submerged-arc welding (A5.17-69) makes no reference to the chemical nature of the fluxes. Rather, the classification of fluxes is based on mechanical properties of weld deposits made with particular electrodes. In practice, selection of submerged-arc fluxes is based on welding performance, rather than on technical considerations *per se*, and a multiplicity of combinations of electrode and flux are used.

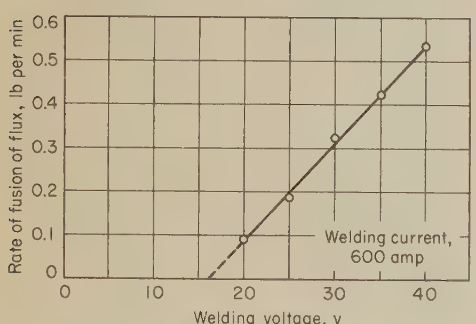

Fig. 46. Effect of increasing voltage on the fusion rate of a calcium silicate submerged-arc welding flux, at a given current

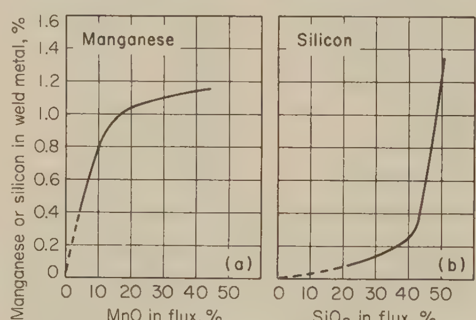

Fig. 47. Effect of MnO and SiO₂ contents of submerged-arc welding fluxes on manganese and silicon contents of weld metal

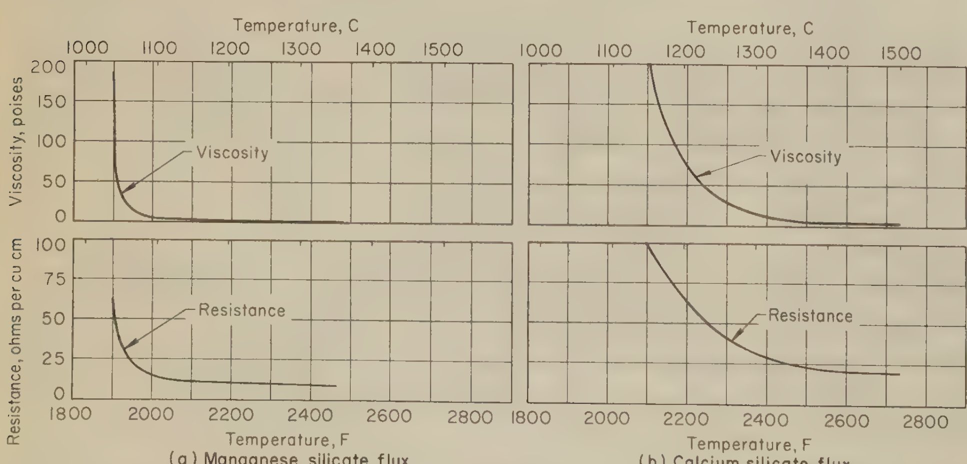

Fig. 48. Effect of temperature on the viscosity and electrical resistance of two types of submerged-arc welding flux

Melting Temperature and Melting Rate of Fluxes

To be effective, a welding flux should have a viscosity at high temperatures that will provide a fluid blanket over the weld metal and protect it from oxidation; it should be brittle at room temperature, to facilitate the removal of slag. Both the melting temperature of the flux and the density of the molten flux must be lower than that of the weld metal so that gases generated between the metal and the flux will permeate the flux. Also, the flux must remain molten until after the weld metal has solidified so that the fluxing action will be complete. Consequently, the upper limit for the melting range of submerged-arc welding fluxes is about 2370 F (1300 C).

The amount of flux fused per minute in submerged-arc welding depends on the welding current and voltage. For a given current, the amount of flux fused per minute increases with voltage, as shown by Fig. 46. In Fig. 46, the zero intercept may be assumed to indicate the anode-plus-cathode potential; this intercept increases with the welding current (see Fig. 52). Under usual practical welding conditions, the weight of flux melted is about the same as the weight of electrode melted.

Effect of Flux Composition on Weld-Metal Composition

During submerged-arc welding, the reactions between liquid weld metal and fused flux are similar to those between molten metal and slag in steelmaking. Removal of impurities from the liquid weld metal and transfer of elements, such as manganese and silicon, between flux and metal follow the technology of molten slag – metal reactions (Ref 4, 5 and 6).

As shown in Fig. 47(a), the manganese content of the weld metal increases rapidly with initial increases of MnO in the flux. Many flux compositions contain about 10% MnO in order to promote the pickup of manganese by the weld metal. A different relationship exists between the SiO_2 content of the flux and the silicon content of the weld metal (Fig. 47b). Normally, a rapid pickup of silicon is not encountered until the SiO_2 content of the flux is approximately 40%. As a result, commercial fluxes are generally restricted to a maximum of about 40% SiO_2, especially fluxes that are to be used for multiple-pass welding.

Some submerged-arc fluxes are formulated to provide control over the transfer of metallic elements. Ferroalloys bonded into the flux can supply alloying elements to the weld metal, to obtain desired properties of the deposit. Oxides added to the flux (Ref 7), such as Cr_2O_3, MoO_3 and NiO, help in the distribution of metallic elements between the molten flux and weld metal. The silicon content of the weld metal is influenced by the Cr_2O_3 content of the flux, the composition of the electrode, the composition of the base metal on which weld metal is being deposited, and the welding technique.

Any factor that affects the time cycle for the flux–metal reaction, or that changes the average temperature of the weld puddle (Ref 6), will affect the distribution of metallic elements between the molten flux and weld metal. Under normal conditions of welding, the speed of travel is probably the most influential factor, although an increase in voltage generally causes additional amounts of metallic elements to transfer to the weld metal.

Viscosity and Conductivity of Fluxes

The viscosity of a welding flux at the weld zone must be high enough to make it impermeable to atmospheric gases and to prevent it from running off the molten weld metal or from flowing in front of the arc, which could lead to molten metal being deposited on top of the flux. On the other hand, during welding, the flux must be fluid enough to permit rapid solution of nonmetallic constituents, such as oxides, and the release of gases from molten metal.

The viscosities of welding fluxes are about 2 to 7 poises at 2550 F (1400 C). The 200-poise viscosity of submerged-arc welding fluxes is typically at about 2000 to 2200 F (1100 to 1200 C).

At room temperature, the granules of submerged-arc welding fluxes are electrical insulators; electrical resistivity decreases with increasing temperature, and the fluxes are highly conductive at the temperatures prevailing in the welding zone.

The effect of temperature on the viscosity and electrical resistance of a typical manganese silicate submerged-arc welding flux is shown in Fig. 48(a). This flux has a narrow melting range, typical of a single compound. The effect of temperature on viscosity and electrical resistance of the more complex calcium silicate flux modified with alumina is shown in Fig. 48(b).

Electrical Relations

The type of flux and the welding technique determine the electrical relations in the welding zone. Typical oscillographic traces of current, voltage and power with three different types of flux are shown in Fig. 49. Figure 49(a), for a magnesia-alumina titanate flux, is typical of electroslag welding, in which there is no arc and the welding zone acts as a simple linear resistance in the circuit. Figure 49(c), for a submerged-arc welding flux of the manganese silicate type, is typical also of other welding processes that operate with a normal arc. Figure 49(b), for a calcium silicate flux, is an intermediate combination of resistance and arc heating.

Oscillographic, spectrographic and radiographic studies indicate the presence of a normal arc in the welding zone during submerged-arc welding. In oscillographic studies, the voltage trace (Fig. 49) is the most significant record in determining electrical relationships.

A radiograph from an x-ray study of the submerged-arc welding process is presented in Fig. 50, which shows the positions of the various components in the welding zone. Spatial relations depend on the welding technique, as well as the type of flux. Correlation of arc length with voltage shows that as voltage increases, the length of the welding arc increases. Under the welding conditions given below Fig. 50, arc length was 0.25 in. at 43 volts. At 35 volts, the arc length was 0.08 in.; the arc length increased to 0.14 in. at 38 volts, and to 0.17 in. at 40 volts.

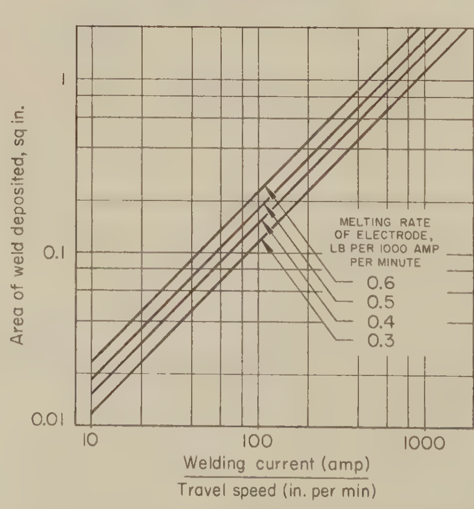

Fig. 59. Effect of ratio of current to speed on the cross-sectional area of weld metal deposited for four rates of electrode melting

Welding Conditions

In submerged-arc welding, the current density in the electrode wire (Fig. 51) is several times greater than in shielded metal-arc welding, and the melting rate of the electrode wire and the speed of welding are increased.

Current-voltage relations typical of industrial applications are shown in Fig. 52. These data suggest that there is a range of about 10 volts for each setting of welding current; the lower voltages give a narrow weld bead, and the higher voltages give a wide bead. Outside the 10-volt working range, soundness of the weld metal deteriorates. Figure 52 shows that as the welding current increases, the working voltage increases. The sum of the anode and cathode potentials increases with increasing current. The amount of submerged-arc welding flux that is fused approaches zero as the voltage decreases toward the anode-plus-cathode potential for each level of current. The decrease in anode-plus-cathode potential is not linear, indicating that there is electrolytic conduction.

The maximum speed of welding, beyond which erratic behavior and undercutting occur, also is controlled by the welding current. In Fig. 53, which is a survey of published data, any combination of current and speed of travel to the right of the diagonal line leads to undercutting.

Techniques have been developed for welding 14-gage (0.078-in.-thick) steel at speeds greater than 100 in. per minute. Single-pass welds in plate 1 in. thick can be made with 1500 amp at 10 in. per minute. Multiple-pass techniques have been developed for joints in heavy plate and joints requiring optimum mechanical properties. Two, three or more electrodes can be fed into a single weld zone in some applications.

Melting Rate

The melting rate of the electrode wire is sometimes expressed in inches or feet per minute, but a more useful unit is pounds per minute or pounds per hour. For comparing applications, the melting rate is sometimes expressed as pounds per minute per ampere, or as pounds per thousand amperes per minute. In submerged-arc welding, the electrode melting rate increases as the current increases, as shown in Fig. 54.

Electrode Stickout. The melting rate of a welding electrode is the sum of the rate due to arc melting and that due to resistance (I^2R) heating in the

Table 11. Data for Use in Calculating I^2R Heating and Electrode Melting Rate

length of electrode that extends beyond the contact tube (Ref 8). Electrode stickout is usually taken as the distance from the surface of the base metal to the contact-tube tip, because the distance from the contact-tube tip to the end of the electrode can vary during welding if large globules of weld metal are transferring. Depending on the arc length, the end of the electrode can be above, at, or below the upper surface of the base metal.

The melting rate due to I^2R heating in the electrode stickout is an exponential function of stickout length, current and electrode diameter. The increase in melting rate due to I^2R heating has been shown to depend on current density and electrode stickout (Fig. 55). Both the current density and the electrode stickout depend on the electrode diameter. Typical current densities for various electrode diameters are given in Fig. 51; the melting rate for a practical electrode stickout of eight times the electrode diameter is shown in Fig. 56. Table 11 presents data useful in calculation of electrode melting rate (see also formula in Table 12).

Penetration

The penetration of a weld deposited in a groove or on the surface of the base metal is usually defined as the distance below the original surface to which metal has been melted. Welding current is the most significant variable in determining penetration; travel speed and voltage are less important. Figure 57 shows the combined effect of current, voltage, and travel speed on penetration for a series of experiments with submerged-arc welding. A similar linear relationship has been shown for other arc welding processes, including shielded metal-arc and gas metal-arc welding. The slope of the diagonal line varies with the process, being the greatest for processes that use helium or carbon dioxide shielding gas. For convenience, the empirical equation for arc penetration is also given in Table 12, together with other useful empirical formulas for submerged-arc welding.

Table 12. Empirical Formulas for Submerged-Arc Welding

Electrode Melting Rate, Lb per Min

$$MR = \frac{I}{1000}\left[0.35 + d^2 + 2.08 \times 10^{-7}\left(\frac{IL}{d^2}\right)^{1.22}\right]$$

Area of Weld Bead, Sq In.

$$\text{Log } A = 0.903 \log\left(\frac{I^{1.716}}{S}\right) - 3.95$$

$$A = \frac{I^{1.55}}{10^{3.95}\ S^{0.903}}$$

Weld Dilution, %

$$\%\ \text{dilution} = \left(\frac{A - \dfrac{MR}{0.283S}}{A}\right)100$$

$$= 100 - \frac{353MR}{AS}$$

Arc Penetration, In.

$$P = K\ \sqrt[3]{I^4/SE^2}$$

MR = electrode melting rate, lb per minute
I = welding current, amp
L = electrode stickout, in.
d = electrode diameter, in.
A = area of weld-bead section, sq in.
P = arc penetration, in.
K = process penetration constant (0.0012 for calcium silicate flux)
E = welding voltage
S = speed of travel, in. per minute

In calculations of thermal input and cooling rates, the heat content of the molten weld metal is important. It is proportional to the cross-sectional area of the weld bead, which represents the amount of metal (see inset in Fig. 58) that has been heated to the molten state. For any given welding technique, the efficiency of the process is inherent in the measurement of this area. Weld-bead area increases with increasing welding current and decreases with increasing travel speed. It is affected only slightly by normal changes in arc voltage. The alignment chart of Fig. 58 is based on data for submerged-arc welding, which generally provides for 100% transfer of filler metal.

Dilution

The ratio of base metal melted to weld metal deposited is important in controlling the mechanical properties of the weld metal. Dilution of the weld metal by the base metal can be expressed as the percentage of the bead volume (cross-sectional area times bead length) that is base metal.

Dilution of weld metal by base metal increases with an increasing ratio of current to speed of travel. An increase in voltage may increase the amount of dilution, as a consequence of the slightly lower electrode melting rate that results with the higher-voltage condition.

Dilution for a weld bead can be estimated if the melting rate of the electrode and the process variables are known, by the use of the charts in Fig. 58 and 59 and the formulas in Table 12. Weld-metal cracking usually increases as the amount of dilution by the base metal increases.

Gas Metal-Arc Welding (MIG Welding)

*By the ASM Committee on Gas Metal-Arc Welding and Flux-Cored Arc Welding of Steel**

GAS METAL-ARC WELDING (often called MIG welding) is an arc welding process in which the heat for welding is generated by an arc between a consumable electrode and the work metal. The electrode, a bare solid wire that is continuously fed to the weld area, becomes the filler metal as it is consumed. The electrode, weld puddle, arc and adjacent areas of the base metal are protected from atmospheric contamination by a gaseous shield provided by a stream of gas, or mixture of gases, fed through the electrode holder. The gas shield must provide full protection, because even a small amount of entrained air can contaminate the weld deposit.

Gas metal-arc welding overcomes the restriction of using an electrode of limited length, as in shielded metal-arc welding, and overcomes the inability to weld in various positions, which is a limitation of submerged-arc welding. A closely related arc welding process that utilizes tubular electrode wires containing flux is described in the article that begins on page 24.

Advantages. The principal advantage of gas metal-arc welding over shielded metal-arc welding (usually its closest competitor) is greater speed, which is mainly accounted for by: (*a*) continuous feed of filler metal, so that the welder need not stop to replace used-up electrodes, as is required in shielded metal-arc welding; (*b*) absence of slag, which must be removed after each pass when welding with flux-covered electrodes; and (*c*) use of a smaller-diameter electrode wire than for shielded metal-arc welding for a given welding current — thus, current density is higher and weld-metal deposition rate is greater.

Use of the gas metal-arc process results in weld metal with a low hydrogen content, which can be important, especially in welding hardenable steels. The potential for deep penetration with the gas metal-arc process can sometimes allow the use of smaller fillet welds, and produce more consistent root penetration, than with shielded metal-arc welding. Gas metal-arc welding is also better adapted than shielded metal-arc welding for joining of thin sheets, although the gas tungsten-arc process is often used for welding thin sheets when no filler metal is required.

The minimum work-metal thickness usually considered practical for shielded metal-arc welding is about 1/16 in. However, the use of small-diameter wire as filler metal with the gas metal-arc process permits welding of metals considerably thinner than 1/16 in.; the minimum thickness depends greatly on welding position and skill of the welder. With careful control of current characteristics, metal as thin as 0.020 in. can be successfully gas metal-arc welded.

It is often possible to produce welds of higher quality by gas metal-arc than by shielded metal-arc welding, because in the gas metal-arc process there is no slag to contend with. Slag is often the direct cause of weld defects, and it is sometimes an indirect cause, because it can obscure the welder's view of the weld puddle and the arc.

Disadvantages or limitations of gas metal-arc welding as compared with the shielded metal-arc process include:

1. Equipment for gas metal-arc welding is more complex, and consequently is more costly and less portable.
2. In gas metal-arc welding, the electrode holder must be close to the work, and consequently gas metal-arc welding is less adaptable than the shielded metal-arc process for welding in difficult-to-reach areas.
3. In hardenable steels, gas metal-arc welded joints can be more susceptible to weld-metal cracking, because there is no slag cover to reduce the rate of cooling.
4. Gas metal-arc welding requires positive protection from strong drafts, which blow the stream of shielding gas away from the weld; for this reason, the gas metal-arc process may be less practical than the shielded metal-arc process for welding outdoors.

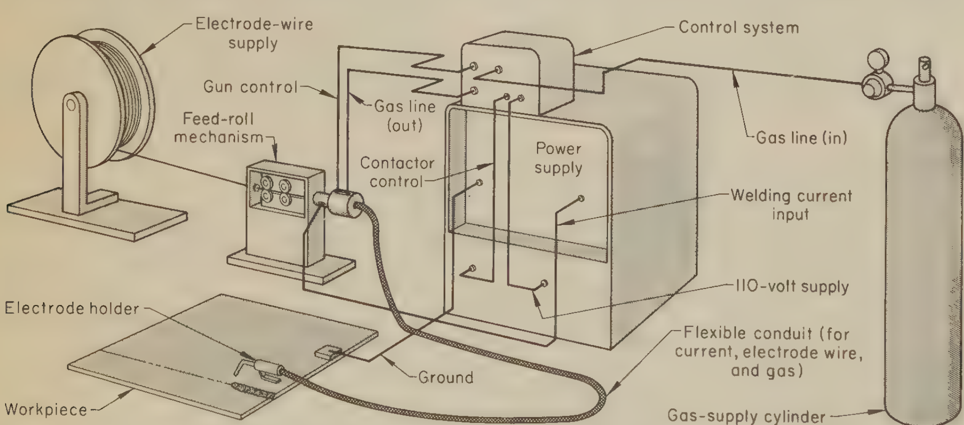

Fig. 1. Schematic of essential requirements for gas metal-arc welding, employing a constant-speed push-type wire-feed system and a constant-voltage power supply

Applicability

In all gas metal-arc welding, the electrode wire is fed automatically to the electrode holder at a controlled rate, even though the electrode holder may be manipulated by the welder. This process cannot be considered manual; it is semiautomatic, machine, or automatic.

In semiautomatic welding, the equipment controls only the electrode-wire feed rate. Manipulation of the electrode is manually controlled. Starting and stopping of the wire feed, of shielding-gas flow, and of current are also manually controlled.

In machine welding, the equipment and setup are fully mechanized but one or more controls require observation and adjustment by a welding operator. The operator starts the operation and performs necessary controlling functions until welding is completed.

In automatic welding, the equipment and setup are fully mechanized and automatically controlled to a degree that requires little or no observation or adjustment by an operator. The operator starts the operation, and the

controls take over until welding is completed. Workpieces may or may not be loaded and unloaded automatically.

Metals Welded. The gas metal-arc process was first applied to the welding of magnesium and aluminum alloys and stainless steels, because it was often the only method by which satisfactory welds could be produced at an economical rate.

The nature of the process permits its use for welding of most metals and alloys. However, some metals are more adaptable than others, and there are a few that cannot be welded. Those metals most easily welded by the gas metal-arc process include carbon and low-alloy steels, stainless steels, heat-resisting alloys, aluminum and aluminum alloys of the 3000, 5000 and 6000 series, copper and copper alloys other than the high-zinc alloys, and magnesium alloys.

Metals that can be welded by the gas metal-arc process but that may require special procedures are high-strength steels, aluminum alloys of the 2000 and 7000 series, copper alloys that contain high percentages of zinc (such as manganese bronze), cast iron, austenitic manganese steel, titanium and titanium alloys, and refractory metals. Gas metal-arc welding of these metals may require preheating or postheating of the base metal, use of special filler metals, closer-than-normal control of shielding gas, and use of backing gas.

Metals that have a low melting temperature or a low boiling temperature are not amenable to gas metal-arc welding (or any other arc welding process). Lead, tin and zinc are typical of this group. Zinc, for instance, boils at 1663 F, which is far below the arc temperature, and it produces toxic fumes, as does lead.

High-melting-point metals that are coated with a low-melting-point metal (such as lead, tin, cadmium or zinc) are difficult or impossible to weld satisfactorily, because the welding heat causes fuming of the coating or alloying with the base metal, or both — the result of which is welds with poor mechanical properties. When coated metals are to be welded, the coating should first be thoroughly removed from the joint areas. Postweld repair of the coating over the weld area is essential if the protection afforded by the coating is required at this location.

Although aluminum and its alloys are readily welded by the gas metal-arc process, aluminum-coated steel may cause difficulty in welding, because aluminum vaporizes at a low temperature on aluminum-coated steel.

For further information and examples of practice that deal with gas metal-arc welding of metals other than low-carbon steel, see Table 10 on page 112, and the articles in this volume on welding of specific metals.

Work-Metal Thickness. Gas metal-arc welding can be used successfully for a wide range of work-metal thicknesses (see "Thin Sections", p 93; "Intermediate and Thick Sections", p 94; and "Sections of Unequal Thickness", p 95). Sheet as thin as 0.020 in. can be gas metal-arc welded. Although there is no established maximum thickness, for production welding of steel sections thicker than ½ in., another arc welding process (such as submerged-arc welding or flux-cored arc welding) or electroslag welding often costs less than gas metal-arc welding and leaves a more desirable appearance (see the articles on Flux-Cored Arc Welding, page 24, Submerged-Arc Welding, page 46, and Electroslag Welding, page 373).

The limitation on work-metal thickness is sometimes determined by fillet size; a ¼-in. fillet weld is the maximum practical size for most applications.

Welding Position. Gas metal-arc welding is generally considered to be the most versatile of all arc welding processes in terms of the welding positions in which it can be used. As in other welding processes, welding is most efficient in the flat and horizontal positions, but gas metal-arc welding is at least equal to shielded metal-arc welding in the other positions.

Principles of Operation

Operating principles of gas metal-arc welding differ considerably from those of the shielded metal-arc process. The covering on the electrodes used in shielded metal-arc welding contains deoxidizers, and sometimes alloying elements, that contribute favorably to the soundness and mechanical properties of the weld metal. In addition to providing a slag blanket that protects the weld puddle, the covering oxidizes and decomposes to produce a shielding gas that displaces the oxygen-rich atmosphere from the region of the arc stream (see Fig. 1 in the article on Shielded Metal-Arc Welding). The covering also controls arc characteristics, primarily by producing an ionizing gas that ensures arc stabilization, and it can affect metal transfer in the various welding positions (flat, horizontal, vertical, or overhead).

In gas metal-arc welding, the objectives are similar, but they are achieved by a different approach. First, the desired arc characteristics are achieved by control of voltage-amperage relationships, shielding gas, and reactance in the power circuits. Second, metallic elements that have higher affinity for oxygen than has iron are added to the electrode wire to serve as deoxidizers and to provide the weld deposit with the desired physical and mechanical properties and weld soundness. Finally, the oxygen of the atmosphere is displaced by flooding the arc-stream area with a shielding gas from a nozzle that is close to, or coaxial with, the electrode wire where it emerges from the electrode holder.

Essential requirements for gas metal-arc welding are: (*a*) a power supply that provides sufficient voltage to push the current across the gap to make the arc, and sufficient current to melt the electrode to make the weld deposit; (*b*) a wire feeder that continuously advances the electrode as it melts; (*c*) a smooth flow of shielding gas; and (*d*) an electrode holder that carries the current, electrode wire, and shielding gas.

These major essentials are illustrated schematically in Fig. 1. Here the wire-feed system is of the constant-speed, push type, by means of which a specific rate of wire feed can be obtained. The power supply is a constant-voltage type, which will maintain any desired voltage output within its capability, regardless of current flow. Under these conditions, only enough current will flow to melt the electrode wire at a rate equal to that of the wire feed.

Arc Characteristics

The types of arc obtainable in gas metal-arc welding are identified by their mode of metal transfer. These modes of transfer are commonly referred to as spray, globular, short circuiting, and pulsed, although the pulsed arc is a form of spray arc.

Spray-Arc Mode. In a spray arc, the metal is transferred from the end of the electrode wire to the puddle in an axial stream of fine droplets. This condition is illustrated in Fig. 2(a). These small droplets emanate from the tapered end of the electrode; one droplet follows

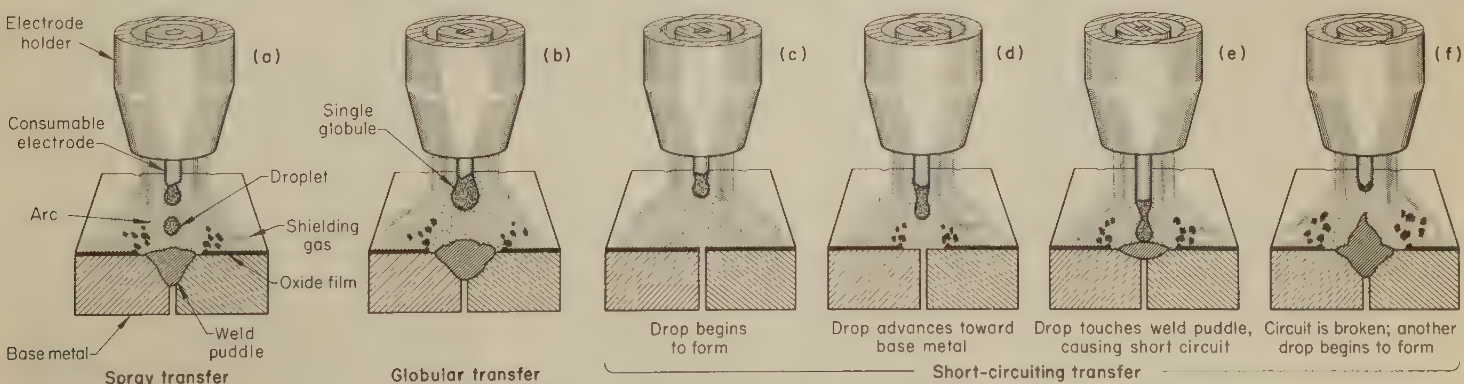

Fig. 2. Modes of metal transfer in gas metal-arc welding: (a) *spray transfer;* (b) *globular transfer;* (c) to (f) *steps in short-circuiting transfer*

another, but they are not connected. The sizes of the droplets may vary, but in a spray arc the maximum diameter is less than that of the electrode wire.

The spray arc occurs at high current density, and generally with argon or an argon-rich shielding gas. A true spray arc cannot be obtained with a shielding gas composed entirely of carbon dioxide.

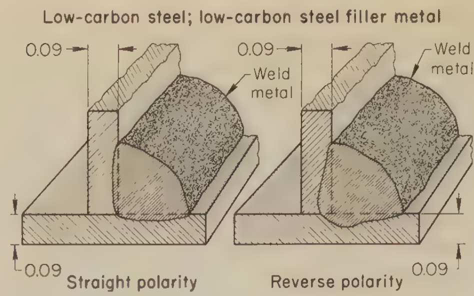
The spray-arc mode of transfer gives high heat input, maximum penetration, and a high deposition rate. In welding steel, it is generally limited to welding in the flat position and the horizontal fillet position.

Globular transfer occurs at lower current densities and is characterized by the formation of a relatively large drop of molten metal at the end of the tapered electrode wire (Fig. 2b). The drop forms at the end of the electrode wire until the force of gravity overcomes the surface tension of the molten drop, at which time the drop falls into the weld puddle. Globular transfer occurs with all types of shielding gases, but it cannot be used for out-of-position welding. If overhead welding were attempted using globular transfer, the molten electrode metal would fall downward into the electrode holder nozzle.

The short-circuiting mode of transfer is used in many applications of gas metal-arc welding. It is especially well adapted to welding of thin sections, because heat input is low; it is less often used for welding thick sections. This mode of transfer permits welding in any position and occurs with carbon dioxide, argon – carbon dioxide mixtures, and helium-base shielding gases.

Steps that occur with the short-circuiting mode of transfer are shown in Fig. 2. At the start of the short-circuiting-arc cycle, the end of the electrode wire melts into a small globule of liquid metal (Fig. 2c). Next, the molten metal moves toward the workpiece, taking the form shown in Fig. 2(d). Then, the molten metal makes contact with the workpiece, creating a short circuit. At this stage of the cycle, metal transfer is by gravity and surface tension and the arc is extinguished (Fig. 2e). Finally, the molten metal bridge is broken by pinch force, the squeezing action common to current carriers, the amount and suddenness of pinch being controlled by the power supply. At this stage, the electrical contact is broken and the arc is re-ignited (Fig. 2f). With the arc renewed, the cycle begins again. Frequency of arc extinction and re-ignition varies from 20 to 200 times per second, in accordance with preset electrical conditions.

Figure 2(c) to (f) shows the low-current short-circuiting arc. As the current density is increased, using carbon dioxide shielding gas, the molten metal transfer moves from a high-frequency rate of short circuits to a lower rate of short circuits, detaching much larger molten metal drops. At the higher current densities and normal arc voltages, metal transfer is much more violent. Short-circuiting transfer is usually associated with lower current density and a rather exact arc-voltage setting. If, for example, a 0.035-in.-diam steel electrode wire is fed at a rate requiring



Joint type	T
Weld type	Fillet
Welding position	Horizontal
Electrode wire	1/32-in.-diam low-carbon steel
Shielding gas	Carbon dioxide
Current	120 amp, dc
Voltage	19 v
Melting rate	280 ipm

Fig. 3. Depths of penetration obtained in gas metal-arc welding with straight-polarity and reverse-polarity direct current under otherwise identical conditions

120 amp of current, and carbon dioxide shielding gas is used, an excellent short-circuiting mode of transfer requires arc voltage of about 19 to 20 volts. If the arc voltage is increased to 25 to 26 volts, the short-circuiting mode of transfer reverts to a mild type of globular transfer. Depth of penetration decreases as current density decreases, except for a minor effect on penetration from arc voltage. A decrease in arc voltage can result in a slight increase in penetration, because the decreased arc voltage with carbon dioxide shielding is accompanied by a shorter arc length.

Pulsed-arc transfer is a spray-type transfer that occurs in pulses at regularly spaced intervals rather than at random intervals. In the time interval between pulses, the welding current is reduced and no metal transfer occurs.

The pulsing action is obtained by combining the outputs of two power supplies working at two current levels. One acts as a background current to preheat and precondition the advancing continuously fed electrode; the other power supply furnishes a peak current for forcing the drop from the electrode to the joint being welded. The peaking current is a half-wave direct current; because it is tied into line frequency, drops will be transferred from the electrode to the joint 60 or 120 times per second.

Electrode-wire diameters of 0.045 to 1/16 in. are most commonly used. The pulsed-arc mode is capable of welding thinner sections than are practical with conventional spray transfer, because heat input is less. Also, because of the low heat input, distortion is less. The pulsed-arc mode of transfer is suited to all welding positions.

Power Supplies

Alternating current is seldom used in gas metal-arc welding. Direct current with reverse polarity is used for most applications, although straight-polarity direct current is sometimes used when penetration must be minimum. Figure 3 compares the depths of penetration obtained in welding with straight and reverse polarity under otherwise identical conditions.

Many types of direct-current power supplies are available, including the rotating types (generators driven by electric motors or internal-combustion engines) and the static types (selenium or silicon rectifiers). Either of these types is available with constant current (drooping voltage) or constant voltage (constant potential).

Constant-current power supplies can be used for shielded metal-arc welding as well as for gas metal-arc welding. A typical volt-ampere curve for a constant-current power supply is illustrated in Fig. 4(a). The high open-circuit voltage (up to 80 volts, and usually about twice the rated voltage) is provided mainly to ensure reliable arc initiation when covered electrodes are used, but it is not required for gas metal-arc welding.

In gas metal-arc welding, when the electrode wire touches the grounded workpiece, the arc length, and therefore the arc voltage, is zero. Thus, short-circuit current flows, melting the wire and initiating the arc instantaneously. As the resistance of the arc increases and the short-circuit current decreases, the voltage rises to the operating range, to a value dictated by the machine setting and its volt-ampere curve. Two characteristics of a constant-current power supply are:

1. Limited short-circuit current capacity — usually 1½ to 2½ times the rated current
2. Ability to maintain a relatively constant current output throughout the normal variations in arc length resulting from manual manipulation of the electrode holder.

The first characteristic serves to protect the machine and the operator.

The use of constant-current power supplies for gas metal-arc welding is rapidly decreasing. They are still used in some plants where both gas metal-arc and shielded metal-arc welding are done, because of their suitability, with limitations, for both processes.

Constant-voltage power supplies, of either the motor-generator type or the transformer-rectifier type, are generally preferred and widely used for gas metal-arc welding. With this type of power supply, the voltage remains nearly constant regardless of the current drawn.

Figure 4(b) shows a typical volt-ampere curve that characterizes the constant-voltage type of power supply. Open-circuit voltage is usually in the range of 40 to 50 volts, with rated voltage at about 35 volts. Because of the relatively small amount of slope in the volt-ampere curve, surging variations in the current will occur when welding is done at low current density. For this reason, a current-stabilizing system may be required for gas metal-arc welding.

Most constant-voltage power supplies are equipped with some means of changing the slope of the volt-ampere curve. This slope control has the effect of limiting the amount of short-circuit current that a power supply can deliver.

A set of theoretical curves that illustrate slope control is shown in Fig. 4(c). In this instance, the voltage is established at 25 volts. Without slope control, there is essentially no slope (uppermost

curve in Fig. 4c). Slope may be added until an extremely steep slope is obtained (lowest curve in Fig. 4c).

Power supplies are available with fixed, stepped, or stepless slope controls. Slope controls are also known as arc stabilizers. They are not always necessary for high current density or for spray-type arcs. For best results, however, they are required when welding is done with small-diameter (0.020 to 0.045 in.) electrode wire at relatively low current and voltage.

For rectifiers, the most efficient way of achieving slope control is by use of a variable reactor in the primary supply circuit (alternating-current side). Another, but less efficient, method is the use of a resistor on the direct-current side. Slope control on a motor-generator power supply is accomplished by the type and position of field and armature windings and the method by which these windings are connected. For instance, on a shunt-wound motor, slope control is obtained by varying the excitation of the shunt. Motor-generators are not designed for ease of slope control, as are rectifier-type power supplies.

Variable inductance may also be an added feature of constant-voltage power supplies. The addition of variable inductance in the output circuit has proved beneficial in developing a stable dc low-current short-circuiting welding arc using 0.030 to 0.045-in.-diam electrode wire and carbon dioxide shielding. Slope control limits the maximum short-circuit magnitude, and inductance control regulates the rate of rise or decrease of welding current. When inductance is insufficient, as the molten end of the electrode wire dips into the weld puddle and short circuiting occurs, the welding current rises rapidly, which causes expulsion of the wire free of the puddle, resulting in weld spatter. Too much inductance results in an insufficient rate of current rise and will cause the electrode wire to stub, almost as if the voltage were set too low.

Control of inductance is obtained by use of a variable reactor in the secondary circuit (direct-current side) of the power supply.

Selection of Power Supply

Power supplies for gas metal-arc welding differ in at least four major respects, each of which must be considered when choosing a power supply for a given application:

1 General type; that is, motor or engine driven, or transformer-rectifier
2 Size (current capacity)
3 Current characteristics (constant current or constant voltage)
4 Degree of complexity, and thus of versatility for a variety of conditions.

The choice between a motor-generator and a transformer-rectifier will be influenced by the supply of current already available in the locations where welding is to be done. If this is ample, transformer-rectifiers are usually the better choice, because they are less expensive and easier to maintain than motor-generators. They are the most popular choice for production welding.

Size, in terms of output current, will be governed by the maximum current that will be needed, or can be foreseen, for a specific installation. This is usually the most important requirement.

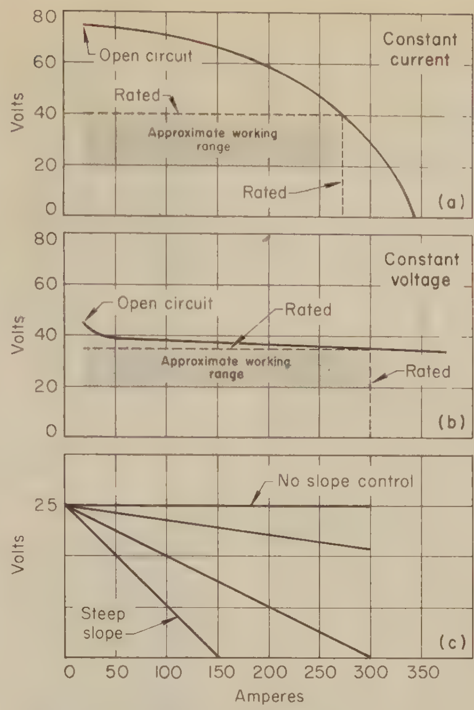


Fig. 4. (a) and (b) *Typical volt-ampere curves for constant-current and constant-voltage power supplies.* (c) *Effect of varying slope control on volt-ampere curves.*

Although many welding machines with constant-current power supplies are still in use, new machines purchased for use in gas metal-arc welding (or flux-cored arc welding) are usually of the constant-voltage type, because their current characteristics are better suited to the process.

The degree of complexity, principally in terms of the ranges and types of adjustment of the power output, is an important factor in selection. Rectifier-type constant-voltage power supplies of the same capacity can vary in cost by a factor of two or three, depending on how they are equipped. The simplest type has a fixed volt-ampere slope and a fixed amount of inductance in the circuit. If such a machine is designed for a particular application (base-metal thickness, fit-up, fillet size, or other specific operating condition), it will do as good a job as a more complex machine, but if welding conditions are changed, results with this machine might be unacceptable.

The most complex machines are those equipped with stepless slope control, stepless control of inductance, and voltage control over a wide range. Such machines can be used with almost any set of conditions that may be encountered in gas metal-arc welding. For example, with a machine of this type, an experienced welder can weld two ¼-in.-thick plates, using high current density and a spray-type arc; a nearly flat volt-ampere slope and a large amount of inductance would be used. In a few minutes, the slope, inductance, voltage, and current (current is determined by the rate of wire feed) could be changed to enable the machine to be used with a short-circuiting arc for welding thin sheet.

If a power supply is to be used mainly for high production, under a fixed set of welding conditions, a simple, comparatively inexpensive machine is the best choice. If a power supply is to be used under various welding conditions, a more versatile (and more costly) machine will be required.

Electrode Holders

Electrode holders for gas metal-arc welding are frequently called guns, because some of them resemble a pistol in outward appearance, or torches, as their counterparts used for gas tungsten-arc welding are often called.

Electrode holders for use with the gas metal-arc process are considerably more complex than are those used for shielded metal-arc welding. First, it is required that the electrode wire should move through the holder at a pre-established rate; second, the holder must be designed to transmit current to the electrode wire and to carry the shielding gas. The method of cooling the holder (air or water), and the location of controls for feeding the wire and the shielding gas, can add to the complexity of electrode holders.

Electrode holders for manual manipulation (semiautomatic welding) may be either air cooled or water cooled. The essentials of a typical air-cooled holder are shown in Fig. 5(a). Important components of this conventional gun-type holder are: (*a*) the nozzle (ordinarily made of copper or beryllium copper), which usually has an inside diameter of ⅜ to ⅞ in., depending on the size of the holder; (*b*) the copper alloy contact tube (also called the contact tip), which guides the electrode wire through the nozzle and also supplies the current to the electrode wire; (*c*) the wire-feed conduit, through which the electrode wire is fed from the source; and (*d*) the duct that supplies the shielding gas to the nozzle. Most hand-manipulated electrode holders have a trigger or lever switch for starting or stopping wire feed and gas flow simultaneously.

For some applications, the contact tube is purposely bent (see detail at lower right in Fig. 5), to ensure positive contact with the moving electrode wire. The curved-neck type of holder (Fig. 5a) ensures positive contact without the need for a bent contact tube. A curved-neck electrode holder is usually preferred for welding in all positions.

The water-cooled type of manual electrode holder is similar to the air-cooled type, with the addition of ducts that permit the cooling water to circulate around the contact tube and the nozzle. Cooling with water decreases adherence of weld spatter to the nozzle. Figure 5(b) shows the essential components of a typical water-cooled manual holder.

The choice between air-cooled and water-cooled holders is based on the type of shielding gas, welding current, voltage, joint design, and existing shop practice. For equivalent welding currents, water-cooled holders operate at considerably lower temperatures.

Arcs shielded with carbon dioxide transfer the least amount of heat to the electrode holder. Arcs shielded with

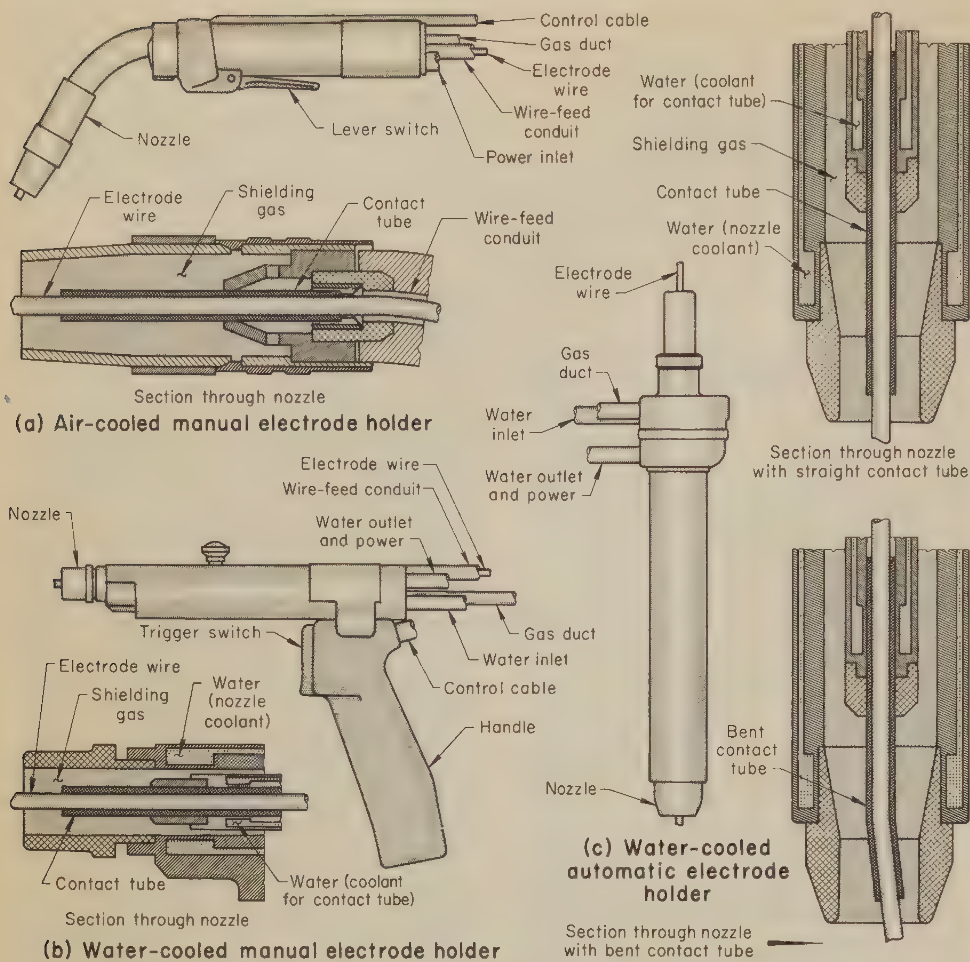

Fig. 5. Details of three types of electrode holders. See text for discussion.

argon, argon-oxygen, helium, helium-oxygen, or argon and carbon dioxide transfer more heat to the electrode holder. However, the type of joint has more influence on the amount of heat transferred to the electrode holder than does the shielding gas. In welding a corner joint or a T-joint, far more heat will be transferred to the electrode holder than in welding a butt, lap or edge joint, in which the heat dissipates in various directions.

Because the ability to absorb heat depends on the mass of the electrode holder, air-cooled holders are heavier for a given rating than are water-cooled holders. Power cables that are cooled only by radiation are also more massive than are water-cooled cables.

The shielding gas used influences the maximum current for air-cooled electrode holders. Because carbon dioxide causes the electrode holder to operate at a lower temperature than argon, higher current can be used with carbon dioxide shielding. Air-cooled electrode holders are rated at 500 amp or less.

Water-cooled holders and power cables are used in applications requiring current ranging from 200 to 750 amp. However, when such electrode holders are manually manipulated, use of the high end of this range depends greatly on whether the welder can tolerate the heat radiated from the arc and from the weld deposit.

Designs of electrode holders vary considerably, depending on the particular manufacturer and specific requirements. For instance, in the three types of holders illustrated in Fig. 5, the electrode wire usually is supplied from a separate and remote push-type wire-feed mechanism through the flexible conduit. One modification of these holders incorporates a small motor in the handle and feeds the electrode wire by pulling it from a remote source. Another modification has a self-contained wire-feed mechanism, as well as its own self-contained wire supply on a spool. Capacity of the spool is usually 1 to 2½ lb of wire.

Many electrode holders are designed with a curve just behind the nozzle so that their outward appearance resembles a gas torch (see Fig. 5a). Many welders find electrode holders of this design easier to manipulate than the straight-neck types.

Electrode holders for automatic or machine welding (in which the electrode holder is held and guided by mechanical means) are also available in a variety of sizes and designs, and can be cooled by either air or water. Major components of a holder for automatic welding are generally the same as those of holders that are manually manipulated. A typical electrode holder for use in machine or automatic welding is shown in Fig. 5(c), together with sections showing straight and bent contact tubes. In some models of both the air-cooled and water-cooled types, the shielding gas is conveyed to the arc area through external passages, instead of through internal passages as in the electrode holders shown in Fig. 5.

Wire-Feed Systems

Numerous types of wire-feed systems are available, of which most are sufficiently flexible to handle a range of wire compositions and sizes. However, it is desirable to choose a system that is best for the particular application.

Most wire-feed systems are of the constant-feed type; that is, the rate of feed (in inches per minute) is established before welding begins. The feed is started and stopped by a switch on the electrode holder for semiautomatic welding, or by other start and stop controls on automatic equipment.

Variable-speed wire-feed systems are adaptable only to constant-current power supplies, and therefore are used less than the constant-feed types.

Wire-feed systems may be of the push type, the pull type, or the push-pull type. The type used depends mainly on the size and composition of electrode wire used, and sometimes on the distance between the wire reel or spool and the electrode holder.

Push-Type Wire-Feed Systems. Most wire-feed systems are of the push type (Fig. 1), in which the wire is pulled from a coil, a spool or a barrel by means of feed rolls and is pushed through a flexible conduit (wire-feed cable) to which the electrode holder is attached. Length of the conduit can be up to 10 ft for steel electrode wire and up to 6 ft for aluminum electrode wire, depending on the column strength of the wire.

If spools or coils are used, some type of friction braking device is usually incorporated in the spindle of the spool to prevent overrun of the wire when the feed motor is stopped. Push-type wire-feed systems are available that can handle hard solid wire from 0.030 to 0.125 in. in diameter, and soft solid wire from 0.045 to 0.093 in. in diameter. The terms "hard" and "soft" refer generally to ferrous and nonferrous wires, respectively.

The system illustrated in Fig. 1 is typical, although there are many variations among systems from different manufacturers. For instance, the feed-roll mechanism in this system has four driven rolls. Many utilize only two rolls, one of which (usually the lower) is driven. Ordinarily, the lower roll (or each of the lower two rolls) has a circumferential V-groove. The upper rolls do not have grooves, but sometimes are knurled to ensure a positive grip on the wire. Regardless of type, a feed-roll mechanism must be designed so that roll pressure on the wire can be increased or decreased as required.

Pull-Type Wire-Feed Systems. Electrode holders that incorporate a wire-feed driving mechanism are also available. The most popular type has a small drive motor in the handle and an attached 4-in.-OD spool of wire. The unit is compact and can easily be manipulated manually. The equipment is relatively delicate, and is best suited to use with electrode wire having a diameter less than 0.045 in. It is particularly useful when welding thin sections, when

the total weight of weld deposit is low, and when the work must be done in a confined space.

Another pull-type wire-feed system is constructed with a gearbox and drive rolls in the electrode holder. Wire is pulled through a conduit from a spool or a coil. The gearbox and drive rolls can be powered either by a motor in the handle of the electrode holder, or by a flexible shaft from a motor located in a console near the source of wire. This system has the advantage that it can be used with small-diameter wires and at the same time retain the advantage of using maximum-size spools or coils. The electrode holder is less portable than when the self-contained pull-type system is used. Portability is about equal to that of a holder equipped with a push-type system.

Push-pull wire-feed systems are particularly suited to use with low-strength wires. The electrode holder is fitted with a motor and drive rolls and is used as the master unit for controlling the speed of wire feed. It receives wire through a flexible conduit, the other end of which is attached to a remote wire-drive mechanism. The speed of the remote mechanism is adjusted to keep the wire in tension. Small-diameter wires (even soft aluminum alloy wires) can be moved 50 ft or more from the source to the electrode holder by a push-pull system. The conduit may have a plastic liner to reduce drag.

Variable-speed wire-feed systems are used only with constant-current power supplies, because they depend on deviations in arc voltage to increase or decrease the rate of wire feed. These systems usually employ variable-speed series-wound direct-current motors. A series-wound motor with a variable resistor is connected in parallel with the welding arc. A current relay is placed in the welding circuit to prevent the drive motor from operating when the welding current is not flowing. To start the arc, it is necessary only to ground the electrode wire. When the arc starts, short-circuit current closes the control relay, and the drive motor also starts. Variable-speed wire-feed systems are self-regulating, because once the wire-feed rate is set, any deviation in arc voltage results in a corresponding change in motor speed. For instance, if there is a reduction in voltage due to surface irregularity, the drive motor will slow down, allowing the arc length to re-establish itself. Welding is stopped by breaking the arc, and thus allowing the current relay to drop out and stop the wire feed.

Maintenance. Wire-feed systems incorporate numerous components that are comparatively delicate, so that a regular program of preventive maintenance is mandatory for prevention of feeding difficulties.

It is especially important that the electrode-wire conduit be kept clean. Common practice is to clean the conduit after each spool of wire is used. If spools are large, more frequent cleaning may be necessary.

Cleaning of the conduit is achieved by removing the wire and blowing clean air through the conduit in the reverse direction from usual flow. In many shops, because clean air is not available, the conduit is cleaned by blowing it out with shielding gas. Oxygen should never be used for this purpose.

Table 1. AWS Classifications and Composition Limits for Electrode Wires for Gas Metal-Arc Welding (AWS A5.18-69)

AWS classification	Composition, %: C	Mn	Si	P, max	S, max	Other
Mild Steel Electrodes(a)

(a) As-welded mechanical properties as determined from an all-weld-metal tension-test specimen, prepared with the shielding gas and current polarity shown. (b) Except for E70U-1 electrode, for each increase of one percentage point in elongation over the minimum, the tensile strength or the yield strength, or both, may decrease 1000 psi to a minimum of 70,000 psi for the tensile strength and 58,000 psi for the yield strength. (c) 1 to 5% oxygen. (d) Type and polarity of current are not specified.

Electrode Wire

Electrode wire for gas metal-arc welding is a high-purity wire of closely controlled chemical composition. The use of ordinary wire generally results in defective welds. Not only must wire composition be closely controlled, but surface condition of the wire must be good, and variations in diameter must be minimal. Surface condition and diametral accuracy both have a marked influence on feeding characteristics. To protect surfaces during storage, most steel electrode wire is flash copper plated. The copper plate also helps to provide good feeding characteristics, and has no adverse effect on the composition of the weld deposit.

Most specifications permit a variation in diameter of ±0.001 in. for wires up to 0.040 in. in diameter, ±0.0015 in. for wires from 0.040 to 1/16 in. in diameter, and ±0.002 in. for wires larger than 1/16 in. in diameter.

It is also important that electrode wires be of uniform hardness (usually measured by tensile strength). Wires that vary in mechanical properties from one package or coil to another are likely to result in erratic feeding behavior.

Proper storage and handling of wire is important for maintenance of wire condition. Oxidized wire impairs welding characteristics, and damage in handling that causes bends or kinks can make feeding difficult.

Composition of electrode wire has a significant effect on results. Because of the importance of electrode composition many large users of electrode wire have established their own specifications, which they have developed from their own experience.

Table 1 lists AWS classifications and composition limits for ten different types of electrodes that are used for gas metal-arc welding of low-carbon steels. For compositions of electrode wire used for welding other metals, see the articles in this volume that deal with the welding of specific metals.

Ranges of carbon content for some of the electrode wires shown in Table 1 are quite wide — sometimes too wide to ensure consistent performance — which explains in part why many users of welding electrodes have established their own specifications on composition. Some have found that ±0.03% carbon is the maximum variation that can be tolerated in critical applications. Most users prefer electrode wires of low carbon content (0.06 or 0.07%), because the carbon content of the base metal is generally higher than this and the base-metal dilution that occurs during welding increases the carbon content of the deposit.

Mechanical Properties. Table 2 shows the minimum mechanical properties specified by AWS for the classes of electrode listed in Table 1, and indicates the shielding gases and the polarity of direct current suitable for use with the various electrodes.

Selection of composition is influenced by the shielding gas used, type of arc (spray, globular or short-circuiting), welding position, service requirements, and condition of the steel being welded. Cost of electrode wires should be considered only after the above requirements have been satisfied. The first six compositions listed in Table 1 do not vary significantly in cost when purchased in the same size, quantity, and type of package. Low-alloy steel electrode E70S-1B may cost as much as

Table 3. Typical Packaging of Steel Electrode Wire for Gas Metal-Arc Welding

Package size, in.	Package weight, lb	Wire diameters, in., available in package sizes in column 1: 0.020	0.025	0.030	0.035	0.045	1/16	5/64	3/32	1/8

23 ID, 30 high	750	...	...	...	...	...	X	X	X	X

40% more than any of the first six classes of electrodes shown in Table 1.

There is a lack of agreement among users regarding selection of electrode wires, but in some areas there is reasonably close agreement. For example, E70S-4, E70S-5 and E70S-6 electrode wires have higher total content of deoxidizing elements (manganese, silicon and aluminum) than do E70S-1, E70S-2 and E70S-3, and thus are better suited for use with carbon dioxide shielding gas (see Table 2).

When the shielding gas is largely argon, electrode wires E70S-1 to E70S-3 are suitable. Electrode wire with a composition like E70S-1, which contains the least amount of deoxidizers of any of the classes shown in Table 1, is well suited for welding rust-free work metal in flat and horizontal positions, using a spray-type arc and a shield of argon and oxygen or of argon and carbon dioxide. For out-of-position welding or when the work metal is rusty, electrodes E70S-2 or E70S-3 generally give better results. The E70S-2 and E70S-3 electrodes also are capable of producing sound welds in semikilled or rimmed steel.

When the base metal is not perfectly clean, or when a slightly reactive shielding gas is used, E70S-4 is more suitable because it has a higher content of deoxidizers.

Aluminum-containing electrode compositions, such as E70S-5, are designed for operation at high current density with a spray-type arc, and should not be used with globular-type transfer. When welding is done with an E70S-5 electrode, some rust or mill scale on the work metal can be tolerated without serious impairment of weld quality.

Some plants prefer an electrode composition like E70S-6 because of its versatility. This composition is best suited for use with carbon dioxide shielding gas and works satisfactorily with both a spray-type arc at high current density and a short-circuiting arc at lower current density. (Example 79 describes an application in which improved weld quality was obtained, in part, by changing from an E70S-3 to an E70S-6 electrode wire.)

For better mechanical properties and weld soundness, many prefer a low-alloy steel electrode like E70S-1B. Some plants insist on using this grade for critical welds in low-carbon (mild) steel when carbon dioxide shielding must be used. The "quick-freeze" characteristics of the electrode make it suitable for out-of-position welding.

Emissive electrodes, of the E70U-1 class, have a specially treated surface that enables the electrode to be used with straight-polarity direct current without loss of arc stability. Emissive electrodes are designed to give a spatter-free, spray-type arc, using argon as a shielding gas, and may be used in the flat and horizontal positions for welds on rimmed steel. The use of straight-polarity direct current with these electrodes permits higher deposition rates than those obtainable when reverse-polarity direct current is used.

Composite Electrodes. Although most electrode wires used for gas metal-arc welding are solid, composite wires are available and are sometimes used for welding alloy steel. A composite wire is similar in construction to a flux-cored wire (see the article on Flux-Cored Arc Welding, which begins on page 24), except that the composite wire used for gas metal-arc welding contains a core of metal powder instead of flux. The tubular exterior of the wire is usually of low-carbon steel, and the composition of the powder core is varied as appropriate to produce welds of desired alloy content under specific welding conditions.

A principal advantage of composite electrode wire is that special compositions can be produced economically in small quantities for specialized welding applications.

Selection of Wire Size (Diameter). Standard electrode-wire diameters for gas metal-arc welding are 0.020, 0.025, 0.030, 0.035, 0.040, 0.045, $\frac{1}{16}$ (0.062), $\frac{5}{64}$ (0.078), $\frac{3}{32}$ (0.094), and ⅛ (0.125) in. Usually, there is a size of wire that will yield minimum-cost welds for a specific application. When experience has been gained on an application, a better choice of wire size may be possible.

No rules have been established for the selection of wire size, but the following should be considered when making an initial choice:

1. Melting rate is a function of current density. If two wires of different diameters are operated at the same current, the smaller of the two will have the higher melting rate.
2. Penetration is also a function of current density. If welds made with two different sizes of wire are cross sectioned, the weld made with the smaller wire will show the deeper penetration (other factors being equal).
3. Large wires deposit wider beads than do small wires under identical travel and joint conditions.
4. Stock thickness affects choice of wire size. Fillet and lap-joint welds on sheet metal 0.032 in. thick are usually made with 0.025 or 0.030-in.-diam wire. These wires also work well with stock thicknesses up to about 0.075 in. As the stock thickness increases, the wire size can be increased.
5. Welding position affects choice of wire diameter. Gas metal-arc welding is adaptable to vertical-down operation on stock up to ⅜ in. thick. Wire diameters for welding this thickness can vary from 0.030 to 0.045 in. Butt welds between beveled plates can be made vertically with wires ranging from 0.030 to 0.045 in. in diameter.
6. Penetration-type welds such as arc spot welds require the largest wire possible, to produce the largest interface or nugget diameter.

Available Packages. Electrode wire is packaged on spools, in coils, or in barrels. Table 3 lists the sizes and weights of the types of package in which electrode wire of various diameters is usually available.

Several factors should be considered in selecting the most practical form of package. Almost without exception, the heavier the spool or coil, the lower the price per pound, but some wires, even when sealed in their packages, have a relatively short shelf life, so that carrying excessive stock is inadvisable.

The type of feeder used often dictates the size of wire package. For instance, when self-contained electrode holders are used, the maximum weight of spool is 1 to 2½ lb.

Small spools or coils may be the most economical because of the reduced risk

Table 4. Shielding Gases Used for Gas Metal-Arc Welding

Shielding gas	Welding applications
Gases Inert to Work Metals	
Argon	Virtually all metals
Helium	Aluminum and copper alloys, for greater heat and minimum porosity
75A-25He to 25A-75He	Same as helium, but quieter and more controlled arc
Helium + 10% argon	High-nickel alloys
Gases Reducing to Work Metals	
Nitrogen	Copper; very powerful arc (not used in U. S.)
Argon + 25-30% nitrogen	Copper; powerful arc, but smoother operating and more controlled than arc obtained with nitrogen alone (seldom used)
Gases Oxidizing to Work Metals	
Argon + 1-2% oxygen	Carbon, alloy and stainless steels
Argon + 3-5% oxygen	Carbon steels; alloy and stainless steels, using deoxidizing wire
Argon + 5-10% oxygen	Steel, using a deoxidizing electrode wire
Argon + 20-30% carbon dioxide	Steel, chiefly with short-circuiting arc
Argon + 5% oxygen + 15% carbon dioxide	Steel, using a deoxidizing electrode wire
Carbon dioxide	Carbon and low-alloy steels, using a deoxidizing electrode wire
Carbon dioxide + 3-10% oxygen	Steel, using a deoxidizing electrode wire
Carbon dioxide + 20% oxygen	Steels

of wastage by contamination. When the spool or coil is placed in the unit, it is exposed to the atmosphere, and contamination results. Therefore, containers that can be used up in one or two shifts should be chosen.

In some compositions, barrels that contain from 250 to 750 lb of wire are available (see Table 3). In addition to being lower in initial cost (per pound), barrel packages reduce the amount of downtime required to change wire in comparison with the smaller spools or coils. This can be an important consideration in high-volume production.

Shielding Gases

The primary purpose of shielding gas is to protect the molten weld metal and the heat-affected zone immediately adjacent to it from oxidation and other contamination. Reactive metals such as titanium require protection over a much greater area in the weld vicinity.

Gases Used. Originally, only the inert gases argon and helium were used for shielding, but carbon dioxide is now used extensively, and oxygen and carbon dioxide are often mixed with the inert gases. Chemical behavior and welding applications of the gases and mixtures of shielding gases commonly used in the gas metal-arc process are presented in Table 4.

Argon. Welding-grade argon is 99.995% pure. It is a monatomic gas (one atom per molecule), is inert, and is insoluble in molten metal. Argon is 38% heavier than air, which is advantageous for welding in the flat position and the horizontal fillet position.

As Table 4 shows, pure argon can be used as a shielding gas for virtually all metals, but it is not ordinarily used in welding steels, for which argon-base mixtures are preferred (see "Gas Mixtures", in next column). The use of argon with reverse-polarity direct current when welding plain carbon steel often results in undercutting along the edges of the weld.

Argon shielding results in a bead shape that is different from those obtained with helium or carbon dioxide shielding. Also, under otherwise identical welding conditions, argon shielding results in a different pattern of penetration than carbon dioxide shielding (see Fig. 6).

Argon has a lower ionization potential than helium has, which results in lower arc voltage for a given arc length. Consequently, less heat is produced at a given amperage with argon than with helium, which makes argon preferable to helium for the welding of thin sections. Argon is about ten times as heavy as helium, so less argon is required to retain a protective blanket over the weld area in the flat position and the horizontal fillet position.

Argon costs less than helium (per unit of volume purchased) and is more plentiful in supply, which partly accounts for its being used far more extensively than helium.

Helium also is inert and monatomic, but because it is only 14% as heavy as air, a greater volume of helium is required to equal the amount of shielding provided by argon for welding in the flat position and the horizontal fillet

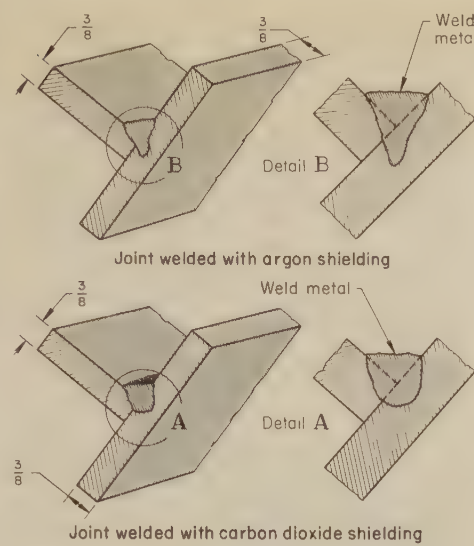

Fig. 6. Patterns of penetration obtained using argon shielding and carbon dioxide shielding in flat-position fillet welding under otherwise identical conditions

position. Higher cost and limited supply have also limited the use of helium as a shielding gas.

Helium shielding results in a higher arc voltage for a given arc length and amperage than that obtained with argon shielding. Consequently, more heat is produced at any given amperage with helium. This characteristic (due to high ionization potential) makes helium preferable for use in welding thick sections and highly conductive metals.

Carbon Dioxide. Most reactive gases cannot be used alone for shielding. Carbon dioxide is the outstanding exception; it is extensively used both by itself and as a component of gas mixtures, to which it imparts improved arc action and metal transfer.

Carbon dioxide has become widely used in the welding of steel by the short-circuiting mode of metal transfer. A true spray arc is not obtained with a shielding gas composed entirely of carbon dioxide. In many applications, carbon dioxide has provided good welding speed and good penetration, and in many applications the welds so shielded have proved to be less expensive than argon-shielded welds.

Carbon dioxide decomposes to carbon monoxide and oxygen at arc temperatures, producing an oxidizing effect approximately equal to that obtained by the use of an inert gas with 8 to 10% oxygen. In spite of this oxidizing effect, sound weld deposits, free of porosity, can be consistently obtained with carbon dioxide shielding when a deoxidizing electrode wire is used with the globular mode of metal transfer.

The major disadvantage of carbon dioxide shielding is that it produces a "harsh" arc, which is likely to make metal transfer somewhat spattery. Weld spatter can be minimized by maintaining a short, uniform arc length.

Gas Mixtures. Often, the advantages of two or more gases can be utilized by mixing them. Common mixtures include argon with helium, argon with oxygen, argon with oxygen and carbon dioxide, and carbon dioxide with oxygen. Some typical proportions are given in Table 4. Mixtures of argon with chlorine or with nitrogen are less frequently used.

Although the pure inert gases are capable of protecting metals at any temperature, they are not suited to all welding applications. By introducing controlled quantities of reactive gases and mixing them with the pure inert-gas shield, improved arc action and metal transfer can be obtained, without degrading the effectiveness of the shielding gas.

Additions of oxygen or carbon dioxide to inert gases help to stabilize the arc, to promote favorable metal transfer, and to minimize weld spatter. At the same time, they change the penetration pattern and promote wetting and flow of the weld metal along the fusion edges in the welding of plain carbon and low-alloy steels, thereby either preventing or substantially reducing undercutting.

The addition of only a small amount of oxygen or carbon dioxide to an inert gas will produce an appreciable change in arc action and metal-transfer characteristics. Additions of 1 to 5% oxygen are the most common, although even ½% oxygen will produce a noticeable change. Oxygen and carbon dioxide are sometimes added to either helium or mixtures of argon and helium, for welding of alloy and stainless steels, when the short-circuiting mode of metal transfer is used.

The addition of oxygen or carbon dioxide to argon causes the gas to become oxidizing, which results in weld porosity in some ferrous metals. To prevent this, electrode wire used in welding with a shielding-gas mixture containing oxygen or carbon dioxide must contain deoxidizers to counteract the undesirable effects of the oxygen on the metal.

Gases used with a short-circuiting arc often differ from those most commonly used with a spray-type arc. For example, mixtures of argon with 20 to 30% carbon dioxide are frequently used with short-circuiting arcs, but are seldom used with spray-type arcs. However, when welding with a short-circuiting arc, almost any gas or gas mixture that is suitable for use with a spray-type arc can be used.

Cost of any given shielding gas per unit volume depends greatly on the amount purchased at one time and on the type of container in which it is received (see the section on Supply and Storage of Shielding Gases, which follows). Geographical location and factors of sales competition also influence cost markedly. Nevertheless, for a given volume of gas purchased under the same conditions, helium is the most expensive, argon is next, and carbon dioxide is the least expensive.

Cost of the completed weldment is the significant figure, so that whether or not the use of a less expensive shielding gas reduces the cost of the weldment depends on whether other processing costs are consequently increased or decreased.

In the example that follows, the use of a lower-cost shielding gas required premium-quality electrode wire and decreased electrode speed; this increased the direct cost of the weldments.

Example 78. Effect of Shielding Gas on Total Cost of Weldments (Table 5)

A cost study was made to evaluate the effects of two different shielding gases (carbon dioxide versus argon plus 5% oxygen) on total direct cost of making two 3⁄16-by-6-in. fillet welds on a 1040 steel farm-implement part (see illustration in Table 5).

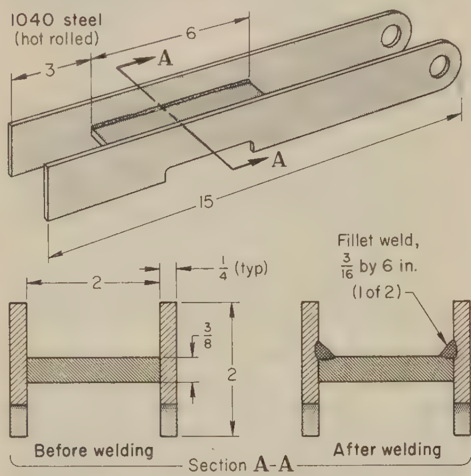
Welding conditions and cost figures for making the welds with the two shielding gases are compared in Table 5. The costs given show that welding cost per 100 parts was 13.6% lower when argon plus oxygen was used, even though this gas mixture cost 2.7 times as much as carbon dioxide. The reasons for this were: (*a*) a high-strength, premium-price electrode wire had to be used with carbon dioxide shielding gas to maintain the weld quality obtained with the argon-oxygen mixture; and (*b*) electrode speed was less with carbon dioxide shielding, which increased labor cost.

Selection of a shielding gas for a given application depends on the type and thickness of the base metal, cost and effectiveness of the different gases, joint design, position of welding, technique to be employed, fixturing, speed and required quality.

There are no strict rules that govern the selection of shielding gas. For instance, in Example 78, use of argon plus oxygen instead of carbon dioxide resulted in a lower-cost weldment. Conversely, in the example that follows, in an entirely different type of operation (different plant, automated welding, and different quality requirements), carbon dioxide proved superior to an argon-oxygen mixture — providing higher-quality welds at greater speed.

Table 5. Effect of Type of Shielding Gas Used on Cost of Welding a Farm-Implement Part (Example 78)

Item	Type of shielding gas(a) Carbon dioxide	Argon plus 5% oxygen
Cost per Hundred Weldments		
Labor	$2.76	$2.19
Shielding gas	0.31	0.83
Electrode wire	2.50	1.79
Total	$5.57	$4.81
Welding Conditions(b)		
Size of electrode wire, in.	0.047	0.045
Type of electrode wire	(c)	(d)
Deposition rate, lb per hr	10.3	11.9
Gas flow, cfh	30	24
Wire-feed rate, ipm	350	440



(a) Both types of shielding gas were purchased in cylinders. (b) Power supply for welding with both shielding gases was a 500-amp constant-voltage three-phase rectifier equipped with variable slope control; electrode holder was water cooled. (c) High-strength, premium-price wire was used to avoid fusion-zone porosity and cracking. (d) Low-carbon steel.

Example 79. Change of Shielding Gas for Improved Quality and Productivity in Automatic Welding of Compressor Housings (Fig. 7)

Originally, 1020 steel compressor housings (see Fig. 7) were welded by the gas metal-arc process with a shielding gas composed of 98% argon and 2% oxygen. The two components of the housing assembly were clamped manually to a rotating positioner and were welded with a machine-held electrode holder fed with 1⁄16-in.-diam E70S-3 electrode wire. When the weldments were tested with a Freon leak-rate detector, rejection rates averaged 7%. Leaks were caused by porosity, incomplete fusion, and misdirected welding arcs. With this technique, welding speed was 45 in. per minute, and average production rate was 30 weldments per hour.

In an effort to improve quality and production rate, plasma-arc welding was considered, but was ruled out because of excessive spatter on the interior wall of the housing. Electron-beam welding was also considered, but it achieved a welding speed of only 12 in. per minute because of the oscillating technique required for bridging the cross section of the joint to attain adequate weld strength; in addition, the initial cost of equipment for electron-beam welding was very high. Flux-cored arc welding was rejected because of the necessity for removing slag, and because of the higher cost of filler metal (compared to the cost of 1⁄16-in. solid wire).

Finally, a dual-head gas metal-arc welding machine was built to replace the original equipment. The new machine included a three-phase transformer-rectifier with a rating of 500 amp at 100% duty cycle, a heavy-duty wire-feed unit with dynamic braking, a custom-built electrode holder and mounting fixture with a mechanical tracking device, automatic V-clamping jigs, and a variable-speed rotating head — all integrated into one machine.

With the new equipment, using the same shielding-gas mixture, electrode wire, and welding speed as in the original method, production rate was increased to 60 weldments per hour. Although the rejection rate was reduced to 5%, that was unacceptably higher than the 3% rejection rate considered reasonable.

Rejection rate was reduced to less than 2% by changing the shielding gas to carbon dioxide (obtained from dry-ice converters) with a dew point of −60 F, and by changing from E70S-3 to E70S-6 electrode wire. The E70S-6 wire provided a weld bead of better shape, and was able to tolerate a greater amount of base-metal surface impurities, such as oil and drawing compound. Welding conditions for the final improved method are given in the table that accompanies Fig. 7. The only new requirement was that the maximum root opening during fit-up had to be held to 0.040 in. (see section A-A in Fig. 7), instead of 0.060 in. as originally specified.

With the carbon dioxide shielding gas, welding speed was doubled, to 90 in. per minute, and weld spatter was barely detectable. As a result, production — from assembly of components through unloading of the welded units — rose to an average of 120 weldments per hour. In addition, the cost of the carbon dioxide was only 9% of the cost of the argon-oxygen mixture, which resulted in a saving of $9000 per year on shielding gas.

Chemical behavior and suggested uses of 15 different shielding gases and gas mixtures are summarized in Table 4. The suggested uses are based on experience with a variety of applications. In some applications, more than one gas or gas mixture has proved satisfactory for a specific metal or set of welding conditions, which indicates that there can be considerable flexibility in the selection of a shielding gas.

In a given plant, every attempt is made to standardize usage of shielding gases so that a minimum number is purchased and a minimum number of mixtures is used. Thus, the range of applications in a particular plant influences the choice of shielding gas.

Other considerations in selecting a type of shielding gas are:

1. Total amount of gas used during a specific period of time
2. Peak demand
3. Consistency of use and length of periods of nonuse
4. Portability of gas containers.

(See also "Shielding Gases" for gas tungsten-arc welding, pages 122-124.)

Supply and Storage of Shielding Gases

Except for portable banks, bulk supply units for shielding gases should be located outdoors (preferably protected from the weather), and away from flammable materials and from buildings and personnel. The site should meet insurance and local code requirements.

Advantages of bulk supply include:

1. Operating pressures are selected by the user and are regulated from a central control unit.
2. The gas supplier checks and services bulk units.
3. Work areas are free from cylinders.
4. The need for trucking cylinders and changing regulators is eliminated.

Portable Bank Supply. In this system, portable banks of cylinders (usually 12) are connected to a duplex manifold header that is normally provided with an automatic control unit. When the operating side of the manifold is exhausted, this control unit cuts in the reserve side to maintain gas supply to the distribution pipeline. The cylinders are mounted in a cradle provided with swivel casters and a crane hook.

A typical portable bank supply is 6 ft, 5⅝ in. high over-all, 3 ft, 1⅞ in. long, and 2 ft, 4½ in. wide; weighs 2000 lb empty and (depending on the type of gas contained) about 2300 lb filled; and has a capacity of 3180 cu ft of helium at 2400 psi and 70 F or 4008 cu ft of argon at 2640 psi and 70 F.

Trailer-storage supply of shielding gas involves the use of a mobile trailer, a stationary storage unit, and an automatic pressure-reducing control. Space is normally provided for two trailers and an adjacent stationary reserve storage unit. One trailer is on the property at all times. The second space allows delivery of a replacement trailer prior to removal of the empty trailer. The reserve storage unit automatically supplies gas to the distribution piping system when the trailer is exhausted. The gas is automatically replaced in the stationary reserve storage unit when a full trailer is delivered and connected to the control unit.

Tow trailers are two-wheeled units usually containing 26 manifolded cylinders (capacity of each cylinder, approximately 400 cu ft), and are normally towed by a regular cylinder-delivery truck. A 26-cylinder tow trailer can

hold 11,583 cu ft of argon (2640 psi, 70 F) and 9,157 cu ft of helium (2400 psi, 70 F), and requires a space of 14 by 35 ft.

Tube trailers are semitrailer units containing 30 or more manifolded 20-ft tubes, and are usually transported by a standard tractor. A tube trailer with 30 tubes can hold 45,148 cu ft of argon (2640 psi, 70 F) and 38,950 cu ft of helium (2400 psi, 70 F), and requires a space of 25 by 35 ft.

The reserve storage unit consists of manifolded cylinders or storage tubes. Cylinders are normally used for argon, and 12-ft tubes are used for helium. The control unit incorporates two regulators, set differentially by approximately 10 to 15 psi.

Bank-fill supply of shielding gas requires high-pressure gas systems consisting of storage and control units. Manifolded cylinders are normally used for argon, and tubes for helium. Each cylinder has a capacity of 245 cu ft of argon at 2200 psi and 70 F.

The storage unit is separated into an operating and a reserve section. The reserve section is available in emergency and is also used for supplying the distribution pipeline during recharging of the operating section. Recharging is done from mobile delivery equipment. The quantity of gas delivered is computed from the volume at standard conditions before and after filling.

The control unit consists of valves, gages and regulators for filling the operating and reserve sections and for delivery of the gas to the distribution system. Space requirements, including allowance for control units, are:

72 cylinders	11½ by 16 ft
108 cylinders	11½ by 21¼ ft
144 cylinders	11½ by 26½ ft
180 cylinders	11½ by 31¾ ft
12-ft tubes, std unit	14½ by 21¼ ft

Additional space of approximately 12 by 32 ft (preferably concrete) is needed for parking the delivery unit.

Liquid-converter bulk supply units store gas in liquid form, vaporize the liquid, and deliver gas to the pipeline at a constant pressure. The complete unit consists of a storage tank with control cabinet, a vaporizer and a fill-connection stand.

Each gas manufacturer has its own standards for converter sizes to handle all demands. The following sizes of converters are available at the indicated maximum delivery flow rates (rated capacities given below are for liquid oxygen; capacities for liquid argon would be slightly higher):

Capacity, scf	Delivery, scf/hr
35,000	500 continuous, 1500 intermittent
65,000	1500 continuous, 3000 intermittent
100,000	10,000
250,000	30,000
500,000	60,000

Standard converters can be modified to increase delivery rates. Custom units are designed to handle any load. Delivery pressure for a converter system is normally limited to 175 psi. Converter storage units having capacities of 35,000, 65,000 and 100,000 cu ft have integral atmospheric vaporizers; those with capacities of 250,000 and 500,000 cu ft require separate vaporizers. Atmospheric vaporizers use atmospheric heat; electrical vaporizers use electrically heated water. Standard atmospheric vaporizers are available with continuous flow rates of 2000, 4000 and 6000 scf per hour; electrical vaporizers (220/440 volts, three-phase), are available with continuous flow rates of 8000 scf per hour (30 kw) and 16,000 scf per hour (60 kw).

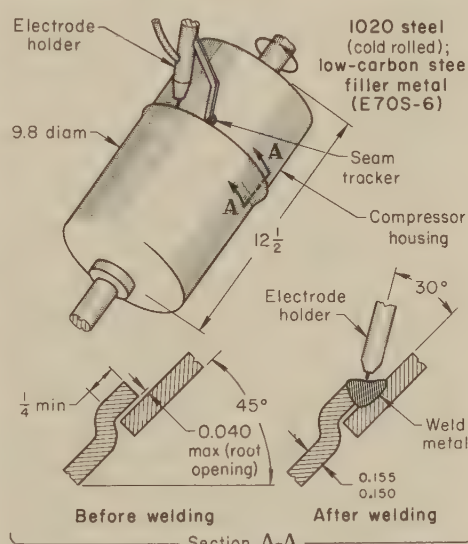
A liquid-converter supply unit provides the arrangement of related equipment best suited for operation, maintenance and delivery to the unit. Filling is accomplished for liquid-delivery equipment through meters, which measure the volume of liquid.

A clean concrete area with protective fencing is required for the liquid converter. The area requirements range from a minimum space of 8 by 8 ft to a maximum of 18 by 20 ft. A hard-surface unloading area at least 12 by 45 ft adjacent to the unit is also required.

Bulk Carbon Dioxide Storage. When a number of welding stations are involved but total usage of carbon dioxide is low, banks of cylinders are located in a suitable area and the gas is piped to the various stations. The banks of cylinders are arranged so that a group of manifolds feeds gas to the main header. Each manifold is attached to a bank of cylinders (14 or 16) and can be turned off independently of the other manifolds. Gas is taken from one or two banks until the pressure in the bank or banks drops to the established minimum delivery pressure. Then the gas source is manually switched to another bank of cylinders. When the last bank of cylinders is being used, the supplier should be notified so that all cylinders can be replenished.

The gas passes through a vapor heater on the main header and is then regulated with a flowmeter to proper flow pressure at the welding stations.

When enough carbon dioxide is used to warrant a low-pressure bulk storage system, a storage tank equipped with a vaporizer is located in a central area that is practical both for filling the storage tank from delivery trucks and for piping the gas to the various welding stations. Piping should be of adequate size and of proper strength to transmit the gas at tank pressure to the stations and to supply all stations with the required volume of gas. A minimum line size of ⅝ in. is recommended. Both one-step and two-step regulation are available. In one-step regulation, tank pressure is carried in the vapor-supply header to the work station, where it is regulated to the proper pressure. In two-step regulation, pressure is regulated at the bulk storage tank to approximately 100 psi, and then is regulated to the proper operating pressure at the station. A regulator is required at each station, and a flowmeter should be installed to control flow rate to the electrode holder. A typical bulk carbon dioxide storage system comprises the following:



Conditions for Gas Metal-Arc Welding With Less Than 2% Rejections

Joint type	Lap
Weld type	Fillet
Power supply	500-amp rectifier(a)
Electrode wire	$\frac{1}{16}$-in.-diam E70S-6
Electrode holder	600 amp, water cooled(b)
Fixtures	Clamping jig, rotating positioner
Current	450 to 475 amp, dcrp
Voltage	32 to 34 v
Shielding gas	Carbon dioxide(c); 60-70 cfh
Welding position	Flat
Number of passes	One
Wire-feed rate	380 ipm
Stickout	¾ to 1 in.
Travel speed	90 ipm (2.9 rpm)
Production rate	120 housings per hour

(a) Constant-voltage type with wire-feed unit. (b) Custom built. (c) Dew point, −60 F max.

Fig. 7. Orientation and joint design for automatic welding of a compressor housing under the conditions listed in the table, which increased production and reduced rejections in comparison with previous methods (Example 79)

1 **Pressure Vessel.** This is a cylindrical steel tank, built to conform with the ASME Code for Unfired Pressure Vessels, designed for a working pressure of 363 psi and tested during manufacture by hydrostatic and vapor-pressure tests applicable to the code.

2 **Insulation.** Not less than two layers of 4-in.-thick blanket-type insulation must surround the vessel, to provide high thermal efficiency. Insulation is securely held in place to prevent moving, sagging or cracking. Normally, no downtime is required for maintenance of insulation.

3 **Housing.** The entire storage unit (in sizes up to 12½ tons) is enclosed in a welded, sheet steel housing mounted on a rigid channel iron base. The housing is hermetically sealed, and the exterior is finished in high-grade enamel to facilitate keeping it clean and sanitary.

4 **Refrigeration.** This is provided by a ruggedly built compressor and refrigeration coil running lengthwise through the pressure vessel near the top. A pressure switch starts the compressor whenever the pressure of the carbon dioxide reaches approximately 305 psi, and stops it when pressure drops to about 295 psi.

5 **Vaporizer and Vapor Heater.** These devices ensure a constant supply of vapor at uniform pressure. The vapor heater also ensures maximum economy in carbon dioxide consumption.

6 **Safety Devices.** The storage unit is fully protected against abnormally high tank pressures, which can result from prolonged compressor operation or power failure, by multiple safety devices. These include a bleeder relief valve that opens at 341 psi, two safety pop valves that open at 357 psi (a two-way switching valve makes it impossible to shut off both safety pop valves simultaneously), and a frangible disk normally connected to a line venting to the outside of the building.

In addition, an alarm sounds automatically if pressure rises to approximately 325 psi, or falls below approximately 275 psi.

7 **Liquid-Level and Pressure Gages.** These gages show carbon dioxide quantity and pressure, and are located on the front of the storage unit.

Liquid carbon dioxide is pumped into the storage unit through the fill line that extends from the side of the tank. No interruption or shutdown of normal operations is necessary during refilling.

The liquid carbon dioxide from the storage unit is passed through a thermostatically controlled vaporizer engineered to provide the volume of vapor the system will normally be required to produce. Automatic controls maintain pressure within predetermined limits. The carbon dioxide vapor is piped back to the tank, where a reservoir of vapor is maintained constantly. From the vapor space in the storage unit, the gas is piped through a filter and a vapor heater to the welding station. Such a system ensures an automatically regulated supply of carbon dioxide gas, even under the heavy demand of peak loads.

Storage units with capacities of 1 to 12½ tons are the sizes most frequently used in bulk liquid carbon dioxide systems, although there is no recognized limitation to the size of a storage unit. Electrical requirements are as follows:

1 All storage units require 1 kw, 110 volts, 60 Hz for the alarm circuit.
2 When vapor is used from the tank with an electrical vaporizer, 12 kw, 220 or 440 volts, 3-phase is required.
3 When vapor is used from the tank with a steam vaporizer, 3 kw, 220 or 440 volts, 3-phase, 60 Hz is required.

Liquid-argon cylinders contain approximately 3000 cu ft of argon gas, and may or may not be classified as bulk-type supply systems. These cylinders have definite limitations on maximum withdrawal rates and desired pressures. They may be manifolded together with an operating side and a reserve side, with a central control-cabinet arrangement.

Cylinder manifolds are recommended where gas volume is insufficient to warrant bulk supply units. Cylinder manifolds provide a centralized location of gas supply for distribution by pipeline. Manifolds may be simplex (one header) or duplex (two headers). Control units may have a single regulator, may be manual with dual regulators, or may be automatic with dual regulators. Manifold installations must be approved by insurance inspectors and must meet NFPA standards 51, 565 and 566.

Equipment for Gas Control

Regardless of the type of gas-supply system used, constant pressure and flow of the gas must be maintained. The main functions of a regulator are to reduce pressure from the source to a working pressure, and to maintain a constant delivery pressure regardless of variations at the source. In addition, a regulator must be adjustable to deliver gas at a certain desired pressure within its rated range. Regulators are broadly classified into four main types: single-stage nozzle regulators, single-stage stem regulators, two-stage nozzle or stem regulators, and line regulators.

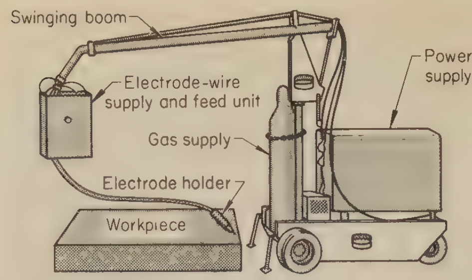


Fig. 8. Self-contained portable unit for on-location gas metal-arc welding

Single-stage nozzle regulators consist of a brass casing, an adjusting screw, springs, a diaphragm, a nozzle and a seat. When the adjusting screw is turned clockwise, the seat is forced away from the nozzle, allowing the gas from the cylinder to enter the working-pressure chamber. This increases the pressure on the diaphragm, which forces the seat closer to the nozzle. In this manner, the regulator mechanism arrives at a balance of forces and the amount of gas withdrawn from the working-pressure chamber is replaced, which keeps pressure constant.

Inlet pressure exerts additional force against the seat member in the opening direction away from the nozzle. This force varies according to the area of the seat. The outlet pressure decreases somewhat as the inlet pressure decreases, because the force acting to move the seat member away from the nozzle is reduced as the inlet pressure decreases. Therefore, a lower outlet pressure on the underside of the diaphragm will close the seat member against the nozzle. The opening between the seat member and the nozzle is thereby reduced, resulting in decreased gas flow.

Single-stage stem regulators operate like the nozzle type, except that the high inlet pressure acts to hold the seat against the nozzle, instead of away from it as in the nozzle type. Therefore, as the inlet pressure drops, the outlet pressure increases somewhat as the cylinder pressure goes down. This increase is caused by a decrease of the force produced by the gas pressure against the seating area. Stem and nozzle regulators reduce gas pressure and are similarly adjusted.

Two-Stage Regulators. In two-stage pressure reduction, the high-pressure gas initially passes through an essentially nonadjustable nozzle or stem assembly. This assembly, equipped with a heavy diaphragm and spring, reduces pressure to an intermediate value. Further pressure reduction is accomplished by passing the gas through a second-stage regulator of either the stem or the nozzle type, which is adjusted to give the desired outlet pressure. Two-stage regulation provides a more nearly constant delivery pressure than is obtained by single-stage regulation. A two-stage regulator will give constant delivery pressure from a full cylinder down to the pressure setting of the first stage. From there on until the cylinder is empty, the first stage remains open and is inactive, insofar as any regulation is concerned, and gas pressure is regulated by the second stage only.

Line regulators can be of either the stem or the nozzle type. They are designed to receive inlet pressures not greater than 500 psi, and are used at welding stations that are fed by a pipeline system containing gas already reduced to an intermediate pressure at the source of supply. For this reason, line regulators are single-stage, and one is required at each welding station.

Application of Regulators. Regulators are available for almost any required pressure and capacity. When gases are supplied from single cylinders, a capacity of 120 cu ft per hour is usually sufficient. When gas cylinders are manifolded, or when a bulk system is used, regulators having capacities as high as 40,000 cu ft per hour may be required. Station regulators in distribution lines are normally low-pressure line regulators available in various sizes to meet the demands of a particular station.

When large-volume distribution lines are used, two-stage regulators are desirable at the source of supply. Total capacity should be more than the total usage of all line stations. Single-stage or two-stage regulators can be used for single-cylinder installations. The single-stage type is commonly used because it costs less than the two-stage type.

Premixed Gases. Commonly used mixtures of gases, such as argon with 1% oxygen and argon with 2% oxygen, are easily obtained premixed, and unusual mixtures can be obtained premixed at reasonable cost if quantities are large enough. The use of premixed gases minimizes handling of cylinders and the need for flowmeters and regulators.

Mixing Argon and Carbon Dioxide. Proportioners are available to mix argon and carbon dioxide with an accuracy of ±1% at flow rates ranging from 1 to 1000 cu ft per hour. An indicated-maximum-time proportioner operates on the surge-tank principle, filling the tank to a predetermined pressure. Then, as the pressure drops from usage, the proportioner refills the tank.

The controls, which require little space, are built on top of the tank. Special controls eliminate the possibility of leakage. Once the gases are mixed, the unit maintains line pressure between 40 and 45 psi, when operating from a 55-psi source of supply. A recording analyzer can be incorporated.

Mixing Argon and Oxygen. Equipment used for mixing argon and oxygen comprises one argon regulator and flowmeter, and one oxygen regulator and flowmeter, with a connecting Y. To adjust the mixture:

1 Connect the argon and oxygen regulators, and tighten them to the cylinder valves.
2 Connect the argon and oxygen flowmeters, position them vertically, and tighten.
3 Adjust the argon and oxygen regulators to equal delivery pressures (25 psi minimum).
4 Adjust the argon flowmeter to the desired flow rate.
5 Adjust the oxygen flowmeter to the desired flow rate.

Argon and carbon dioxide can also be mixed, using an argon and carbon dioxide regulator with flow meters connected to a Y-connector.

Each of the flowmeters is adjusted with the needle valve at the base of the

meter. When adjusting the flowmeters, it is necessary to open the control valve or to disconnect the hose at the base of the Y. It is important that both regulators be adjusted to an equal pressure of not less than 25 psi.

Cylinder and regulator connections for different gases are of different sizes and shapes to eliminate the possibility of a mismatched regulator and cylinder. The Compressed Gas Association has formulated a complete set of specifications for noninterchangeable cylinder valves and regulator inlet connections. Regulators should be used only for the service for which they were designed.

Regulator outlet fittings differ in size and thread, depending on the size and capacity of the regulator.

Flowmeters control the rate of gas flow. They may be designed and calibrated for a specific gas, although some flowmeters are available that have several calibrated scales and can be used for different gases. The scale on shielding-gas flowmeters is marked in cubic feet per hour, and flowmeters are available that will handle up to 200 cu ft per hour. With most flowmeters, gas flow is controlled by a valve on the outlet side and is read by movement of an indicator in a calibrated glass tube. Flowmeters can be purchased separately and attached to a regulator, or a regulator and flowmeter can be purchased as an assembly called a flowmeter-type regulator. Ordinarily, the flowmeter is attached to the outlet of the regulator. Flowmeter gas-inlet pressure is specified by the manufacturer, and the regulator must be adjusted accordingly to ensure accuracy of the meter. On flowmeter-type regulators, the pressure can be set and locked, and further adjustment is necessary only after repair. Both one-stage and two-stage regulators can be used. Because of the constant pressure obtained by using two-stage regulators, a more accurate reading may be expected than when using one-stage regulators.

Flowmeters are similar in design but they differ in the method adopted to adjust the flow. In the types previously described, the gas-control valve is on the outlet side of the meter. Some manufacturers eliminate this valve and control the flow by changing the pressure of the regulator. However, the valve-adjustment type is more common in welding applications.

Selection of Regulators and Flowmeters. In selecting regulators and flowmeters, the volume of gas per unit of time required at the electrode holder is the most important consideration. The following may be used as a guide:

1 Select equipment of adequate capacity.
2 If possible, standardize on one make, to simplify maintenance.
3 Select regulators having filters in the inlet connections.
4 Select flowmeter-type regulators for welding stations.

Care of Regulators. Regulators are precision instruments and should be treated as such. By observing the following, long periods of service, with minimum maintenance, can be expected:

1 Clean cylinder valve outlets with a clean cloth, and open valve momentarily, in order to blow out dust, before attaching regulator to cylinder.
2 Release regulator adjusting screw counterclockwise before opening cylinder valve.
3 Open cylinder valve slowly. A sudden surge of high-pressure gas can damage regulators.
4 Use a correct-size wrench (not a pipe wrench) to connect regulator to cylinder, and never force a connection.
5 When checking for leaks, use a grease-free soap-and-water solution.
6 Never use oil or grease on regulators. Only a lubricant approved by the manufacturer should be used.
7 Never use a regulator for other than its specified purpose. Slight traces of oil or dirt in an oxygen regulator can cause a violent explosion.
8 Allow maintenance of regulators to be performed only by qualified personnel using specified parts.

Prevention of Gas Loss

Loss of shielding gas occurs mainly from one or more of three causes: (*a*) use of excessive amounts in welding, or in preparing to weld or to stop welding, (*b*) leaks in gas lines, and (*c*) overfilling the storage unit in bulk systems.

The first cause of loss usually can be corrected by teaching welders that excessive flow of shielding gas results in turbulence and reduced coverage, and wastes gas.

Overfilling of bulk storage units is often the cause of large losses in bulk systems — especially units containing argon, which boils at approximately −300 F. Often, to reduce the frequency of trips, delivery men fill the units to seven-eighths capacity instead of a maximum of three-fourths. This practice may not cause losses during winter months, or when usage is heavy and reasonably constant. However, if the unit is nearly full there is little room for a head of gas, and during a shutdown (for instance, over a weekend), especially in hot weather, the safety valve will open and gas can be lost.

Under no circumstances should an argon storage unit be filled to more than three-fourths capacity. If a lengthy shutdown is expected, the gas supplier should remove some of the liquid argon and keep it until needed.

In a single year, one large plant saved almost $80,000 by correcting the causes of gas loss discussed above.

Equipment Installations

Type and size of equipment, number of welding stations, available space, workpiece size, and number of similar workpieces to be welded influence location and installation of equipment.

Support equipment required for the apparatus used in gas metal-arc welding is considerably more elaborate than that needed for shielded metal-arc welding. In shielded metal-arc welding, all that is required is that electric power (and sometimes water) be supplied to the welding station. In contrast, a power supply weighing from 350 to 1800 lb, gas cylinders weighing from 60 to 150 lb each, a wire supply, and sometimes a tank that holds 30 to 40 gal of cooling water may be needed for gas metal-arc welding. Compact units with swivel booms can be used to increase the area in which welding can be done without moving the main unit.

If welding is done within a relatively small area, the wire-feed motor can be suspended from a column-mounted jib boom. The boom should be equipped with a trolley suspension hook or a small hoist to permit loading of the electrode wire at floor level, and suspension hooks to prevent the power cables and hoses from dragging and tangling.

Portable Units. For many applications, portability of equipment is required. Figure 8 illustrates a portable "package" unit that can be quickly transported for on-location welding. In this unit, both the power supply (engine-driven direct-current generator) and the gas supply are mounted on a truck equipped with a boom that supports the electrode-wire feed and supply, cables, hose and electrode holder. The gas cylinder must be secured at all times, to prevent it from falling.

Typical Stationary Installations. Three types of installation employing swinging booms are illustrated in Fig. 9. Fig-

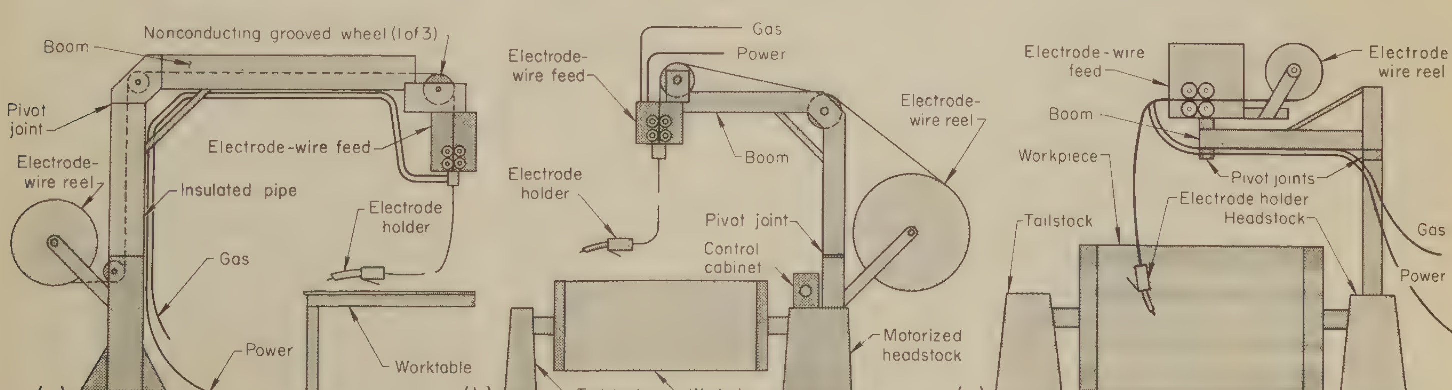

Fig. 9. Three types of swinging-boom installations for gas metal-arc welding. See text for discussion.

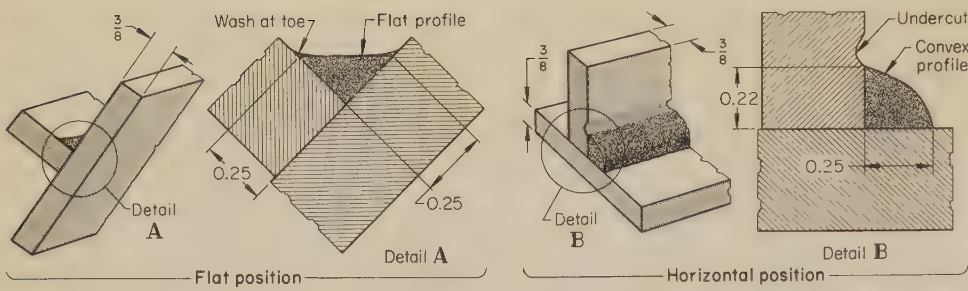

Fig. 10. Comparison of profiles and leg lengths of fillet welds made in the flat position and the horizontal position. Note undercut above horizontal-position weld.

ure 9(a) shows a typical stationary installation that is particularly well-adapted to gas metal-arc welding. The wire-feed mechanism is a considerable distance away from the wire-supply reel. The wire-supply location permits use of large coils of wire. Power and gas supplies are remotely located. The pivot joint permits welding to be performed over a considerable area.

The installation shown in Fig. 9(b) includes a positioner with a motorized headstock, which is helpful for welding massive workpieces; in other respects, this installation is similar to the type shown in Fig. 9(a).

In the installation shown in Fig. 9(c), the electrode-wire reel and the wire-feed mechanism are mounted close together on the end of the boom. Major disadvantages of this arrangement are height of the wire supply and weight on the boom. Extra weight on the boom requires a larger boom and hence higher initial cost. Height of the wire supply above the floor can be a hazard for the operator when reloading wire coils or reels. The rotary positioner used with this installation is not motorized.

Cables and hoses should be kept as short as possible and should not be looped in coils when the welding operation is close to the power supply. Looped coils of welding conductors, functioning as reactors, change the characteristics of the power supply and adversely affect arc operation. Long hoses and cables are susceptible to tangling and kinking, which may cause a restriction in gas or water flow, hence overheating of electrode holders, or porosity in the weld. Long power cables also cause a voltage drop between the arc and the power supply. Large power cables and ground cables are recommended for any installation. The ground cable from the power supply should be securely attached to the workpiece. The use of structural steel and casual bar-stock welding links, or bridges, between numerous weldments is not recommended because they cause voltage drop and stray arcing.

Water-Cooling Systems. Apart from permitting the use of lighter-weight electrode holders and considerably less copper in the power lead, and decreasing the difficulty of removing weld spatter, water cooling adds to the service life of the welding equipment. Proper design, installation and preventive maintenance have largely eliminated the corrosion and plugging at one time associated with gas metal-arc equipment. Sealed recirculating water-cooling systems are preferred, because they enable corrosion to be stopped by the use of inhibitors, and because dirt particles that normally plug small water passages settle to the bottom of the tank. Tap water can be filtered, but this does not remove materials that cause corrosion, and water conditioning is usually too expensive to be considered. Another advantage of sealed systems is that they do not cause the condensation that results from the use of low-temperature tap water.

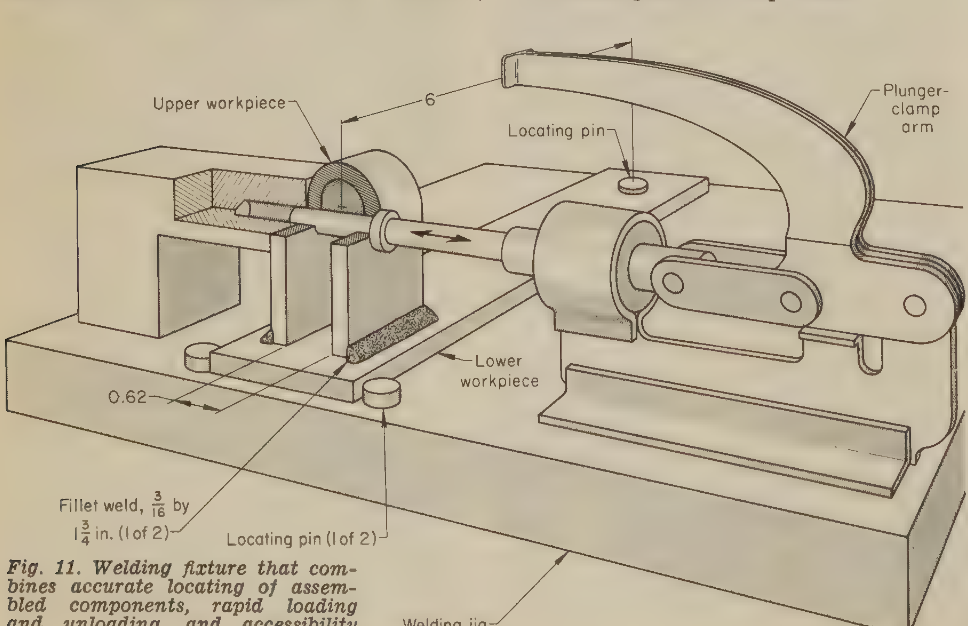

Fig. 11. Welding fixture that combines accurate locating of assembled components, rapid loading and unloading, and accessibility

Holding and Handling Workpieces

Requirements for jigging or fixturing for gas metal-arc welding are usually based on the same considerations as those for other arc welding processes, especially when the electrode holder is hand guided. For additional information on jigging, fixturing and positioning, see pages 11 and 12 in the article on Shielded Metal-Arc Welding, and page 126 in the article on Gas Tungsten-Arc Welding.

Full automation can be achieved in gas metal-arc welding by the use of appropriate fixturing. The continuity of operation that can result from the use of an electrode of virtually unlimited length enables the use of turning rolls and the mounting of electrodes on carriages, and the high welding speeds attainable result in much less heat transfer to the base metal than occurs in the shielded metal-arc and submerged-arc processes. This, in turn, calls for a comparatively small amount of clamping to prevent distortion.

Fixturing for welding in the flat position is generally the simplest and most economical for relatively small weldments. Fillet welds made in the flat position are usually more uniform, less likely to have unequal legs and convex profiles, and less susceptible to undercutting than fillet welds made in the horizontal position (see Fig. 10).

Fixtures for gas metal-arc welding should be designed and built so that locating, clamping and gaging permit good joint accessibility. Fixtures with few protruding clamp arms and gage points allow easy manipulation of the electrode holder.

Figure 11 shows a simple well-designed fixture used in the welding of relatively small parts. By one movement of the plunger-clamp arm, the U-shape workpiece can be secured in position, or the welded assembly can be removed. With minor modifications, the same fixture can be used to weld several different sizes of the same assembly.

Small-diameter (under about 10 in.) circumferential welds are often difficult to make unless the workpiece is rotated during welding. The difficulty is generally greater when gas metal-arc welding than when shielded metal-arc welding, because the electrode holder for gas metal-arc welding is less maneuverable than the simple electrode holder used in the shielded metal-arc process and the travel speed is greater than in shielded metal-arc welding.

The difficulty encountered in the welding of small circular parts can be minimized by the use of a suitable adapting fixture and a motorized rotary positioner. One such fixture, in which the workpieces are held securely to an adapter plate by means of an arbor and a C-washer, is shown in Fig. 12. The adapter plate is secured to a welding jig. The clamping arrangement permits quick assembly and release. The fixture is fastened to the worktable of a rotary positioner of the type shown in Fig. 16 in the article on Shielded Metal-Arc Welding, and is rotated at a speed that will provide the required rate of welding.

The circumferential welding of circular metal parts can often be facilitated by selecting the most suitable type of joint (see Example 81).

Other arrangements for holding and positioning joint assemblies are discussed in the section on Automatic Welding in this article.

Minimizing Distortion. In gas metal-arc welding, as in any other process that involves rapid local heating and cooling, distortion of workpieces is likely to occur. Sometimes distortion can be prevented simply by changing the direction of consecutive passes (see Fig. 14 in the article on Shielded Metal-Arc Welding in this volume). In other applications, there may be no practical means of keeping distortion to an acceptable level, and postweld straightening has to be done. Straightening, however, is tedious and costly and should be avoided whenever possible.

In the example that follows, straightening was eliminated by a change in fixturing.

Example 80. Change in Fixturing Method To Eliminate Postweld Straightening (Fig. 13)

Originally, the hub-and-plate assembly shown in Fig. 13 was welded on a stationary jig. Each component was secured with a toggle clamp. The operation was performed in the following steps:

1. Assemble plate and hub on stationary-jig locating pin.
2. Clamp plate and hub with toggle clamps.
3. Weld half of the circular fillet.
4. Reposition jig-and-workpiece assembly.
5. Weld second half of fillet.
6. Unclamp and lay weldment aside.

By the above procedure, weld quality was acceptable and production rate was 75 weldments per hour. However, postweld straightening was required to correct distortion of the plate; this cost approximately $1.70 per 100 weldments.

An improved procedure (Fig. 13) made use of a fixture in which the hub and the plate, located by a jig pin, were held securely against a support ring by means of a toggle clamp (not shown in Fig. 13), and two sliding cam clamps forced the ends of the plate slightly downward (the direction opposite to that in which they had originally distorted). The entire assembly was then placed on a rotary positioner and welded as it rotated in a plane 45° from horizontal. The following results were obtained:

1. Presetting of the plate eliminated the need for straightening after welding.
2. Production rate was increased to 90 weldments per hour.
3. Weld quality was improved.

Additional welding details are given in the table that accompanies Fig. 13.

Joint Design

Gas metal-arc welding is applicable to all five basic types of joint — butt, lap, T, corner and edge — and to most modifications of these basic types.

The rules of joint design for gas metal-arc welding are not necessarily different from those for shielded metal-arc welding, but some design considerations are unique to the gas metal-arc process, mainly because of the differences in size and complexity of equipment. If these differences are not taken into consideration in locating a particular weld joint, the welder may be prevented from properly manipulating the electrode holder. Joints must not be located so as to cause an excessive gap between the nozzle of the electrode holder and the root of the joint, because such a gap reduces the effectiveness of the shielding gas and may prevent root penetration. Inadequate shielding gas is evidenced by weld discoloration, excessive weld spatter, and porosity.

Recommended proportions of grooves for gas metal-arc welding are shown in Fig. 1, 2 and 3 on pages 148 to 150 in this volume. With some exceptions, the proportions of joints for gas metal-arc welding often are the same as those for shielded metal-arc welding. For joint designs used in welding 1-in. and 1½-in. plate, the reader may refer to Examples 88 and 89 (Fig. 21), on pages 94 and 95 in this article.

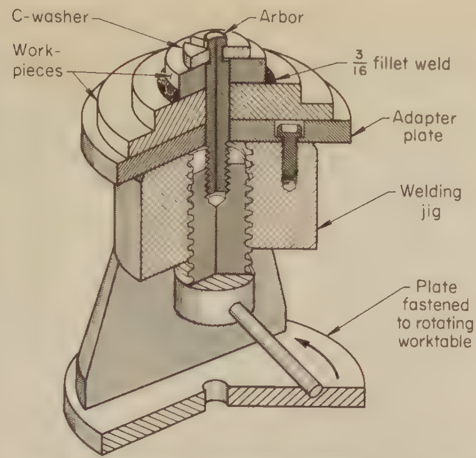

Fig. 12. Typical adapting fixture for fillet welding of small circular parts using a rotary positioner

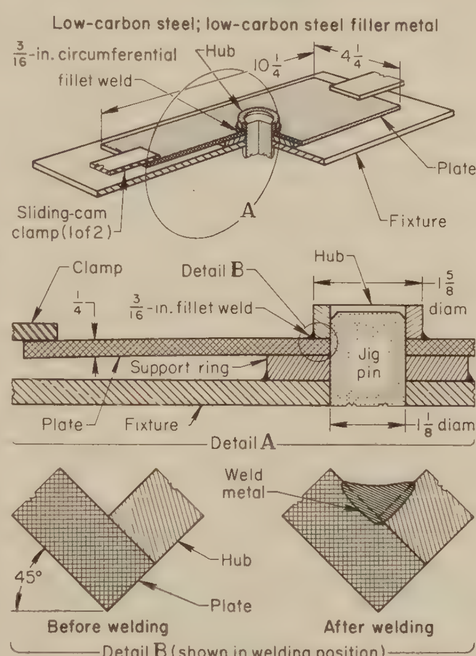


Joint type	Circumferential corner
Weld type	$\frac{3}{16}$-in. fillet
Power supply	500-amp, constant-voltage transformer-rectifier, with slope control
Welding current	280 to 300 amp, dcrp
Electrode wire	0.045-in.-diam E70S-3
Voltage:	
Original procedure	25 v
Improved procedure	500 ipm
Shielding gas	98% argon – 2% oxygen, at 25 cfh
Wire-feed rate:	
Original procedure	440 ipm
Improved procedure	500 ipm
Production rate:	
Original procedure	75 weldments per hour
Improved procedure	90 weldments per hour

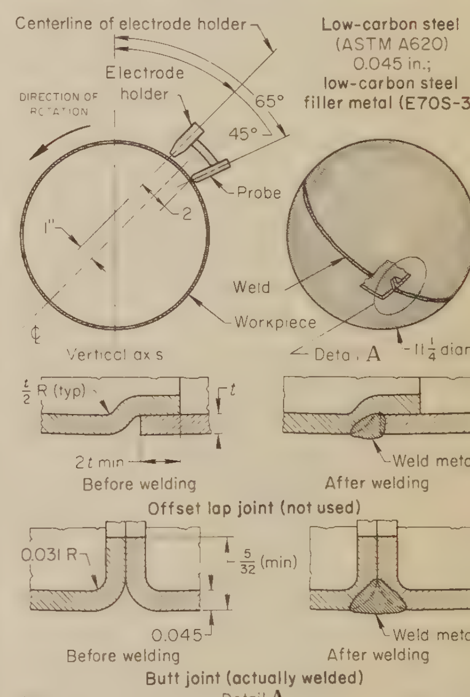
Fig. 13. Use of a special clamping fixture that eliminated a postweld straightening operation (Example 80)

Selection of Joints for Economy. Careful selection of type of joint can often result in manufacturing economies. These economies are not always confined to the welding operation, but may apply in other manufacturing operations, as shown in the next example.

Example 81. Use of a Modified Butt Joint Instead of an Offset Lap Joint To Reduce Tooling and Labor Costs (Fig. 14)

For welding the spherical refrigerant container shown in Fig. 14, an offset lap joint (middle view in Fig. 14), although frequently used in welding the components of a variety of pressure cylinders and spheres, would have resulted in high labor and tooling costs. The lip of the offset hemisphere would have caused interference in assembly, and additional tooling would have been needed to offset the lip.

The modified butt joint shown at bottom in Fig. 14 allowed use of identical forming tools for both halves of the sphere and was the best compromise among weldability, tooling costs, and labor costs. To reduce labor costs still further, each welder op-



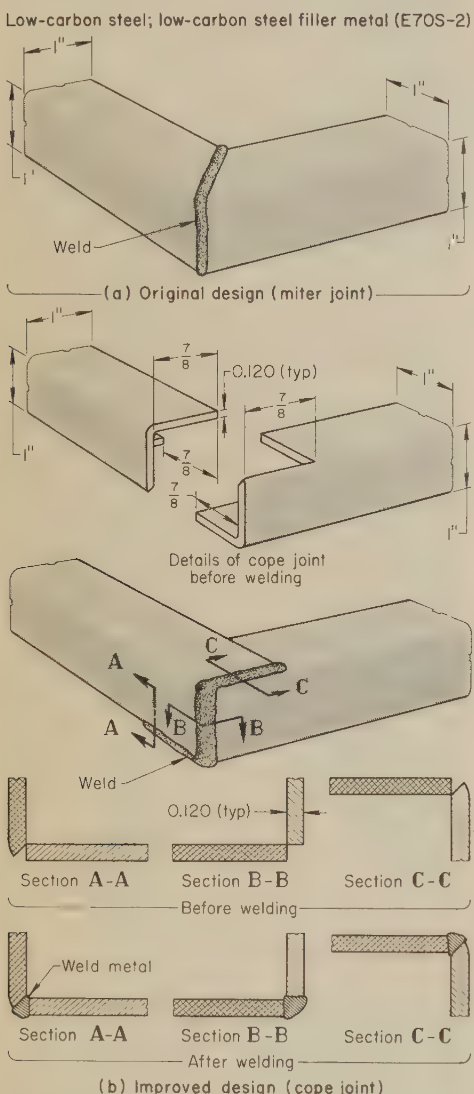
Joint type	Circumferential modified butt
Weld type	Single-flare V-groove
Power supply	300-amp transformer-rectifier
Electrode wire(a)	0.030-in.-diam E70S-3
Electrode holder	Mechanized, fixed, water cooled
Wire feed	Push-type motor, on electrode holder
Current	170 to 190 amp, dcrp
Voltage	22 to 23 v
Shielding gas(b)	98% argon – 2% oxygen, at 35 cfh
Number of passes	One
Wire-feed rate	340 to 380 ipm
Stickout	¼ to ⅜ in.
Welding speed	46.6 ipm
Weld time per container	42 sec

(a) Selection of wire wound to a large diameter eliminated need for wire straighteners and reduced leakage rate. (b) Argon of 99.999% purity from bulk-liquid holder.

Fig. 14. Girth welded refrigerant container for which labor and tooling costs were reduced by use of a modified butt joint instead of an offset lap joint (Example 81)

erated two girth welding machines, and thus was not able to observe the welding operation; therefore, automatic seam tracking was necessary.

The automatic tracking system consisted of two recirculating ball-screw cross slides mounted at right angles and driven by reversible alternating-current motors. A probe, which was mounted to move with the electrode holder (see view at upper left in Fig. 14), sensed the location of the joint in relation to the electrode holder. A movement of the probe tip caused the appropriate slide to bring the probe and electrode holder back to the neutral position. The probe was mounted on a small screw-adjusted slide to provide quick and accurate adjustment of both the horizontal position of the electrode holder and the distance between the electrode holder and the work.



Joint type	Corner
Weld type	Fillet and V
Power supply	200-amp, constant-voltage rectifier
Electrode wire	0.030-in.-diam E70S-2(a)
Wire feed	Constant feed
Current	80 to 85 amp, dcsp

Welding position	Horizontal
Number of passes	One

Fig. 16. Oversize splash guard formed in two sections and joined by fillet welding and bolting (Example 83)

At the end of the welding cycle, the probe and the electrode holder were raised by the vertical slide. After the next assembly was in place, the probe and electrode holder were lowered by the same means and welding was started automatically.

The hemispheres were held in a special welding machine (lathe) consisting of one fixture rotated by a continuously variable drive and a second fixture mounted on the tailstock. Both fixtures were mounted on air-operated slides. Thus, the parts were held together and rotated under the electrode holder. When the electrode holder was retracted after completing the weld, the air cylinders separated, releasing the welded workpiece.

The operator loaded the hemispheres in the machine and pushed a button to close the fixtures. The operator then had an option of using automatic start, by which the weld started as soon as the electrode holder was in position, or manual start, whereby he could observe the position of the electrode holder, make corrections if required, and then start the weld by pushing a button. While one container was being welded, the operator loaded and started a second machine. After each container had been welded, the operator checked it for visible defects. Those requiring repair welding were set aside, and those with no visible defects were transferred on a conveyor to the testing area.

The workpiece was a disposable refrigerant container with a water capacity of 25.5 lb, produced under a special permit that specified two types of pressure tests. Each welded container was tested by subjecting it to 300-psi internal air pressure while within a heavy steel safety chamber. The pressure in the container was then reduced to 100 psi, the chamber was opened, and the sphere was forced under water to check for leaks. If repairs were required, the spheres were retested after repair. A destructive test was required on one container out of each lot of 1000, with a minimum of one per day (although in practice, at least one container was tested from each machine during each shift). This test consisted of filling the container with water, connecting it to a high-pressure pump and increasing the pressure until the container burst. The minimum bursting strength was 800 psi. Fewer than 5% of the spheres required weld repairs.

The guidance system caused some problems, primarily because of the maintenance required. Repair and adjustment of the probe switch were difficult, and improperly adjusted probes could cause misplaced welds. Spare systems were available for replacement of defective probe units.

Although the guidance system added to the machine cost and caused maintenance problems, these disadvantages were soon canceled out by decreased labor costs. Satisfactory welds were difficult to produce manually, because the horizontal variance of the electrode-holder position had to be held to 1/32 in. to prevent melt-through. In addition, it would have been necessary for the manual operator to correct for differences in the heights of the weld seams, which would have limited him to operating one machine, thus doubling the labor cost.

The hemispheres were press formed and vapor degreased. No edge preparation or postweld finishing were done. Welding conditions are given in the table with Fig. 14.

Selection of Joints for Dimensional Control. A change in design of a joint can often aid in the maintenance of close dimensional control, as demonstrated by the application described in the following example.

Example 82. Use of a Cope Joint Instead of a Miter Joint for Closer Dimensional Control (Fig. 15)

The corner-welded channel sections shown in Fig. 15 were parts of rectangular frames for data-processing machines. Originally, 45° miter joints were used (Fig. 15a), but dimensions after welding were unsatisfactory because of joint location and weld restraint.

To provide a more positive joint location with less weld restraint, cope joints (Fig. 15b) were substituted for the miter joints. Tolerances of ±0.010 in. on length and width, and ±0.032 in. on squareness were met on channel sections welded with the improved joint design.

The channel sections were contour roll formed from 0.120-in.-thick low-carbon steel strip. Pieces were cut to length by a cutoff die in a press. The cut lengths were also coped by a die in a press, and all parts were inspected. Tolerances on individual pieces were held to ±0.005 in.

Joints for Special Applications. When the length of a part to be formed from sheet metal exceeds the length of the forming dies, it may be necessary to make the part in shorter lengths and to join the parts after forming. Welding is the joining method most commonly used for these formed assemblies, but the use of welding alone can cause difficulties in some applications. In the example that follows, a problem in joining was solved with an improved joint design that incorporated both bolting and welding.

Example 83. Use of a Combination of Bolting and Welding To Minimize Warpage (Fig. 16)

The splash guard shown in Fig. 16 had to be formed in two pieces because it was too long to form from a single sheet in available equipment. Originally, the two pieces were joined by butt welding, but

this resulted in warpage. Also, grinding to remove excess weld metal left scratches on the sheet metal, and these scratches became even more noticeable after painting.

An improved method of joining eliminated warpage and the need for grinding of welds, and reduced welding time and material used. In this method the two formed sheets were butted, and two pieces of structural angle that had been predrilled in pairs and bolted together were placed on the sheets so that the angle and sheet seams were aligned. The edges of the legs of the angles in contact with the sheets were joined to the sheets by intermittent fillet welds, as shown in Fig. 16. An added advantage of this improved method was that the final joint was mechanical, which allowed the splash guard to be shipped in two pieces.

Manipulation of the Electrode Holder

For best results in flat-position welding, the electrode holder should be held nearly vertical. The angle is not critical and may be as much as 30° from vertical in any direction without any noticeable effect on results; however, if the electrode holder is positioned far from vertical, the effectiveness of gas shielding may be impaired.

The distance from the end of the contact tube to the end of the nozzle (see electrode holders in Fig. 5, page 82) should be ¼ to ⅜ in., although when using the short-circuiting mode of metal transfer, the contact tube can be extended beyond the end of the nozzle as much as ⅛ in. The amount of electrode extension from the contact tube to the weld puddle (stickout) is not critical, although it is related to the mode of metal transfer and does affect deposition rate. As stickout is increased, deposition rate increases, penetration decreases, and the amount of weld spatter increases. Also, as the stickout is increased so is the distance between the end of the nozzle and the weld puddle, and the effect of the gas shield is decreased. Generally, the end of the nozzle should be ⅝ to ¾ in. from the work (stickout of ¼ to ½ in.).

Specific types of beads can be produced by different techniques. Stringer beads generally have deeper penetration, and beads made by weaving have less penetration. In many applications of multiple-pass welding, the first pass is a stringer, and the following one or more passes are made with the weaving technique.

Direction. Both forehand and backhand techniques are used, the choice in any application depending on which technique seems to be most appropriate. The backhand technique allows the welder a better view of the weld puddle. Penetration is influenced by technique. It is greater with forehand technique than with backhand technique.

Thin Sections

The minimum metal thickness appropriate to gas metal-arc welding is about 0.020 in., which is thin enough to present problems. The most common approach to welding of thin sections (⅛ in. thick or less) is to use a short-circuiting arc, which permits metal transfer with a lower heat input than that of a spray-type arc. By this technique, adequate penetration is obtained and the possibility of melt-through is minimized. Similar results can be obtained in welding of thin sections by use of an emissive-type electrode, such as E70U-1, and straight-polarity direct current.

Examples 84, 85 and 86, which follow, describe techniques used in welding metal less than ⅛ in. thick. In Examples 84 and 85, a short-circuiting arc was used. An emissive electrode was used in Example 86. Table 6 lists other examples in this article that deal with gas metal-arc welding of thin steel.

(a) Minimum, in applications where metals of two or more thicknesses were welded.

Example 84. Use of a Short-Circuiting Arc for Welding Between 0.120-In.-Wall Tubes (Fig. 17)

A package boiler assembly was produced by welding between adjacent low-carbon steel tubes, in the vertical position. As Fig. 17 shows, the tubes were 3 in. in outside diameter and 0.120 in. in wall thickness, and were spaced 3/32 to 5/32 in. apart.

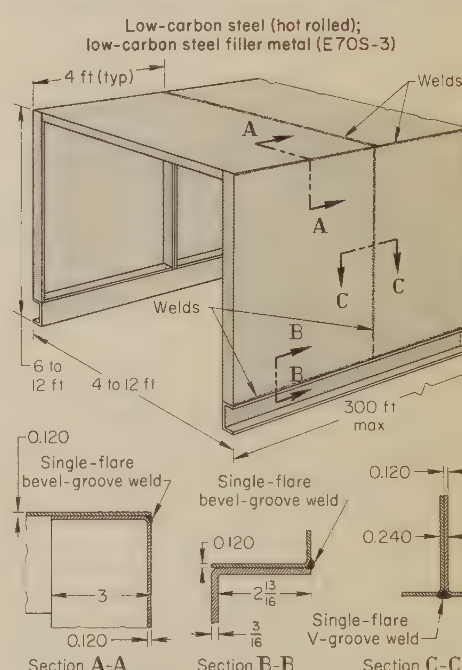
Because of the low penetration, the low heat input into the base metal, and the relatively high deposition rates that could be obtained, a short-circuiting arc was selected. The welding technique consisted in beginning the weld at the top of the tube panel and progressing downward, while oscillating the electrode holder transversely in an arc approximately 3/16 in. wide. This technique resulted in an effective seal weld. Additional welding details are given in the table that accompanies Fig. 17.

Example 85. Change From Shielded Metal-Arc to Gas Metal-Arc Welding With a Short-Circuiting Arc To Simplify Welder Training and Increase Welding Speed (Fig. 18)

Housings for spray-type, conveyorized metal-treatment equipment were made from hot rolled low-carbon steel sheet 0.120 in. thick and ranged in length from 30 to 300 ft. The height and width were 6 to 12 ft and 4 to 12 ft, respectively. Components for housings were made in 4-ft-long sections, partly fabricated in the shop, and shipped "knocked down" for field erection. Installations often involved several hundred feet of welded joints.

Conventionally, welding was done by the shielded metal-arc process, using small-diameter covered electrodes at low amperage. The training of men to use this process on 0.120-in.-thick sheet proved difficult and expensive. By changing to gas metal-arc welding with a short-circuiting arc, welder training was greatly simplified and welding speed was more than doubled.

A typical housing, together with details of the welded joints, is shown in Fig. 18. To prevent melt-through, the joints were designed for single-pass welding, and heat input was kept low by using the short-circuiting type of metal transfer. Conditions that made this type of weld deposition possible are given in the table with Fig. 18, and consisted principally of: (*a*) a constant-voltage power supply with variable inductance; (*b*) small-diameter electrode wire; (*c*) low welding current; and (*d*) a shielding-gas mixture that gave good arc stability and minimized weld spatter.



Conditions for Gas Metal-Arc Welding

Power supply	200-amp, constant-voltage rectifier, with variable inductance
Wire feed	Push type
Electrode wire	0.030-in.-diam E70S-3
Electrode holder	200 amp, air cooled
Current	140 amp, dcrp
Voltage	20 v
Arc type	Short circuiting
Shielding gas	75% argon – 25% carbon dioxide, at 15 cfh
Welding positions	Horizontal, vertical
Number of passes	One
Wire-feed rate	200 ipm
Stickout	½ to ¾ in.

Fig. 18. Field-erected housing for which changing from shielded metal-arc welding to gas metal-arc welding simplified training of welders and more than doubled the welding speed (Example 85)

Because of variations in groove size and because of the fit-up conditions that existed in field assembly, specific welding rates were not determined. However, a comparison of over-all job times showed that deposition rate in gas metal-arc welding was 2½ times the rate obtained in shielded metal-arc welding. Furthermore, slag cleaning was eliminated and weld spatter was considerably reduced.

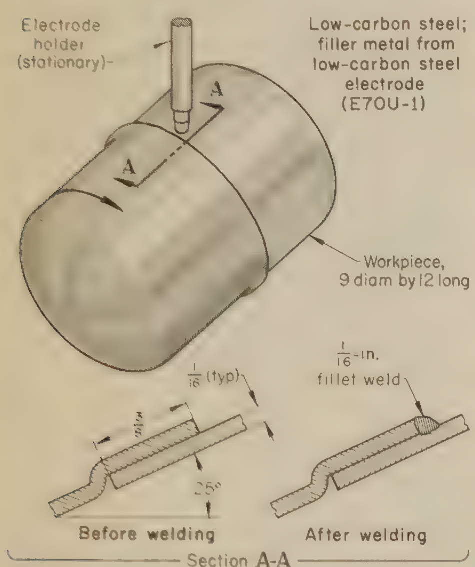
As a result of these improvements in the field, the manufacturer adopted the gas metal-arc process for welding of sheet metal in the shop.

Example 86. Use of Automatic Gas Metal-Arc Welding With Emissive Electrodes for High Welding Speed (Fig. 19)

Refrigerator compressor housings were made of two deep drawn 1⁄16-in.-thick low-carbon steel cups joined with a single-pass circumferential weld (see Fig. 19). To avoid melt-through and to obtain the high production rate demanded for the unit, the compressor housings were automatic gas metal-arc welded with emissive electrodes. Welding conditions are given in the table that accompanies Fig. 19.

The emissive coating on the electrode wire provided the arc stabilization needed to operate on straight-polarity direct current (in contrast to the reverse polarity normally used for gas metal-arc welding). The use of straight polarity provided maximum melting rate with controlled penetration. Penetration was adequate for the weld to withstand an underwater pressure test (using air at 350 psi), but did not cause melt-through.

The mechanical equipment used consisted of (*a*) a clamping jig to hold the two parts in alignment at the proper angle for weld-



Joint type	Lap
Weld type	Fillet
Power supply	500-amp, constant-voltage rectifier, with wire-feed unit and cycle sequencer

Joint type	T
Weld type	Fillet
Power supply	300-amp, constant-voltage motor-generator
Electrode wire	0.045-in.-diam E70S-6
Electrode holder	300 amp, air cooled
Current	200 amp, dcrp
Voltage	24 v
Shielding gas	75% argon – 25% carbon dioxide, at 15 cfh
Welding position	Flat
Wire-feed rate	300 ipm
Travel speed	16 ipm, per single bead
Welding speed	6 ipm, per full weld

Fig. 20. Heavy-duty tank for processing liquids, made up of components ½ and ¾ in. thick, fillet welded as shown (Example 87)

ing in the flat position, (*b*) a variable-speed drive to rotate the jigged part, (*c*) an adjustable mount to hold the water-cooled electrode holder in a proper fixed position, and (*d*) a wire-feed unit to supply the filler metal.

One welding operator manned two welding stations; while one station was in operation, the other was being loaded. Loading and unloading were the only manual operations. About 75 housings per hour were welded by this procedure. Arc time for each weld was only 30 sec.

After being welded, the compressor housings were pressure tested by filling them with air at 350 psi and immersing them in water on a conveyor line. An average of 3% of the welded housings were rejected for leaks in the test; about two-thirds of the rejected housings were salvaged by weld repair.

Welding cost per unit (including the cost of direct labor, filler metal and shielding gas) was 13¢. Cost of power supply, control unit, wire feed, electrode holder, cables and hoses was approximately $9000.

Intermediate and Thick Sections

In a majority of applications, the most significant difference in technique for gas metal-arc welding of intermediate and thick sections (as opposed to thin sections) is the type of arc used. For welding thin sections (⅛ in. or less), a short-circuiting arc is generally used, to minimize heat input (see Examples 84 and 85). Sections of intermediate thickness (about ⅛ to ½ in.) and thick sections (more than about ½ in.) require greater heat input, and therefore are more often welded with the use of a spray-type arc.

For groove welds, the joint design requires additional consideration as section thickness increases (see pages 148 to 150). The three examples that follow describe typical practice for welding sections ½ to 1½ in. thick.

Example 87. Fillet Welding of ½-In.-Thick and ¾-In.-Thick Components of a Heavy-Duty Tank for Processing Liquids (Fig. 20)

A large rectangular tank with baffled internal compartments was made by joining hot rolled low-carbon steel plates by fillet welds, as shown in Fig. 20. This tank was used for processing liquids, and therefore had to be leakproof. In addition, it was required to support heavy machinery mounted on its top side, and to withstand vibrational stress during operation.

To meet requirements, while maintaining a simple fabricating procedure, the tank was constructed of ¾-in. plate (top) and ½-in. plate (sides, bottom, baffles and central partition) joined by ½-in. fillet welds. Double fillet welding was used on all joints except those formed by final closure, which could only be single fillet welded from the outside.

The tank was made up of three subassemblies, as shown in Fig. 20. After fit-up, each subassembly was tack welded by the shielded metal-arc process, using 3⁄16-in. E6012 electrodes, and 200-amp alternating current from a 400-amp power supply.

The tack welded components of the subassemblies then were double fillet welded by the gas metal-arc process, under the conditions given in the table with Fig. 20. Welding was done in the flat position. No clamps were used.

For joining of the welded subassemblies to complete the tank, the top one was turned over and the two bottom ones were fitted onto it. After tack welding (same conditions as for the subassembly components), the unit was closed by means of single fillet welds (section A-A, Fig. 20).

Examples 88 and 89. Joint Design and Welding Practice for Butt Welds in Plates 1 In. and 1½ In. Thick (Fig. 21)

Example 88 — Plates 1 In. Thick (Fig. 21a). The gas metal-arc process and the single-V-groove joint design shown in Fig. 21(a) were selected for butt welding of 1-in.-thick low-carbon steel plates. This joint required 100% penetration and high quality. The gas shield permitted the welder to see the arc action without obstruction, which was helpful in obtaining the required quality.

The weld was made in nine passes, using a backing strip, as shown in Fig. 21(a). A short cooling period followed passes 3, 5 and 7. The filler metal was 1⁄16-in.-diam low-carbon steel wire fed at 220 in. per minute. Reverse-polarity direct current was

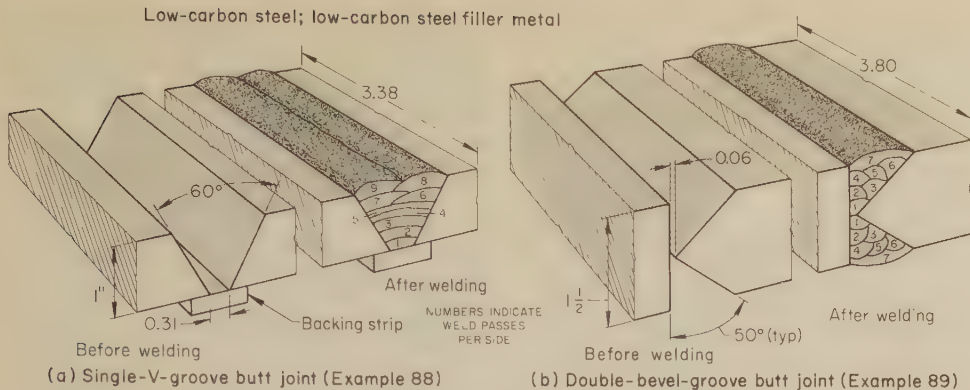

Fig. 21. Joint designs and buildup sequences for butt welding of plates 1 and 1½ in. thick (Examples 88 and 89)

used at 29 volts. A mixture of argon (at 27 cu ft per hour) and carbon dioxide (at 18 cu ft per hour) was used as the shielding gas.

Example 89 — Plates 1½ In. Thick (Fig. 21b). A double-bevel groove was selected for the butt joint in welding the 1½-in.-thick plates shown in Fig. 21(b). This type of joint was selected not only to minimize the amount of weld metal used, but also to permit full accessibility of the electrode holder and shielding gas to the root of the joint. The gas metal-arc process was selected mainly to avoid the risk of entrapping slag, which could have occurred with the shielded metal-arc process.

The weld was completed in 14 passes (seven on each side) using 1/16-in.-diam low-carbon steel electrode wire fed at 210 in. per minute. Reverse-polarity direct current was used at 29 volts. A mixture of argon and carbon dioxide was used as the shielding gas; argon flow was 27 cu ft per hour; carbon dioxide, 18 cu ft per hour.

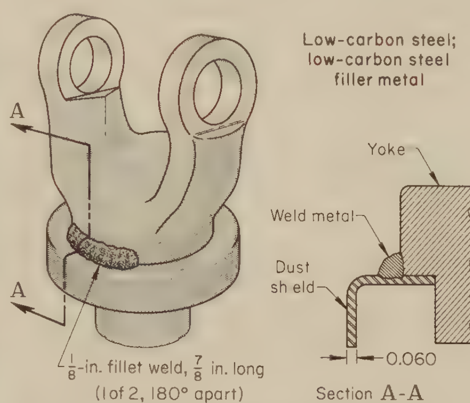
Sections of Unequal Thickness

The difference in thickness that can be tolerated between sections being welded is generally the same for gas metal-arc welding as for other arc welding processes. Often the amount of penetration required in the thicker section is the governing factor, because the current used and the resulting heat input must be low enough to avoid overheating the thinner section.

There are two possible approaches to minimizing heat-sink differential when there are wide differences in thickness between two sections. One approach is to machine a groove in the thick section close to the joint to be welded; then, in effect, two sections of more nearly the same thickness are welded. This approach is commonly used in making boilers and heat exchangers, where relatively thin-wall tubes must be welded to thick tube sheets. (For details of such a procedure see Fig. 30 in the article on Shielded Metal-Arc Welding, page 18.)

Another approach is to hold a copper backing bar or block against the thin section during welding, using the bar or block as a heat sink. (For more details on this technique, see Fig. 31 in the article on Shielded Metal-Arc Welding, page 19.)

In many applications, if requirements are not stringent, a considerable difference in thickness between parts being welded can be tolerated without the use of special techniques. One such application is described in the example that follows.



Electrode wire	0.035-in.-diam low-carbon steel(a)
Current	160 amp
Voltage	23.5 v(b)
Shielding gas	Carbon dioxide, at 20 cfh
Wire-feed rate	276 ipm
Stickout	7/16 to ½ in.
Welding speed	17.5 ipm
Welding time per piece (two welds)	6 sec

(a) 0.17 C, 1.44 Mn, 0.017 P, 0.023 S, 0.56 Si. (b) Direct meter reading across arc.

Fig. 22. Universal-joint assembly in which a dust shield of formed thin sheet was welded to a heavy-section forging (Example 90)

Example 90. Welding 0.060-In. Sheet to a Thick Section (Fig. 22)

A dust shield made from 0.060-in.-thick low-carbon steel was welded to a relatively thick yoke forged from low-carbon steel, to make the universal-joint assembly shown in Fig. 22.

The dust shield was supported on a cutout ring, and clamping pressure was applied on the end of the yoke to hold the parts in position for welding. Welding was done by the gas metal-arc process, using a hand-manipulated water-cooled electrode holder at a 45° work angle and a 0° lead angle. The electrode wire was fed by a motorized wire feed. Additional welding details are given in the table that accompanies Fig. 22. Thousands of these assemblies were produced, with no melt-through of the 0.060-in.-thick sheet.

Weld Design for Improved Accessibility

The complexity of the electrode holders used in gas metal-arc welding may make the process less versatile than the shielded metal-arc process for applications in which welding is done on intricate assemblies that have joints in difficult-to-reach locations.

Suitable fixtures and positioning devices can greatly increase the versatility of gas metal-arc welding (see the section in this article on Holding and Handling Workpieces, page 90, and the section on Jigs, Fixtures and Positioners on page 11 in the article on Shielded Metal-Arc Welding).

Sometimes the gas metal-arc process can be simplified, or its efficiency can be increased, by minor changes in weld design — particularly in placement of the welds for greater accessibility. Two weldments that serve as examples are shown in Fig. 23 and 24.

Figure 23 shows a three-piece weldment that requires a square-groove butt weld at one end, and a fillet weld for securing a section of tubing in place at the other. If the fillet weld were to be made as an ⅛-in. continuous circumferential bead (Fig. 23a), this would present two difficulties: (*a*) the two welds could not be made in one setup, because the wire-feed rate required for

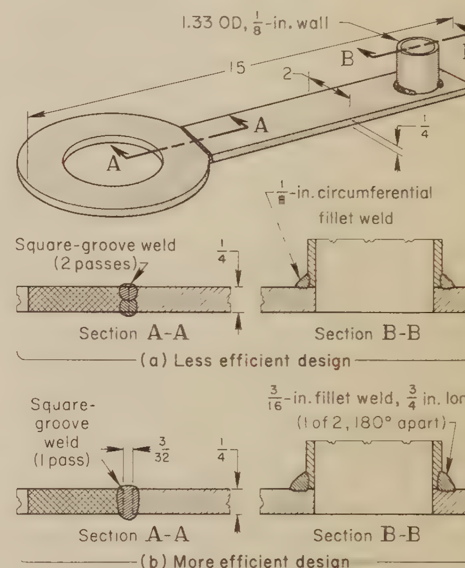


Fig. 23. Three-piece weldment for which change in size and placement of fillet weld would allow use of same wire-feed rate for both welds, and would improve joint accessibility

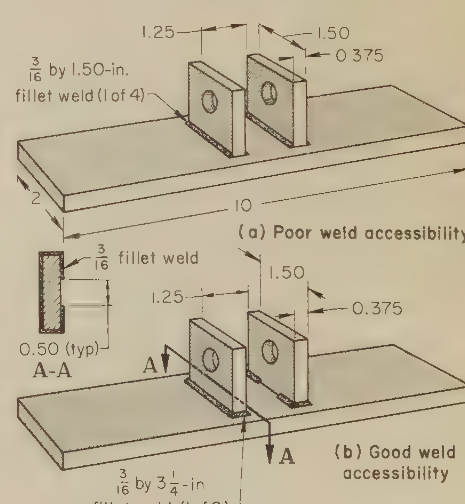

Fig. 24. Assembly for which relocation of fillet welds would improve accessibility and thus allow use of gas metal-arc welding

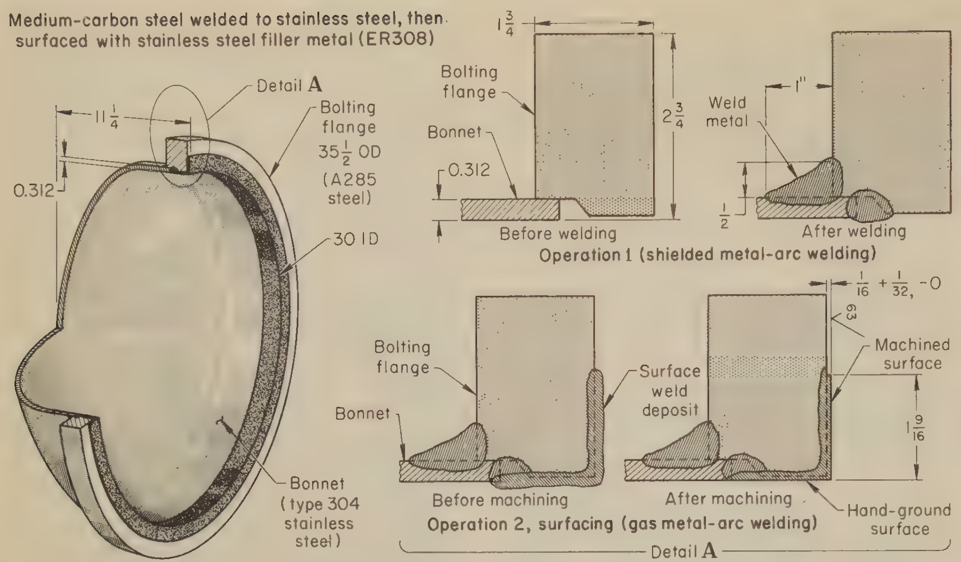


Conditions for Gas Metal-Arc Welding

Surface preparation	Sand blasting	Welding position	Flat
Power supply	300-amp transformer-rectifier	Number of passes	Two or three
Electrode wire	0.035-in.-diam ER308	Welding speed	37 ipm
Electrode holder	Fixed; rated at 250 amp	Gas metering	Flowmeter
Current	165 amp, dc	Stickout	½ in.
Voltage	31.5 v	Preheat (start)	200 F
Shielding gas	95% argon – 5% oxygen, at 30 cfh	Interpass temperature	200 to 300 F
		Postheat	None

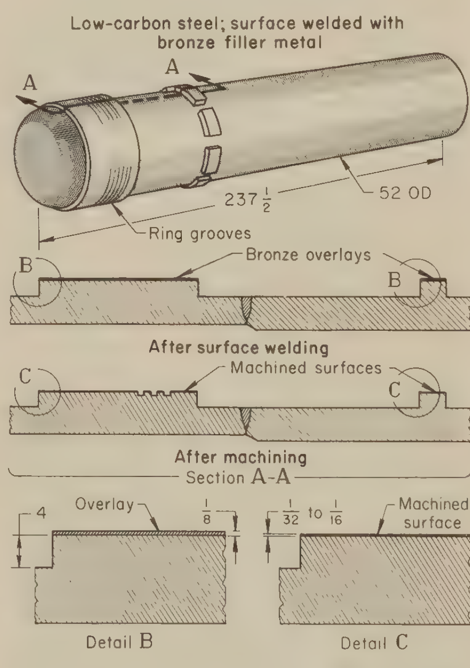
Fig. 25. Water bonnet for which cost of material was reduced by use of a carbon steel bolting flange with a surface deposit of stainless steel (applied by gas metal-arc welding, under conditions listed in the table), instead of a solid stainless steel flange (Example 91)

the butt weld would not be appropriate for the fillet weld; and (*b*) welding completely around a small circumference would be difficult unless the workpiece were rotated. If the weldment were to be redesigned so that a larger (3⁄16-in.), two-segment fillet weld (Fig. 23b) replaced the complete circumferential fillet weld, the same wire-feed rate could be used for both the butt and the fillet welds. The change from a circumferential to a two-segment weld would also greatly increase accessibility. Also note in Fig. 23 that the square-groove butt weld would require two ⅛-in. welds (one on each side) and that there would be no root opening. In the more efficient design (Fig. 23b), a 3⁄32-in. root opening could be used, which would permit the weld to be made with a single-pass ¼-in. weld (one side only).

Figure 24(a) shows a weldment designed with four fillet welds. With the fillet placement shown, gas metal-arc welding would be impractical, because the 1.25-in. space between the two components would not permit access by the electrode holder for the full 1.50-in. weld length. Changing weld placement as shown in Fig. 24(b) would provide essentially the same fillet length, and reduce need for accessibility so that gas metal-arc welding could be used.

Surfacing Applications

Gas metal-arc welding can be adapted to various applications of surfacing — an operation in which metal is welded onto the surface of another metal to confer corrosion resistance or some other specific property, or to salvage a part (see also the article on Hard Facing by Arc Welding, beginning on page 152 in this volume).



Weld type	Surfacing
Power supply	500-amp, pulsed-arc welder
Electrode wire	1⁄16-in.-diam ECuAl-type wire
Electrode holder	Air cooled, manually held
Wire feed	Push-pull, speed-control dial
Fixture	50-ton variable-speed rolls
Current, average	250 to 280 amp, dcrp
Voltage:	
Background	27 v
Pulse peak	47 v
Shielding gas	Argon, at 20 to 25 cfh
Welding position	Horizontal rolled
Number of layers	One
Stickout	½ in.
Welding speed	10 ipm
Bead height	⅛ in.

Fig. 26. Cast steel hydraulic-jack piston, and details of the bronze overlays deposited by pulsed-arc gas metal-arc welding (Example 92)

Some surfacing operations are automated in order to obtain uniform deposits. The four examples that follow describe techniques used for typical surfacing applications.

Example 91. Cost Reduction by Use of a Stainless Steel Surfaced Carbon Steel Flange Instead of a Solid Stainless Steel Flange (Fig. 25)

Figure 25 shows a water bonnet for a water cooler (shell-and-tube process) that was required to have a corrosion-proof tube chamber. This requirement was met by shielded metal-arc welding a sand blasted carbon steel bolting flange to the stainless steel bonnet (Operation 1 in Fig. 25), and then gas metal-arc welding a surfacing deposit of stainless steel to the inside of the flange and to the gasket face of the flange (Operation 2 in Fig. 25). The original design of this weldment had specified a solid stainless steel bolting flange, but because of the quantity required, and the size and shape of the flange, procuring it in solid stainless steel proved to be difficult and costly. The use of the low-carbon steel flange surfaced with stainless steel resulted in a 50 to 60% saving in cost of material.

The use of a carbon steel bolting flange clad with type 304 stainless steel had been considered, but it was difficult and expensive to procure clad material in the required thickness and in small quantities (some mills would supply only a complete mill run). Sprayed-on stainless steel was tried, but was discarded because of the porosity of the deposits.

For the surfacing operation, the weldment was mounted on a conventional mechanical positioner and was supported on turning rolls. The starting area was preheated with a gas burner to 200 F, and the surfacing weld was deposited in the flat position. Two or three passes were required, depending on the buildup necessary. The interpass temperature was held between 200 and 300 F. (Both the preheating and the interpass temperatures were measured by temperature-indicating crayons.) No postheating was required. After welding, the surfaces were visually inspected for porosity. The bonnet conformed with Section VIII, Division 1, of the ASME Boiler and Pressure Vessel Code, and the welder was qualified under the rules of Section IX of that code.

As shown at lower right in Fig. 25, the surfacing deposit corresponding to the inside diameter of the bonnet was hand ground flush with the wall of the semi-elliptical head, and the deposit corresponding to the face of the bolting flange was machined to provide a 1⁄16-in.-thick seal and a raised face. Additional conditions for the surfacing operation are given in the table that accompanies Fig. 25.

Example 92. Gas Metal-Arc Welding With Pulsed-Arc Transfer for Depositing a Bronze Overlay on Bearing Areas of Hydraulic Jack Pistons (Fig. 26)

In the manufacture of a 48-ton hydraulic-jack piston (see Fig. 26), the surfaces of the piston in contact with the cylinder wall were coated with bronze overlays by gas metal-arc welding, using pulsed-arc transfer. This method for depositing the overlays was selected to avoid difficulties experienced with similar but smaller units having wall thicknesses of 3 to 5 in. The overlays on these smaller pistons had been applied manually by the shielded metal-arc process, and deposition was relatively slow. Another problem encountered with the smaller pistons was that scattered areas of severe porosity were evident after the rough machining cut on the overlays. These had to be machined out and rewelded, which was time-consuming and costly.

For the surfacing operation, the machined piston, which had been made by joining three low-carbon steel castings with submerged-arc girth welds, was placed on a 50-ton variable-speed roll positioner for rotation during welding. One layer of bronze

about ⅛ in. thick was deposited by the gas metal-arc process, as shown in Fig. 26. The electrode holder was manipulated manually, and a ½-in.-wide bead was deposited, with ⅛-in. overlap. No preheat or postheat was used; other conditions for the surfacing operation are given in the table that accompanies Fig. 26.

Visual inspection after a rough machining cut on each overlay showed no porosity and no lack of fusion, and no pistons surfaced by the gas metal-arc process were rejected. Time for depositing the bronze layers was about one-fourth that predicted from experience with the shielded metal-arc method. As shown in detail C in Fig. 26, the bronze overlays were 1⁄32 to 1⁄16 in. thick after final machining.

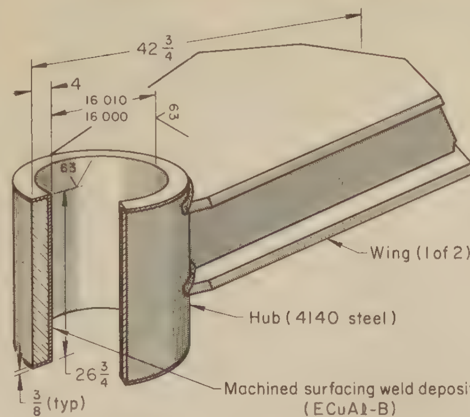
Example 93. Elimination of Preheat and Interpass Heating To Avoid Disturbance of the Gas Shield and Resultant Porosity of Welds (Fig. 27)

After the trunnion-hub assembly shown in Fig. 27 had been welded and stress relieved, a copper alloy surface weld deposit ½ in. thick, to give a ⅜-in.-thick finished dimension, was applied to the bore and ends of the hub by the gas metal-arc process. The hub was used on a floodgate, and the surfacing was required for corrosion resistance.

An insulated box, 7 ft square and 3 ft deep, was made to fit a 2000-lb-capacity welding positioner so that the hub, with the wings welded to it, could be rotated for the surfacing operation. The electrode holder was mounted on a fixture, but was operated manually, for welding inside the bore of the hub.

Preheating to 400 F and heating to hold the interpass temperature at 200 to 300 F was tried, but the draft from the burners under the insulated box disturbed the shielding-gas cover, and porous welds resulted. By eliminating preheating and interpass heating, 90% of the porosity was eliminated. It was also found that a shielding gas of 90% helium, 7½% argon, and 2½% carbon dioxide could be replaced by argon gas at about one-sixth the cost. Additional conditions for surface welding are given in the table with Fig. 27.

4140 steel; surface welded with copper alloy filler metal (ECuAl-B)



Weld type	Surfacing
Power supply	600-amp rectifier
Electrode wire	⅛-in.-diam ECuAl-B
Electrode holder	Fixture mounted, water cooled
Wire feed	Automatic
Fixtures	Rotating positioner, counterweighted electrode-holder fixture for horizontal and vertical travel
Current	280 amp, dcrp
Voltage	30 v
Shielding gas	Argon, at 35 cfh(a)
Welding position	Flat
Wire-feed rate	225 ipm
Preheat and interpass heat	None
Surface welding time per hub	48 hr

(a) Replaced mixture of 7½% argon, 90% helium, and 2½% carbon dioxide

Fig. 27. Floodgate trunnion on which the hub was surface welded without preheat or interpass heat, to reduce porosity (Example 93)

Various types of vessels used in papermaking undergo corrosive wear due to chemical action in reducing wood to pulp, bleaching and other operations. Low-carbon steel vessels often have a short life expectancy, but because of their low cost, it is sometimes more economical to replace or salvage them than to make the vessels from more costly corrosion-resistant alloys.

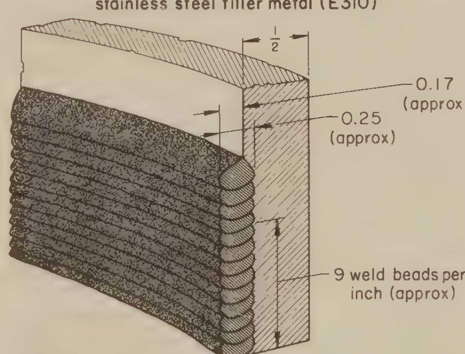
Salvaging is accomplished by surfacing the eroded walls of the vessel with a corrosion-resistant filler metal, as described in the following example.

Example 94. Surfacing a Low-Carbon Steel Paper-Pulp Digester With Stainless Steel for Corrosion Resistance (Fig. 28)

Paper-pulp digesters made of low-carbon steel, which were subject to rapid wear by corrosion, were salvaged by being gas metal-arc surface welded with E310 stainless steel filler metal when wall thicknesses reached the minimum safe limit. Although some of these vessels were surfaced by manual welding, operator fatigue and error often resulted in nonuniform and defective deposits. Automatic welding, under the conditions in the table with Fig. 28, provided more uniform deposits, with fewer defects, at lower cost and with less delay in returning the vessels to service.

The inside surface of the cylindrical wall of each vessel was welded with the vessel in a fixed vertical position and with the welding head rotated about a central shaft. Successive circumferential beads were deposited in vertical progression to the top edge of the vessel. Minimum dilution of the

Low-carbon steel; surface welded with stainless steel filler metal (E310)



Weld type	Surfacing
Electrode wire	0.062-in.-diam E310
Fixtures	Vertical rotating shaft with boom
Current	300 amp, dcrp
Voltage	27 v
Shielding gas	Argon, at 35 cfh
Welding position	Horizontal
Wire-feed rate	210 ipm
Travel speed	36 ipm
Nozzle-to-plate distance	¾ in.
Bead overlap	⅓ to ½ of previous bead
Vertical progression	9 beads per inch, approx

Buildup	0.17 in., approx
Deposition rate	11 lb per hour

Fig. 28. Portion of the wall of a low-carbon steel paper-pulp digester on which overlapping beads of stainless steel were deposited by automatic gas metal-arc surface welding, under conditions in table (Example 94)

E310 stainless steel deposit with the base metal was achieved by lapping each weld bead ⅓ to ½ over the face of the preceding bead (see Fig. 28).

Welding equipment was the same as for any automatic gas metal-arc welding setup, including a power supply, a wire-feed mechanism, shielding-gas supply, and a control panel — all installed inside the vessel. The central shaft operated like a rotating manipulator, with the welding head being mounted at the end of a boom. The axis of the welding torch was radial and, in addition, was inclined at 30° to the horizontal with the tip pointing down.

Automatic Welding

Use of automatic gas metal-arc welding is considered when one or more of the following conditions prevail:

1 Quantity of similar parts to be welded is large enough to warrant the cost of using specially designed fixtures and mechanisms.
2 Skilled welders (needed for semiautomatic welding, with hand-held electrode holders) are not available.
3 Workpiece configuration or the type of welding (surfacing, for example) makes the use of a hand-held electrode holder impractical.

Tooling for automatic welding is likely to be prohibitively expensive, or to be impractical, where:

1 The required weld is such that the arc must operate successively in more than one plane.
2 Several changes of welding direction or location are required.
3 Welding conditions must be changed during the cycle.

The configuration of the workpiece, especially if it requires a more difficult-to-deposit weld bead, is a major factor to be considered in arriving at a decision as to whether or not to use automatic welding. Although automatic welding can be applied to almost any joint or series of joints, the cost of tooling may be prohibitive even if production quantities are large.

In most applications, tooling can be simplified by moving the components to be welded while the electrode holder remains stationary, but if the workpiece is large or of complex shape, moving it may not be practical, and the more costly alternative of moving the electrode holder will have to be adopted.

Circumferential welding is usually easy to automate, because round workpieces of all sizes can almost always be held and rotated without difficulty. In practice, the electrode holder remains stationary and makes the weld as the workpiece slowly rotates. Lathes are ideal for this type of operation. The workpiece is chucked between the headstock and the tailstock, and the electrode holder is mounted on the tool carriage. Depending on how the particular lathe is equipped, the operation can be automated to almost any degree. The welding current must bypass the lathe bearings, to avoid damaging them. Circular welding is also readily mechanized, using a rotating worktable.

Production Examples. The eight examples that follow describe production applications in which automatic gas metal-arc welding proved advantageous.

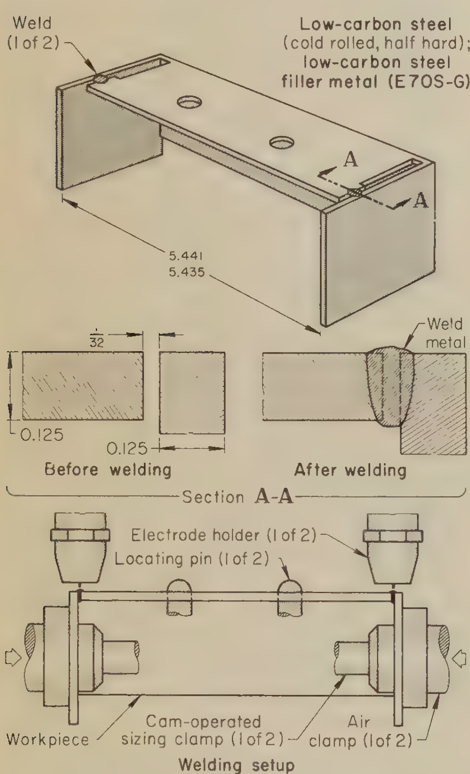
Example 95. Change From Semiautomatic to Automatic Welding That Resulted in a Saving of Time and Material (Fig. 29)

The handle assembly shown in Fig. 29 was part of a hand-operated business machine. Originally, the two welds were made by the semiautomatic gas metal-arc process (manually operated electrode holder),

using a short-circuiting arc. Later, increased production demand warranted the cost of an automatic welding system (about $6000 for welding equipment and $3000 for a fixture). The setup for the automatic system is shown schematically in Fig. 29. The short-circuiting method of gas metal-arc welding was also selected in the automatic system because of its simplicity in automating, reliability and availability.

The automatic system allowed the operator to load the workpiece on locating pins in the fixture with one hand and, with one motion of the other hand, to activate the cam-operated sizing clamps and the air clamps and to trigger the electrode holders. After welding, a built-in clamp-release delay allowed the welds to cool in the fixture, which prevented weld shrinkage and loss of dimensional accuracy. Operating conditions for automatic welding are given in the table with Fig. 29.

In comparison with the semiautomatic method, the automatic system placed the weld deposits more accurately, and thus less filler metal was needed. Also, the appearance and consistency of the welds were improved. Production rate was nearly tripled, resulting in a saving of 45 man-

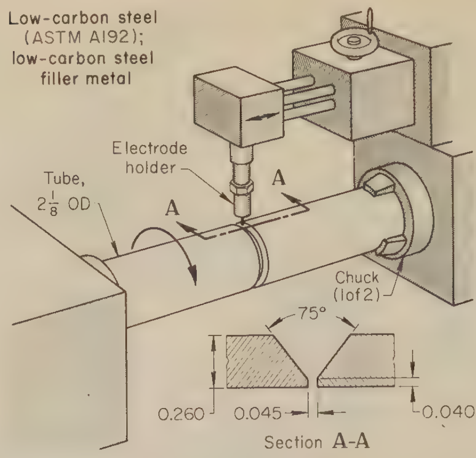


Automatic Gas Metal-Arc Welding

Joint type	Butt
Weld type	Square groove
Power supply	300-amp, three-phase, constant-voltage rectifier
Electrode wire	0.030-in.-diam E70S-G
Electrode holder	Time controlled(a)
Wire feed	Push type, with arc-spot timer and burnback control
Current	190 amp, dcrp
Voltage	30 v
Arc type	Short circuiting
Shielding gas	Argon and carbon dioxide, both at 10 cfh
Welding position	Flat
Wire-feed rate	430 ipm
Welding time	0.7 sec
Production rate	1.158 hr per 100 pieces(b)

(a) Operated in sequence with clamps. (b) Standard hours. When semiautomatic method (hand-held electrode holder) had been used, 100 pieces required 3.268 standard hours.

Fig. 29. Business-machine handle assembly that was welded by automatic gas metal-arc welding in the setup shown, to reduce labor and material costs (Example 95)



Power supply	300-amp rectifier, with variable slope and inductance
Current	Direct, reverse polarity
Electrode wire	0.030-in.-diam low-carbon steel
Shielding gas	80% carbon dioxide – 20% argon
Deposition rate	3¼ lb per hour
Welding time per tube	2 min, 21 sec

Fig. 30. Setup and design of joint used in automatic gas metal-arc welding of tubes for pressure piping systems (Example 96)

hours per week (in the production of 3000 pieces per week), and operator fatigue was considerably reduced.

Quality control consisted of destructive testing of one part out of each 1000 parts, and visual inspection for weld penetration of one part out of each 25. On more than 500,000 parts produced, virtually no field failures were reported.

Example 96. Butt Welding of Tube Sections (Fig. 30)

Sections of steel tubing of a variety of compositions (including ASTM A192) were welded together for use in pressure piping systems, using special automatic welding equipment and a special setup. As shown in Fig. 30, the tubes were held in alignment between hollow universal chucks, with the weld joint (see section A-A in Fig. 30) centered beneath the welding head. At the start of the welding cycle, the tubes were rotated synchronously as the electrode holder initiated the arc. The welding head oscillated in a plane transverse to the direction of welding, thereby distributing the weld puddle evenly between the two tubes.

Although the welding operation was fully automatic up to completion of the weld, loading and unloading of tubes were performed manually.

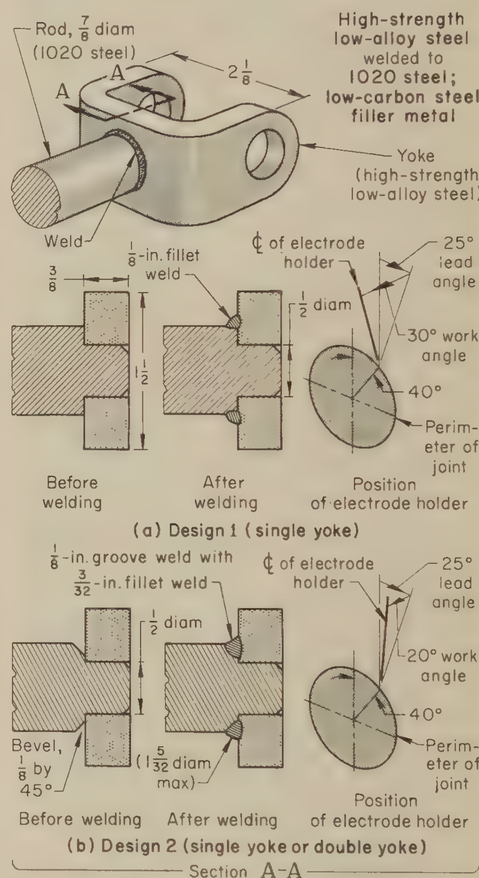
Example 97. Automatic Welding of Universal-Joint Assemblies for Uniform Strength and Dimensional Accuracy (Fig. 31)

Figure 31 shows two designs of joints used in welding 1020 steel rods to yokes made of high-strength low-alloy steel (0.22 max C, 1.25 max Mn, 0.04 max P, 0.05 max S, 0.30 max Si, 0.02 to 0.07 V, 0.20 min Cu), in the production of single-yoke and double-yoke universal-joint assemblies. These weldments were used in steering mechanisms for trucks and agricultural machines, and were required to withstand a testing torque of 4000 in.-lb. In addition, the welds made in the assemblies of bevel-joint design (Fig. 31b) had to be held to close dimensional tolerances to avoid subsequent machining in the weld area. These requirements were met by the use of automatic gas metal-arc welding, under the conditions listed in the table with Fig. 31.

On some single-yoke assemblies, the rod was not beveled at the joint with the yoke (Fig. 31a). On other assemblies, both single-yoke and double-yoke, the rod *was* beveled (Fig. 31b) — not for weld strength, but to avoid a machining operation for maintaining a maximum weld diameter of $1\frac{5}{32}$ in. This maximum diameter was required for fit of a $1\frac{5}{32}$-in.-ID washer on the rod against the yoke. Positions of the electrode holders in welding joints of both designs were the same, except that a smaller work angle was required for the beveled joint (see views at right in Fig. 31a and b).

The tooling used to align the components for welding was the same for all assemblies. The yoke was picked up by a V-type locator in the driving end of the lathe-type welding machine. For single-yoke assemblies, the yoke was held on centerline to receive the piloted end of the shaft, which was slipped into the hole in the yoke. Double-yoke assemblies were aligned in a similar manner, except that the assembly fixtures were the same at both ends.

The single-yoke assemblies were held in position for welding with a self-centering cone adapter that lined up the shaft with the centerline of the yoke. A longitudinal force of 500 lb applied at the tailstock held the assembly in alignment for welding.



Electrode wire	0.035-in.-diam low-carbon steel(a)
Electrode holder	Air cooled; side-delivery gas tube
Current	195 amp, dcrp(b)
Voltage	21 v(c)
Shielding gas	Carbon dioxide, at 50 cfh(d)
Wire-feed rate	350 ipm
Stickout	½ in.
Welding speed	18 ipm
Welding time	9 sec
Electrode wire consumed per piece	52¼ in.

(a) 0.17 C, 1.44 Mn, 0.017 P, 0.023 S, 0.56 Si. (b) From constant-voltage power supply with secondary reactance. (c) Direct meter reading across arc. (d) Flow rate was high to maintain proper shielding; with the air-cooled electrode holder and side-delivery gas tube, lower flow rates resulted in poor shielding due to drafts, and reworks were necessary.

Fig. 31. Universal-joint assembly for which automatic gas metal-arc welding was used on joints of two different designs (Example 97)

A variable-speed direct-current motor was employed to control the rotational speed of the welding lathe, and a timer controlled the duration of the welding cycle. The two welds required on assemblies with yokes at both ends of the rod were deposited simultaneously.

Example 98. Use of Automatic Gas Metal-Arc Welding for High-Quality Welds in Bell-and-Tube Assemblies (Fig. 32)

A manufacturer of universal joints and drive-line components for agricultural implements selected the automatic gas metal-arc process to weld assemblies consisting of shield bells and tubes in a variety of designs and sizes. A typical assembly after welding is shown in Fig. 32, together with sectional views of the weld-joint area of a bell joined to the tube with a continuous circumferential weld (design 1) and with four 1-in.-long intermittent welds, spaced 90° apart around the periphery (design 2). The intermittent-weld design was necessitated by the presence of equally spaced drive lugs on the outer surface of some bells.

The gas metal-arc process was chosen because of its ability to satisfy several major requirements, including high welding speed, good appearance of welds, a weld strength equivalent to the strength of adjoining parts, and the elimination of cleaning operations after welding.

The setup included a welding lathe designed to handle a variety of assemblies, a rake-off bar that prevented lateral travel and shifting of the shield bell, V-locators positioned along the tube (see view at top in Fig. 32), and a retractable headstock and tailstock fitted with bearing-surface locators. An air-hydraulic actuator connected to a rack and pinion was employed to rotate the lathe spindle 360° (for a continuous circumferential weld) or in quadratic intervals (for intermittent welding) and to control rotational speed.

Because hundreds of different combinations of tube lengths (ranging from 4 to 120 in.), bell sizes and bell shapes were welded, it was desirable to standardize the wall thickness and inside and outside throat diameters of the bell to minimize both tooling costs and setup time. In all assemblies, the inner surface of the throat of the bell served as a bearing surface for mounting the bell on the headstock during welding, while the outer surface served as a bearing surface for connecting bell and tube. Both bearing surfaces on the bell served as principal locating areas for the assembly and were vital for preventing mislocated welds.

Before being welded, tubes were cut to length in an automatic cutoff machine. Tubes and bells were assembled in one of two ways, depending on the type of weld. Tubes for circumferential welding were expanded and swaged over the outside throat diameter of the bell. Tubes for intermittent welding were also expanded and swaged to fit over the bell throat, but the two components were assembled by press fitting. After assembly, holes were punched in bells, as required. These preliminary assembly operations required more time than did the welding cycle.

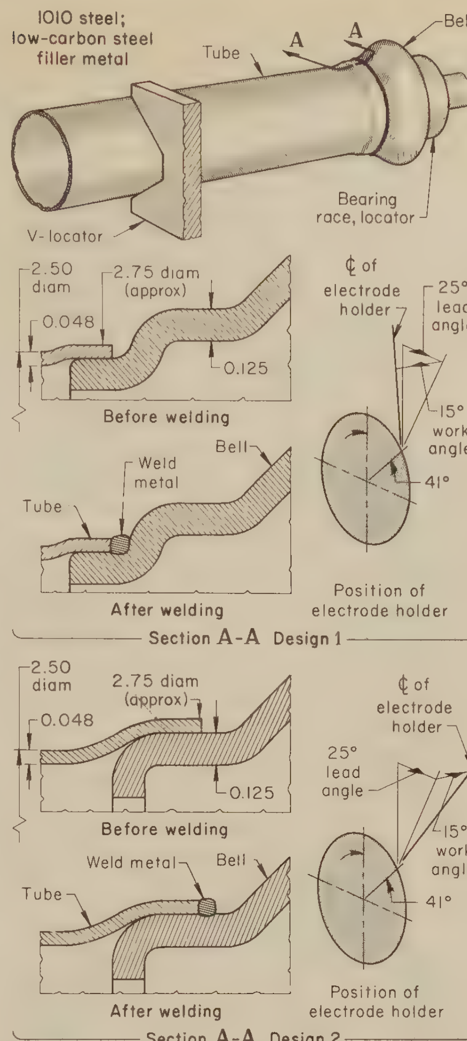
At the outset of the welding cycle, a preassembled tube and bell were placed in the lathe by setting the tube in the V-locators. By depressing a foot switch, the headstock tooling (including the internal bearing-surface locator) was extended to position in the bell. Rotation of the spindle began, and the tailstock was then brought into position at the tube end. Pressure at the headstock was 10 psi higher than that at the tailstock, to prevent the tailstock from pushing the weld joint out of alignment with the electrode holder. The electrode holder was brought into position (see Fig. 32) and peripheral welding (either continuous or intermittent) was accomplished without external backing, using self-backing joints (section A-A in Fig. 32).

Additional welding conditions are given in the table that accompanies Fig. 32. These conditions apply specifically to an assembly consisting of a 1010 steel tube, 2½-in. OD with a 0.048-in.-thick wall, and of a 1010 steel shield bell, 0.125 in. thick. The tube was expanded to an inside diameter of 2.655 to 2.660 in. and an outside diameter of about 2¾ in. This assembly, shown as design 1 in Fig. 32, required a continuous weld.

When welding was completed, the headstock retracted, and the finished assembly fell from the V-locators into a finished-part holder. The machine was then ready for the next part, with both the headstock and the tailstock retracted.

The shield-bell assembly shown as design 2 in Fig. 32 presented a special problem because of drive lugs that were spaced 90° apart on the outer surface of the bell. This press-fitted assembly required the use of the rack and pinion on the welding lathe to ensure that the spindle would always return to a common starting point and that the electrode holder would skip past the drive lugs to produce an intermittent weld. Although the basic welding conditions did not differ markedly from those for the continuous circumferential weld, welding (or arc) starts were inconsistent, resulting in inconsistent weld lengths. This condition was encountered using reactance in the circuit and maximum amperage on the 0.035-in.-diam electrode wire. The problem was solved by adding a contactor that bypassed the reactor at the start of the weld. Thus, at the instant the arc was established, the contactor dropped out, providing reactance in the circuit, but when the electrode touched the work, reactance was eliminated and power was supplied at straight constant voltage. This resulted in good starts and welds of consistent length.

The presence of a light film of oil in the weld zone, due to cutoff coolant or swaging and expanding lubricants, was not deleterious. The violent agitation of the welding arc, characteristic of the gas metal-arc process, helped in volatilizing such contaminants, thereby minimizing the possibility of blowholes or porosity.



Welding Conditions for Design 1(a)

Electrode wire	0.035-in.-diam low-carbon steel(b)
Current	220 amp, dcrp
Voltage (across arc)	22 v
Shielding gas	Carbon dioxide, at 50 cfh
Stickout	½ in.
Wire-feed rate	400 ipm
Wire consumed per weldment	59¾ in.
Welding speed	58.5 ipm

(a) Design 1 had a continuous circumferential weld. Design 2 (four 1-in.-long intermittent welds, 90° apart) was welded under similar conditions except as noted in the text of Example 98. (b) 0.17 C, 1.44 Mn, 0.017 P, 0.023 Si.

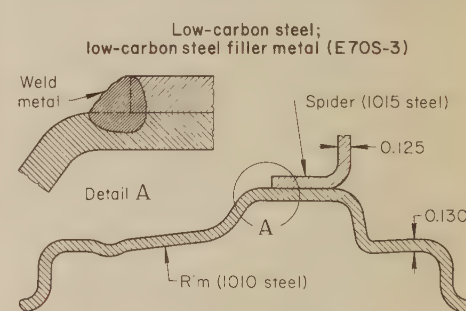
Fig. 32. Two designs of joints between shield bells and tubes that were automatically gas metal-arc welded, using V-locators and electrode-holder positions as shown (Example 98)

Example 99. Use of Automatic Gas Metal-Arc Welding for Joining Rim and Spider of Automotive Wheels (Fig. 33)

Figure 33 shows a cross-sectional view of an automotive wheel comprised of a 1010 steel rim and a 1015 steel spider. The rim was a ring of strip steel, butt welded, and roll formed to shape. The spider was a stamping with four legs that were press fitted into the rim.

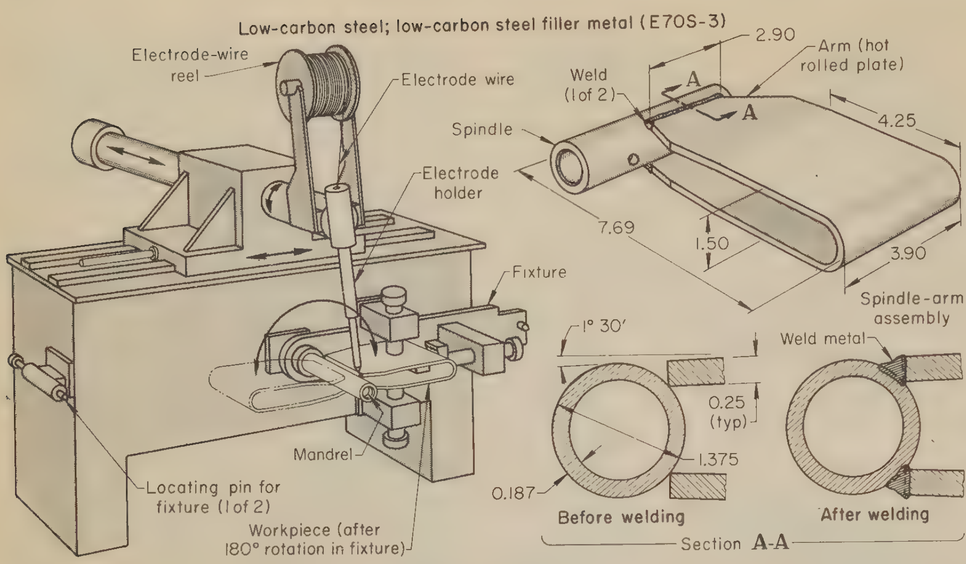
Because of the varied cyclic loading exerted on the wheel during service, it was necessary to select the welding process and weld location that would provide maximum resistance to fatigue failure. The design of the wheel assembly dictated the use of gas metal-arc welding instead of resistance spot welding (the usual process).

The wheel was welded on a high-speed production line that consisted of a die pressing station for assembly and staking, an automatic welding station with four automatic arc welding heads (one for each leg of the spider), and a valve-piercing station. The positioning of the spider leg was held to a tolerance of ±0.015 in., to



Joint type	Lap
Weld type	Continuous fillet
Length of weld	4 in., curved
Power supply	500-amp, 40-v, constant-voltage transformer-rectifier, 100% duty cycle
Electrode wire	1⁄16-in.-diam E70S-3
Electrode holders (four)	Mechanized, fixed; air cooled
Wire-feed system	Variable speed, motor driven
Current	430 amp, dcrp
Voltage	27 v
Shielding gas	Carbon dioxide, at 35 cfh
Welding position	Horizontal
Number of passes	One
Wire-feed rate	245 ipm
Welding speed	50 ipm
Production rate	1000 pieces per hour, using four electrode holders

Fig. 33. Automotive-wheel assembly that was welded by the automatic gas metal-arc process for maximum fatigue resistance (Example 99)



Weld type	Single-flare bevel groove
Power supply	500-amp rectifier
Electrode wire	0.045-in.-diam E70S-3
Electrode holder	500 amp, air cooled
Current	240 amp, dcrp
Voltage	21 v
Shielding gas	Carbon dioxide, at 20 to 25 cfh
Welding position	Flat
Wire-feed rate	400 ipm
Welding speed	30 ipm
Arc time	6.5 sec per side
Floor-to-floor time	76 sec per part

Fig. 34. Machine used for automatic gas metal-arc welding of a spindle-arm assembly with welds on opposite sides, as shown (Example 100)

ensure accurate positioning of electrode wire. Each of the four legs was continuously lap fillet welded along its 4-in. outer edge.

The completed wheel assembly was visually and mechanically inspected for weld integrity and dimensional accuracy.

Example 100. Automatic Welding of Spindle-Arm Assembly (Fig. 34)

The automatic welding machine shown at the left in Fig. 34 was used for making two welds 2.90 in. long in a spindle-arm assembly (shown, together with joint details, at right in Fig. 34). This machine was one unit in a partly manual, partly automated production line that saved 3 lb of material and 2 hr total manufacturing time per piece in comparison with former methods. The savings of material and time resulted in a 25% reduction in over-all cost.

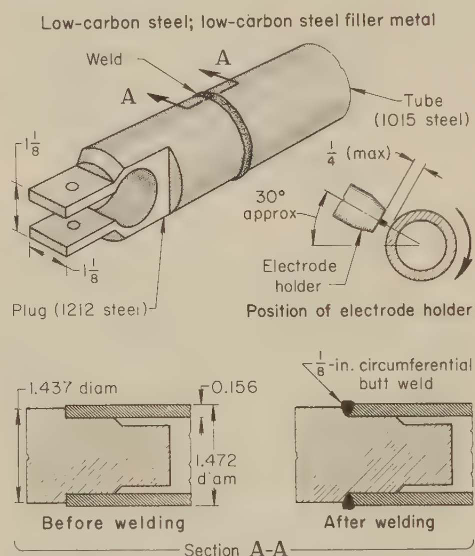
Arc welding equipment included a 500-amp rectifier with an automatic sequencer, a heavy-duty automatic wire feed, a heavy-duty air-cooled electrode holder, and a flowmeter for control of carbon dioxide shielding gas supplied from cylinders. The mechanical equipment provided for advance-retract motion of the electrode holder in the horizontal plane, rotation of the electrode holder in the vertical plane, and 180° rotation of the fixtured workpiece to present each joint in turn for welding, without reclamping (Fig. 34).

A control panel provided for regulation of welding current, wire-feed rate, and travel speed of the electrode holder, and had push buttons for starting and stopping gas flow, starting the automatic welding sequence, and controlling rotation and lateral motion of the electrode holder.

The machine required setting up of travel limits only for the first operation. Subsequent travel was initiated by a push button and terminated by interlock switches. The only manual operations after setup consisted in loading parts, swinging the clamping fixture 180°, pinning the fixture, and unloading the welded assembly.

Welding conditions are given in the table that accompanies Fig. 34. The sequence of operations was as follows:

1 With the electrode holder retracted, the two components were manually loaded in the fixture — the spindle being placed on the mandrel and the U-shape arm clamped in position against the spindle.
2 The electrode holder was rotated to a work angle 15° from the vertical.



Joint type	Circumferential butt
Weld type	Square groove
Power supply	250-amp, three-phase, constant-voltage rectifier
Electrode wire	0.035-in.-diam low-carbon steel
Electrode holder	Retractable, machine held, air cooled and operated
Wire-feed system	Fully automatic
Current	225 amp, dcrp
Voltage	22 v
Shielding gas	Carbon dioxide, at 5 to 10 psi (from cylinder)
Number of passes	One
Wire-feed rate	400 ipm
Production rate	112 pieces per hour(a)

(a) Production rate by the original method (semiautomatic gas metal-arc welding) was 58.2 pieces per hour.

Fig. 35. Fork-spring tube that was welded by the automatic gas metal-arc process to increase production (Example 101)

3 The start button was pushed, feeding the electrode holder forward and simultaneously starting gas flow, welding current, and wire feed. At the end of the weld traverse, current downsloped for crater fill; then wire feed and gas flow stopped. The electrode holder was rapidly retracted.
4 The fixture was manually pivoted 180°. The electrode holder was rotated to an opposite 15° work angle and the lateral slide was indexed to the new position. Operation 3 was then repeated.
5 The welded assembly was manually unloaded; the welds were snag ground, and the spindle was finish machined to size.

Total time cycle per side was 10.5 sec, and index time (for 180° rotation) was 10 sec, making total machine time per assembly 31 sec. Loading and unloading time was 45 sec, thus resulting in a floor-to-floor time of 76 sec per weldment.

Example 101. Use of Automatic Welding for Increased Production Rate and Better Appearance (Fig. 35)

The fork-spring tube shown in Fig. 35 was originally welded by the semiautomatic gas metal-arc process. When the process was fully automated except for loading and unloading, production rate was increased by 92.4% and less highly skilled workers were needed.

In preparation for welding, the two parts of each assembly were degreased and the plug was pressed into the tube. For automatic gas metal-arc welding, each assembly was manually loaded in a special chucking fixture in a horizontal position. The assembled tube and plug were rotated at a fixed speed during welding. The electrode holder was held in a retractable air-operated mechanism at 30° above the horizontal, as shown in Fig. 35. The weld was completed in one pass, and no preheat or postheat was necessary. Other conditions for automatic welding are given in the table that accompanies Fig. 35.

After welding, the workpiece was manually removed from the chucking fixture and turned in a lathe to remove excess weld metal, and the outside diameter was ground to finished size (1.4295-in. OD). The workpiece was then washed, zinc plated, and heated for 1 hr at 350 F.

All parts were inspected for weld appearance and straightness before they were sent to production assembly. It was essential that the welds have good penetration and be free of inclusions, and that the maximum curvature of the entire length of the workpiece be less than 0.003 in.

Example 102. Change From Shielded Metal-Arc to Automatic Gas Metal-Arc Welding of Axial-Flow Compressor Casings (Fig. 36)

A 30-in.-ID axial-flow compressor casing, 23 in. long, was built in two sections to simplify maintenance and reduce weight and cost. Each section consisted of a ribbed semicylindrical low-alloy steel forging (half of the casing) and two cast low-alloy steel flanges that were welded to the axial edges of the casing half (see Fig. 36). Nominal composition of the castings and of the forging was 0.20 C, 1.0 Cr, 1.0 Mo, and 0.10 V.

When the components were welded by the shielded metal-arc process, 20 hr (including 5 hr for weld repair) was required for completing one casing (welding four flanges to two casing halves). Changing to automatic gas metal-arc welding reduced welding time per casing to 2½ hr (this also included time for machine maintenance), and less time was needed for weld repair.

For automatic gas metal-arc welding, fixtures were designed so that both flanges were clamped to each casing half, thus ensuring good fit-up and reproducible final dimensions. Electromechanical relays controlled height and location of the electrode holder. Each flange was welded in two passes (see Fig. 36). For the root pass, the electrode holder followed the joint line (without being oscillated), and provided an average root penetration of ¼ in. The second pass was a fill pass, in which the electrode holder was oscillated to make a weld of two different widths, for outer and inner ribs; the welding current controlled the feed rate of the electrode wire. Additional welding conditions are given in the table that accompanies Fig. 36.

Weldments were inspected by visual and magnetic-particle methods. Despite the reduction in welding time and in the amount of weld repair needed, automatic welding presented three continuing problems: (a) weld porosity, resulting from nitrogen in the work metal; (b) maintenance of the automatic equipment; and (c) incomplete fusion, resulting from starting the welds on cold metal. Porosity caused by nitrogen in the work metal was prevented by subjecting the cast flanges to a 12-hr vacuum treatment at 1900 F prior to welding. The forged component did not require this treatment. Maintenance of equipment remained a problem, but the installation of numerically controlled equipment as a replacement for the electromechanical setup was expected to reduce maintenance costs. Incomplete fusion was minimized through careful selection of welding conditions, but it was not eliminated.

Timed Intermittent Welding

A portable gas metal-arc electrode holder with a nozzle-guide tube (see Fig. 37) can be used with a timer-controller to join sheets, plates, and bars in welded assemblies by intermittent (or "spot") fillet welds.

For timed intermittent welding, the parts to be joined are positioned and clamped together, or positioned in a welding fixture. The welder positions the electrode holder and initiates a preset timed sequence that starts the arc and feeds the wire. At the proper time, the arc and wire-feed automatically stop and the weld is completed. The electrode holder is then moved quickly to a new location, and the welding sequence starts over again. The size of the weld and the depth of penetration are determined by the arc time (expressed in cycles; 1 cycle equals 1/60 sec). The spacing of the welds is determined by the strength and rigidity of the design. Welds can be positioned as close as desired, but no closer than half the diameter of the nozzle-guide tube on the electrode holder. A typical application of timed intermittent welding is described in the next example.

Example 103. Timed Intermittent Welding of Motor-End Panels (Fig. 37)

Figure 37 shows a motor-end panel to which support bars and channel sections were "spot" fillet welded by timed intermittent gas metal-arc welding. As shown at the right in Fig. 37, the electrode holder had a nozzle-guide tube with a 45° bevel on opposite sides, so that when the tube was seated against two right-angled surfaces, the electrode holder was automatically positioned at a 45° angle from each of the two surfaces. For welding in the vertical position, as in this application, the electrode holder was lowered 15° from horizontal (see Fig. 37). A ceramic bushing was inserted over the guide tube. The end of the guide tube was preset for a 5/8-in. nozzle standoff. Welding conditions are given in the table accompanying Fig. 37.

In comparison with shielded metal-arc intermittent fillet welding, the method previously used for joining of these panels, the timed intermittent gas metal-arc process resulted in a 30% decrease in welding time and required less welder skill.

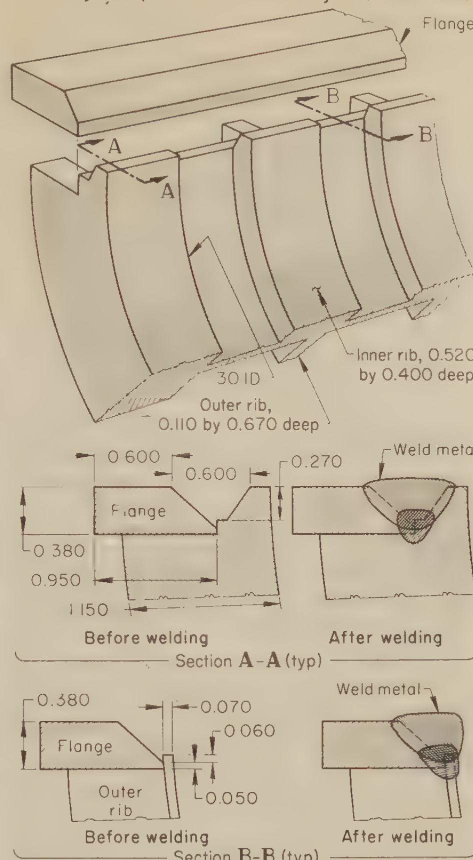
Common Causes of Difficulty

In gas metal-arc welding, with either a hand-held or a mechanically held electrode holder, production rate or weld quality, or both, may be impaired as a result of defective contact at the electrode tip (in the contact tube), erratic wire feeding, inadequate capacity of the wire-feed motor, faulty ground connection to the workpiece, and power fluctuation. These common causes of difficulty, together with methods of avoiding or correcting them, are discussed in the paragraphs that follow.

Contact-Tube Problems. Gas metal-arc welding depends on a transfer of current from a tip of copper or some low-resistance alloy to the electrode wire by means of a sliding contact within the contact tube.

Changes in resistance at this point will change arc voltage and, in turn, arc characteristics and may result in weld defects. The current density that must be passed across this point is higher than that used in other welding processes such as submerged-arc welding. Thus, small irregularities on the electrode wire, such as microscopic laps, seams and slivers, which would have little effect in submerged-arc welding, may significantly affect gas metal-arc welding. This effect increases in importance as electrode size decreases, and is more significant when welding alloys having higher resistance than carbon steel or low-alloy steel.

Residual drawing lubricants that have been allowed to remain on the electrode wire can result in a glazed condition within the contact tube and can increase the resistance to current passage. Electrode wire that has insufficient temper is a potential source of trouble, because the resulting low bearing pressure of the electrode within the contact tube can cause arc instability.

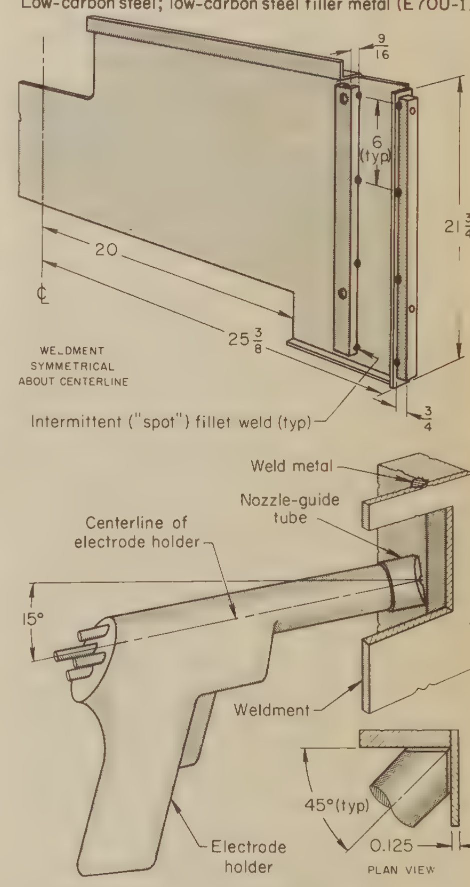


Conditions for Automatic Gas Metal-Arc Welding

Joint type	Butt
Weld type	Groove
Power supply	300-amp, 40-v rectifier, with variable inductance
Electrode wire	0.030-in.-diam(a)
Electrode holder	Mechanically held, water cooled
Wire-feed system	Automatically controlled
Current:	
Root pass	180 amp, dcrp
Fill pass	175 amp, dcrp
Voltage	32 v
Shielding gas:	
At electrode	75% argon – 25% carbon dioxide, at 30 to 40 cfh
Backing gas	Argon, at 40 to 50 cfh
Welding position	Flat
Number of passes	Two
Preheat and postheat	None

(a) 0.20 C, 1.0 Cr, 1.0 Mo, 0.10 V

Fig. 36. Partial view of a compressor casing, produced in two halves, for which a change from shielded metal-arc welding to automatic gas metal-arc welding decreased welding time and weld repair (Example 102)



Power supply	Constant-voltage rectifier
Electrode wire	1/16-in.-diam E70U-1
Electrode holder	Portable automatic, with constant wire-feed rate
Current	380 to 400 amp, dcsp
Voltage	30 v
Arc time, cycles	25(a)
Shielding gas	Argon plus 27% oxygen, at 14 cu ft per hour (measured by flowmeter)
Welding position	Vertical(a)
Bead size	1/4-in. fillet leg and 1/4 in. long(a)

(a) Electrode holder was stationary during arc time. On panels of other designs, welds were made in the horizontal position (with the electrode holder at 45° to joint), at an arc time of 35 cycles. These horizontal welds also had 1/4-in. fillet legs, but were 5/16 in. long.

Fig. 37. Motor-end panel (top) *in which "spot" fillet welds were made by timed intermittent gas metal-arc welding, using a portable electrode holder with a nozzle-guide tube, positioned as shown at bottom* (Example 103)

Erratic Wire Feeding. When small-diameter electrode wires are fed through relatively long flexible cables such as those used in semiautomatic gas metal-arc welding systems, sharp bends and turns in the cable can cause varying amounts of friction at these points, which in turn causes jumpy and erratic electrode-wire feed. This variation in friction can be significantly reduced by using lubricant-impregnated cable liners. Cable liners of nylon and teflon are also available. The use of cables and liners considerably larger in diameter than the electrode wire being used can also result in erratic feeding by allowing the wire to collapse or kink between the feed rolls and the contact tube.

Feed-roll slippage, a problem with some installations, can often be prevented by the use of knurled rolls, multiple rolls, or rolls designed to produce a locking taper with the wire.

Wire-Feed Motor Capacity. Some wire-feed systems have borderline torque capacity, which can cause variations in feeding rate. This is particularly prevalent in semiautomatic push systems, where there is a likelihood of varying torque requirements because of the frequent bending of the flexible cables. Wire-feed motors that have high torque capacity are therefore essential.

Power Fluctuations. In some critical applications, a sudden rise or fall of voltage in the main line supplying the welding power can cause difficulties, the severity of which depends on the type of welding being performed and the number of welding machines being supplied by the primary circuit. In most applications, power changes that occur over relatively long time periods will cause little trouble, since manual machine adjustments can compensate for them. However, wide power changes that occur because of high starting-power requirements of equipment on the same circuit can disrupt the equilibrium of the arc and increase the occurrence of defective welds. Any of three methods can effectively compensate for power fluctuation: (*a*) use of separate power-supply circuits that will not be susceptible to abrupt voltage swings for critical welding applications; (*b*) use of a motor-driven alternator or other type of line-voltage compensator between the power-supply line and the welding-power supply; and (*c*) use of welding-power supplies designed to provide line-voltage compensation.

Cost

Each application must be considered separately in selecting the most economical welding process. However, when an application is well adapted to gas metal-arc welding and when arc time is more than half of the floor-to-floor time, gas metal-arc welding usually costs less than shielded metal-arc welding.

In one plant, welding costs were studied for eight years. At the beginning of the study, approximately 85% of the welding was shielded metal-arc and 15% was gas metal-arc. At the end of the study only about 5% of the welding was shielded metal-arc and 95% was gas metal-arc. Results are shown graphically in Fig. 38. The upper curve in Fig. 38 shows that the average wage of welders increased about 65%. Despite this increase, total cost per pound of weld deposited decreased approximately 45% (lower curve). The fluctuation in cost of expendable welding materials (center curve) was caused in part by changes in the cost of shielding gas.

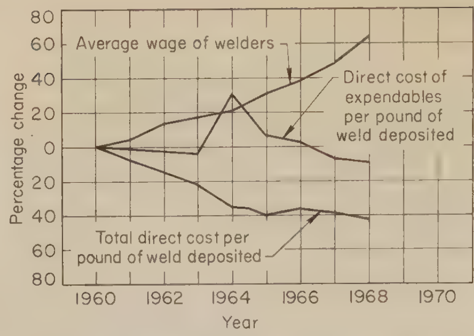


Fig. 38. Reduction in total welding cost, despite higher labor cost, by a gradual change from shielded metal-arc to gas metal-arc welding over eight years

Variables that can influence the cost of gas metal-arc welding, especially in the production of quantities of similar weldments, include the type of shielding gas used (see Examples 78 and 79), size of electrode wire (see Example 106), and joint design (see Example 81). Fit-up, because it affects arc time and welding speed, can also influence cost. Fit-up is generally more significant in gas metal-arc welding than in shielded metal-arc welding (see the section "Fit-up" on page 14 in the article on Shielded Metal-Arc Welding).

Table 7. Costs and Conditions for Gas Metal-Arc vs Shielded Metal-Arc Welding of a Radiator-Support Assembly (Example 104)

Item	Shielded metal-arc welding	Gas metal-arc welding
Cost per Foot of Weld		
Labor, at $2.50/hr	$0.1605	$0.0634
Overhead, at $5/hr	0.3210	0.1268

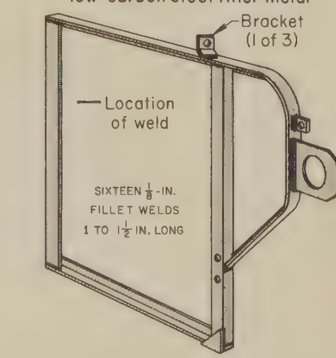
Wt of deposit, lb/ft	0.106	0.106
Deposit efficiency, %	68	95

1010 steel, 0.059 to 0.119 in.; low-carbon steel filler metal



(a) At $0.12 per pound. (b) At $0.32 per pound. (c) At $0.01 per cubic foot. (d) Composition: 0.07-0.19 C, 0.90-1.40 Mn, 0.30-0.50 Si, 0.025 max P, 0.035 max S.

Production Examples. In Examples 104 and 105, which follow, welding costs were reduced by changing from other processes to gas metal-arc welding. In Example 106, costs for gas metal-arc welding were reduced by a change to a larger-diameter electrode wire.

Example 104. Change From Shielded Metal-Arc to Gas Metal-Arc Welding That Reduced Welding Cost by 54% (Table 7)

A cost comparison and time study of the welding of radiator-support assemblies for trucks showed that gas metal-arc welding was more economical and required less time than shielded metal-arc welding, under the conditions shown in Table 7. The assembly, which is also shown in Table 7, was of cold rolled 1010 steel sheet 0.059 to 0.119 in. thick and required 16 fillet welds that were 1 to 1½ in. long. It was tack welded together in both vertical and horizontal positions before welding, and then placed in the best position for final welding by use of a positioner.

The cost comparison, details of which are given in Table 7, showed that the total cost per foot of weld for shielded metal-arc welding was $0.50, compared with $0.23 for gas metal-arc welding (a saving of 54% in cost per foot).

The time study showed that welding time per piece was 0.300 hr for gas metal-arc welding, compared with 0.442 hr for shielded metal-arc welding. In one year, time saved on 3404 assemblies was 484 hr.

Example 105. Change From Submerged-Arc to Gas Metal-Arc Welding That Reduced Welding Cost by 34% (Fig. 39)

In the production of a low-carbon steel support-bracket assembly for a camshaft and chamber (see Fig. 39), two circumferential fillet welds were used to join one end of a machined tube to a bracket, and the other end to a flange.

Originally, after the components had been tack welded, the assembly was mounted in a welding lathe equipped with air clamps and an air-operated, adjustable-stroke tailstock, and the fillet welds were made by the submerged-arc process, under the conditions listed in the table with Fig. 39. Production rate was 23 assemblies per hour, or 10,000 per month. Hand repair of welds was required on 10% of the assemblies, because of difficulty in controlling the position of the electrode. Also, a dam was required for holding the flux in position (see Fig. 17 on page 58 in the article on Submerged-Arc Welding), and it was difficult to keep the flux clean.

To overcome these drawbacks, processing was changed to gas metal-arc welding, in which two specially designed machines, controlled by one operator, were used to weld both joints simultaneously. The use of gas metal-arc welding reduced weld repairs to ½%, reduced welding costs by 34% (see cost comparison in the table with Fig. 39), and increased production rate to 70 assemblies per hour, or 30,000 per month. Most of the cost saving resulted from a 50% decrease in setup time.

The machines for gas metal-arc welding were used with a welding lathe that had an air-operated tailstock. A quick-change dividing head was located on the tailstock so that the bracket and flange would have the proper angular relationship after the assembly was clamped together. Two electrode holders were positioned to make the two fillet welds simultaneously as the assembly was rotated in the lathe. A variable-speed drive was mechanically linked to both

the headstock and the tailstock. To prevent arc blow, clamping fixtures in the headstock and the tailstock were independently grounded.

All components were washed before being welded. The bracket was positioned on the headstock of the welding lathe and clamped, and the tube was inserted in the round hole in the bracket. The flange was mounted on the quick-change dividing head on the tailstock. When the tailstock was advanced, the flange was forced onto the tube, and the assembly was clamped together at the end of the stroke. Welding conditions are given in the table that accompanies Fig. 39.

Quality control of the assembly consisted of hourly visual inspection and weld-size measurement. Periodic metallurgical examination of sections cut from weldments determined the solidification characteristics of the weld metal.

Example 106. Increase in Electrode Size That Reduced Cost by Increasing Welding Speed (Table 8)

In gas metal-arc tack welding a truck-frame siderail subassembly (illustrated in Table 8), downtime was excessive because of *(a)* erratic contact and arcing in the electrode-holder contact tube; *(b)* soiled condition of the contact tube; *(c)* the use of a tapered nozzle, which increased the occurrence of arcing between the electrode wire and the contact tube; and *(d)* kinking of the electrode wire, which occurred because of its small diameter (0.035 in.) and because the cable assembly was located on the floor.

These faults were remedied by substituting a straight nozzle for the tapered nozzle; by locating the control box in an overhead position, so that the electrode wire could travel vertically to the electrode holder; and by using a larger-diameter (0.045-in.) electrode wire, which was stiffer and thus more resistant to kinking.

In addition to helping to reduce downtime, the change to the larger-diameter wire resulted in a 31% decrease in cost per foot of weld (see Table 8). This occurred because current input was increased to accommodate the melting (burnoff) characteristics of the larger wire, and the increase in current required an increase in welding speed, to avoid melt-through of the relatively thin steel sheet. Welding conditions employed with the two sizes of electrode wire are compared in Table 8.

Table 8. Cost Saving That Resulted From a Change From 0.035-In. to 0.045-In. Electrode Wire (Example 106)

Item	Diameter of wire, in. 0.035	0.045
Cost per Foot of Weld		
Labor, at $2.50/hr	$0.0634	$0.0423
Overhead, at $5/hr	0.1268	0.0846
Electrode wire	0.0084(a)	0.0107(b)

(a) Includes cost of flux. (b) Drooping-voltage type, with high-frequency start. (c) Lathe also had an air-operated, adjustable-stroke tailstock, and a 360°-indexing headstock clamp. An alignment fixture with a dividing head was used for tack welding components in proper angular position before final welding.
(d) 100% fill. (e) Constant-voltage type, with high-frequency start and stub-burnoff delay. (f) 0.24 lb consumed per assembly. (g) With automatic positioning and retraction.

Fig. 39. Assembly with two circumferential fillet welds that were made at less cost by gas metal-arc than by submerged-arc welding (Example 105)

Gas Metal-Arc Welding vs Alternative Welding Processes

The welding processes that are usually the most closely competitive with gas metal-arc welding for joining of carbon and alloy steels are shielded metal-arc welding, flux-cored arc welding, and submerged-arc welding. (These three processes are discussed in the articles that begin, respectively, on pages 1, 24 and 46 in this volume.)

Gas metal-arc welding is generally faster than shielded metal-arc welding, which is not readily adaptable to automatic welding. Shielded metal-arc welding, however, may be preferred for difficult-to-reach locations and for outdoor applications.

Flux-cored arc welding, which can be automated, is sometimes more economical than gas metal-arc welding, depending mainly on whether or not a shielding gas is used to supplement the shielding provided by the flux.

Examples of Improvements Obtained by Use of Gas Metal-Arc Instead of Shielded Metal-Arc Welding

The 14 examples that follow describe applications in which production rate was increased, weld quality was improved, or other benefits were obtained, by a change from shielded metal-arc welding to gas metal-arc welding. Other applications for which gas metal-arc welding proved superior to shielded metal-arc welding are described in Examples 85 and 104, in this article.

Example 107. Saving of 29% in Total Time

Lap and corner joints in various sizes and shapes of fuel tanks made of ⅛-in.-thick low-carbon steel required ⅛-in. fillet welds to be made in several positions. Originally, the tanks were shielded metal-arc welded, with 5/32-in. E6012 electrodes and 175-amp current, at a travel speed of 13 in. per minute.

Subsequently, processing was changed to gas metal-arc welding. As a result, total time, including time for handling and cleaning, was reduced 29%, because in gas metal-arc welding:

1. Arc time was reduced 44.5%, because travel speed was increased from 13 to 25 in. per minute.
2. Time for cleaning was reduced because there was no slag to remove.
3. Amount of repositioning was reduced because gas metal-arc welding is more adaptable to multiple-position welding.

The gas metal-arc welding was done with 0.045-in.-diam electrode wire, fed at 240 in. per minute, with the power supply set at 20 volts. Shielding gas was a mixture of argon, at 15 cu ft per hour, and carbon dioxide, at 5 cu ft per hour.

Examples 108, 109, and 110. Reductions in Floor-to-Floor Time (Fig. 40)

Figure 40 shows three farm-equipment components — a filter housing (Example 108), an axle arm (Example 109), and a bracket (Example 110) — for which a change from shielded metal-arc to semiautomatic gas metal-arc welding resulted in savings in floor-to-floor time of 54%, 52%, and 58%, respectively. These savings significantly reduced production costs. Floor-to-floor times, together with welding conditions,

Fig. 40. Three farm-equipment components for which floor-to-floor time was reduced by a change from shielded metal-arc to semiautomatic gas metal-arc welding, under the conditions shown in table (Examples 108, 109 and 110)

are compared for the two processes and the three components in the table with Fig. 40. As this table shows, gas metal-arc welding also required less filler metal — mainly because it was not necessary to pile up filler metal to prevent melt-through.

Example 111. Doubled Production Rate, Despite Short Arc Time, for Welding Lugs to Plate

In the fabrication of a 3-lb cowl-support floorplate, four ¼-in. fillet welds ½ in. long and two ¼-in. fillet welds 1 in. long were required for attaching lugs to the plate (⅜-in.-thick low-carbon steel).

Originally, shielded metal-arc welding was used, and production rate was 16 floorplates per hour. When monthly production requirements increased from 400 to 1000 floorplates, the purchase of equipment for semiautomatic gas metal-arc welding was warranted. The change to gas metal-arc welding resulted in more than a twofold increase in production rate — to 34 floorplates per hour.

The large increase in production rate for a weldment of this type was unusual, because arc time per piece was only 20 sec. Because the weldment was light and could be quickly positioned by the use of a simple fixture, and because the joints were readily accessible, the ratio of arc time to setup and handling time was large enough to make semiautomatic welding practical. Elimination of deslagging (required for shielded metal-arc welding) contributed significantly to the increased production rate for gas metal-arc welding.

Example 112. Increase of 84% in Welding Speed, and Elimination of Repositioning (Fig. 41)

Figure 41 shows a fuel tank with a baffle fillet welded in place; both parts were of 0.150-in.-thick low-carbon steel sheet.

Originally, the assembly was shielded metal-arc welded, with 5⁄32-in. E6012 electrodes, but frequent repositioning of the work was required to obtain a maximum welding speed of 13.6 in. per minute.

When processing was changed to gas metal-arc welding, repositioning was eliminated, welding speed was increased 84%, and weld quality was improved. The assembly was positioned as shown in Fig. 41, and the ⅛-in. fillet welds were deposited at a welding speed of 25 in. per minute. No difficulty was encountered with the welds that had to be made in the vertical-down position. Little weld spatter was produced, and only minimum cleaning was required. Other conditions for gas metal-arc welding are given in the table with Fig. 41.

Example 113. Improved Weld Quality and Increased Production Rate (Fig. 42)

A 1⁄16-in. fillet weld 3⁄16 in. long was made in a corner joint on an electrical mounting base (see Fig. 42), which was subsequently zinc plated and chromate treated. Originally, the joint, which had a 1⁄32-in. root opening to simplify forming of the part, was shielded metal-arc welded, four workpieces being clamped onto a fixture for each setup. This arrangement made it difficult to locate the weld accurately, and as a result weld quality was poor. In addition, there was excessive weld spatter, which complicated the zinc-plating operation. Production rate, about 250 pieces per hour, was unsatisfactory.

A change to gas metal-arc welding, using a hand-held electrode holder, provided the following two improvements in technique.

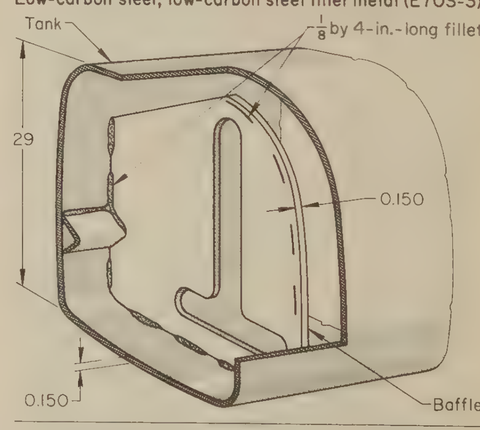
1 The electrode holder had a positioning guide, which facilitated locating the weld.
2 A new fixture (a simple rack type) that held ten workpieces and that eliminated clamping of the parts was constructed. Use of this fixture reduced loading and unloading time.

Figure 42 shows the electrode holder and fixture; the operating conditions for gas metal-arc welding are given in the table that accompanies Fig. 42. The simplified torch positioning eliminated false strikes and spatter, and improved weld quality. Locating time, welding time and loading time were reduced, and the improvement in production increased output to 643 pieces per hour.

Before welding, workpieces were degreased and loaded, ten at a time, into the fixture. As shown in Fig. 42, they were tilted 45°, which permitted the joint to be welded in the flat position and the electrode holder to be held vertical. The electrode holder, whose accessibility was limited by the adjacent flanges, was positioned on the first workpiece with the guide against the appropriate flange; it was then triggered and held during timed fillet welding. The procedure was repeated for the nine other workpieces in the fixture. Each weld was checked visually for loose weld spatter before the parts were removed from the fixture, and one part in each batch was checked with a pry bar to proof test the weld. If the weld was good, the test was nondestructive.

To maintain weld quality, the nozzle and the contact tube were cleaned at regular specified intervals. In addition, the settings of the welding machine and timer, the speed of the electrode wire, and the flow rate of the shielding gas were checked at least once every day.

Low-carbon steel; low-carbon steel filler metal (E70S-3)



Conditions for Gas Metal-Arc Welding

Joint type	T
Weld type	Fillet
Power supply	400-amp, constant-voltage rectifier

Welding speed	25 ipm

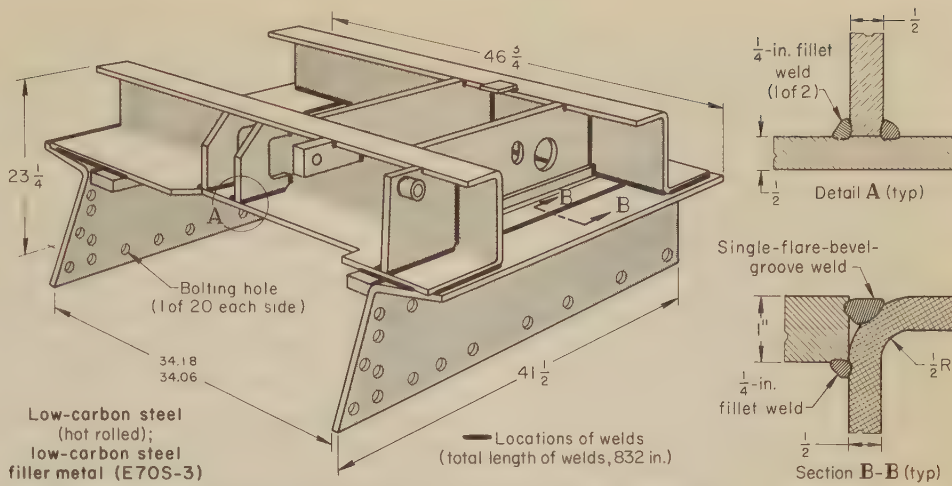
Fig. 41. Fuel tank and baffle for which a change from shielded metal-arc welding to gas metal-arc welding eliminated repositioning, increased welding speed 84%, and improved weld quality (Example 112)

Example 114. Reduction in Welding Time, Distortion, Weld Repairs and Cleaning Time (Fig. 43)

A 430-lb main base for a truck-mounted 15-ton winch was fabricated by welding components made from hot rolled low-carbon steel ½ in. and 1 in. thick, as shown in Fig. 43. The base was subsequently bolted to the truck frame through matching holes, which had been punched in the plates before forming. During forming and welding, opposing pairs of holes had to be kept aligned within a total tolerance of about 0.010 in., to facilitate subsequent use of a bridge reamer and insertion of bolts.

Originally, the base was shielded metal-arc welded with a 5⁄16-in. E7024 electrode, using 260-amp direct current from a rectifier. The components were in the mill-finish condition and had no edge preparation. Welding time per assembly was 13 hr. Two types of distortion occurred: (*a*) warping of mating surfaces, and (*b*) misalignment of bolting holes on assembly.

When semiautomatic gas metal-arc welding, with a spray arc, replaced shielded metal-arc welding, welding time per assembly was reduced to 10 hr, and faster welding resulted in less distortion. Also, weld repairs were minimized, and because of the absence of slag, cleanup time (chipping) per assembly was reduced by 30 min; electrode-drying ovens were not needed. Existing welding machines were used, although



Conditions for Semiautomatic Gas Metal-Arc Welding

Joint types	Butt, corner, T, lap
Weld types	Groove, fillet
Power supply	300-amp, constant-voltage transformer-rectifier

Welding position	Flat
Wire-feed rate	110 ipm
Welding time	22 cycles
Production rate	643 pieces per hour

(a) Timer controlled. Nozzle had a positioning guide (see drawing) to locate it in corner joint and against adjacent flange. (b) From cylinder.

Fig. 42. Electrical mounting base for which a change from shielded metal-arc to gas metal-arc welding improved weld quality and increased productivity (Example 113)

machine maintenance increased. Welding conditions are in the table with Fig. 43.

As before, the parts were welded in the mill-finish condition, without surface preparation. Subassemblies were welded on locating fixtures, to maintain alignment of the bolting holes. The fixture used for final assembly utilized the same holes for locating as were used in subassembly, to maintain proper hole locations. All assemblies were shot-blast cleaned after welding; chipping was sometimes needed.

The welders were certified according to the applicable military specifications, and there was constant visual inspection of work in process by qualified specialists.

Examples 115 and 116. Savings in Time for Welding, Straightening and Cleaning (Fig. 44 and Table 9)

The two low-carbon steel splash guards shown in Fig. 44 had to be clean and smooth for painting, and flat for attachment to a machine frame. After welding, the necessary flatness was obtained by rocking each weldment on a flat plate and straightening it with a hammer until rocking was negligible. Then the weldments were disk sanded and finish machined, before being painted and fitted to the machine frame.

Originally, these splash guards were shielded metal-arc welded, using an ⅛-in. covered electrode. Straightening time was excessive (see table with Fig. 44).

The process was changed to gas metal-arc welding, under the conditions listed in Table 9. As the comparisons in the table with Fig. 44 show, the change resulted in reductions in time for straightening to correct distortion, reductions in welding time (mainly because there were no interruptions for changing electrodes and for cleaning the weld to restrike the arc), and reductions in cleaning time (because slag removal was eliminated).

Example 117. Reduction in Welding and Cleaning Time (Fig. 45 and Table 9)

A sump tank, used for collecting lapping compounds, was produced from low-carbon steel by bending a sheet to a U-shape to form the long sides and sloping bottom, and then welding end panels, a splash plate, corner baffle, and fittings to the formed sheet as shown in Fig. 45. The major requirement, apart from leaktightness, was that the interior of the tank be relatively smooth, clean, and free of sharp corners and pockets. The splash plate and the corner baffle helped to promote circulation and to prevent the buildup of solids, as well as to simplify cleanout. Single-pass welds, as shown in the joint details in Fig. 45, provided satisfactory joints for all components.

Originally, the tank was welded by the shielded metal-arc process, using an ⅛-in. covered electrode. Total time per tank was 80 min, of which positioning and welding required 60 min, and cleaning and dressing of the welds required 20 min. Removal of slag from welds in the interior of the tank accounted for 4 min of the cleaning time, which was considered excessive.

When processing was changed to the use of gas metal-arc welding, under the conditions given in Table 9, total time per tank was reduced to 57 min — 42 min for positioning and welding, and 15 min for cleaning and dressing of the welds. The greatest portion of the 25% reduction in

Table 9. Conditions for Gas Metal-Arc Welding the Splash Guards and Sump Tank Shown in Fig. 44 and 45 (Examples 115, 116 and 117)

Power supply	300-amp, three-phase, constant-voltage rectifier, with variable slope control and variable inductance
Electrode wire	0.035-in.-diam E70S-3
Electrode holder	Hand held, 250 amp, air cooled
Wire feed	Push type, controlled speed
Current	160 amp, dcrp
Voltage	22 v
Arc type	Short circuiting
Shielding gas	Carbon dioxide, at 20 cfh (from cylinders, flowmeter controlled)
Number of passes per weld	One
Wire-feed rate	130 ipm
Stickout	5⁄16 in.
Welding speed	60 ipm
Joint penetration	25%

postweld cleaning time occurred because the interior of the sump tank required no cleaning following gas metal-arc welding.

Examples 118, 119 and 120. Reductions in Electrode Consumption, Arc Time and Floor-to-Floor Time (Fig. 46)

Figure 46 shows three 1020 steel weldments — a mast (Example 118), a bracket (Example 119), and a retainer (Example 120) — that, although varying widely in size, shape, and the amount of welding required, were designed for joining with 3/16-in. fillet welds.

Originally, shielded metal-arc welding was used, but to increase production rate, a change was made to semiautomatic gas metal-arc welding. As shown in the table with Fig. 46, the change resulted in reductions in electrode consumption and arc time, and floor-to-floor time was decreased by about 48% (Example 118), 29% (Example 119), and 43% (Example 120).

Before the change to gas metal-arc welding, flux-cored arc welding had been tried. Although floor-to-floor times and arc times were less than with shielded metal-arc welding (but by smaller percentages than the reductions obtained by gas metal-arc welding), the flux-cored arc process was not used because 1/4-in. fillet welds were the smallest that could be made in production.

Examples Comparing Gas Metal-Arc Welding With Joining Processes Other Than Shielded Metal-Arc Welding

The six examples that follow present comparisons of gas metal-arc welding with submerged-arc welding, oxyacetylene welding, gas tungsten-arc welding, resistance spot welding, braze welding, and copper brazing. For the applications described in these examples, gas metal-arc welding proved superior to the alternative process. Another application in which gas metal-arc welding gave improved results and lower cost is described in Example 105 (comparison with submerged-arc welding).

Example 121. Change From Submerged-Arc Welding to Gas Metal-Arc Welding for Faster Welding of Brake Drums (Fig. 47)

The 10-in. brake drum shown in Fig. 47, which is typical of a variety of brake drums for automotive passenger cars and light trucks, required two circumferential fillet welds at lap joints (identified as welds A and B in Fig. 47).

Originally, the joints were submerged-arc welded in separate operations. Then, processing was improved by submerged-arc welding both joints simultaneously, with increased current and voltage. This reduced welding time by 66%, but the cost per pound of weld, for electrode wire and flux, increased from \$0.24 to \$0.26.

A second improvement was to gas metal-arc weld both joints simultaneously. By this method, cost per pound of weld, for electrode wire and shielding gas, was reduced to \$0.15, and welding time was 31% less than that for the simultaneous submerged-arc welding.

The drum was made by centrifugally casting gray iron into the fabricated drum band and subsequently rough boring and facing the cast surfaces. Welding by all three procedures was fully automatic, and was done with machines built specifically for brake-drum welding. These machines advanced the preassembled cooling flange and drum band, positioned the drum back on the drum band, located the assembly for welding, rotated the assembly in a fixture during welding, and ejected the welded assemblies. Other welding conditions for the three procedures are included in the table accompanying Fig. 47.

After being welded, the brake drums were inspected visually for weld defects. Periodically, samples were sectioned to check weld penetration, weld soundness, and weld location.

Example 122. Change From Oxyacetylene Welding to Gas Metal-Arc Welding That Eliminated Finishing Operations and Reduced Welding Time by 39% (Fig. 48)

The center post and corner posts of a truck-windshield frame were joined to the sill, cowl and header by 1/32-in. fillet welds, as shown in Fig. 48. Good penetration was required in all welds, and limited weld buildup was essential to give a good finish for painting.

Originally, oxyacetylene welding was used, but grinding and abrasive blasting were required to produce a surface for painting.

When a change was made to semiautomatic gas metal-arc welding, the finishing operations were eliminated, welding time was reduced by 39%, and an over-all labor savings of 22% resulted. Rejection rate was less than 1%, and the rigidity of the assembly was increased 30%.

For gas metal-arc welding, the workpieces were manually loaded and clamped in a fixture before welding, and the assembly was removed by hand after welding; welding conditions are given in the table accompanying Fig. 48.

Example 123. Change From Gas Tungsten-Arc to Gas Metal-Arc Welding That Increased Production Rate and Decreased Rejection Rate (Fig. 49)

A link for an aircraft nose wheel had four bushings, a bolt stop and a bumper block welded to it, as shown in Fig. 49, and the welded assembly was subsequently

(a) Shielding gas was a mixture of 98% argon and 2% oxygen, supplied from cylinders at 24 cu ft per hour. (b) Shielded metal-arc welding was done with E7018 electrodes ($\frac{5}{32}$ in. in Examples 118 and 119, $\frac{1}{8}$ in. in Example 120). In all three examples, gas metal-arc welding was done with 0.045-in.-diam E70S-3 electrode wire at a feed rate of 440 in. per minute.

Fig. 46. Three different weldments, joined by $\frac{3}{16}$-in. fillet welds, for which production time was reduced by changing from shielded metal-arc to semiautomatic gas metal-arc welding (Examples 118, 119 and 120)

fitted, aligned, reamed and straightened, before being magnetic-particle inspected.

Originally, the components, after being tack welded, were gas tungsten-arc welded, under the conditions listed in the table with Fig. 49. Production rate was 30 weldments per 8-hr day. In magnetic-particle inspection, 50% of the weldments were rejected and required weld repairs and subsequent realignment.

To increase production rate and reduce rejection rate, processing was changed to gas metal-arc welding, which did not require the tack welding operation necessary with gas tungsten-arc welding. Automatic tooling was used for the bolt stop and the bumper block. Conditions for gas metal-arc welding are given in the table with Fig. 49.

The production rate per day by gas metal-arc welding was 100 assemblies. Magnetic-particle tests of the first production run of 100 assemblies resulted in six rejected assemblies, but the defects were minor and no realignment was needed after weld repair. Also, fitting required was negligible, and reaming of the bushings was easier than after gas tungsten-arc welding.

With the gas metal-arc process, the ¼-in.-long bushings for the complete production run were welded first. For this step, a jig was bolted to a turntable. The electrode holder was held in place by a clamp on the arm, and handwheels were used to adjust it vertically, horizontally front to back, and horizontally left to right. Before welding, the bushing was nested in the jig through the link, and the link was fastened to the jig with a spring clamp. After the ¼-in.-long bushings had been welded, the jig was relocated to weld the ⅜-in.-long bushings.

The bumper block also was located by a jig. A pin was inserted through the end of the link containing the ⅜-in.-long bushings and a hole in the end of the welding jig. The bumper block was located by a hole in the face of the jig and the corresponding hole in the bumper block.

The bolt stops were located by placing a bolt in the bushing and placing the bolt stop against the bolt face. The bolt stop was then welded to the link and bushing.

Example 124. Change From Resistance Spot Welding to Gas Metal-Arc Welding for 60% More Production (Fig. 50)

Figure 50 shows a sheave consisting of two matching components (of hot rolled, pickled and oiled low-carbon steel sheet, 0.135 in. thick) welded at an edge joint. The primary requirement of the welded joint was the provision of a solid backing for a belt pulley in fairly severe service.

Originally, the sheave components were joined by 16 resistance spot welds ⅜ in. in diameter, equally spaced around the periphery of the sheave (see left view in detail A, Fig. 50). Welds were satisfactory, but welding time per sheave was 1 min, and production rate was 32 sheaves per hour.

By changing to automatic gas metal-arc welding, under the conditions listed in the table with Fig. 50, welding time per sheave was reduced to 40 sec, and production rate was increased to 51 sheaves per hour. The gas metal-arc weld was a continuous weld along the periphery of the edge joint between the two components (see view at right in detail A in Fig. 50). During the gas metal-arc welding cycle, the operator was able to stack parts and to remove the small amount of weld spatter.

Example 125. Change From Braze Welding to Gas Metal-Arc Welding That Eliminated Failures and Reduced Cost by 50% (Fig. 51)

Fig. 47. Brake drum for which gas metal-arc was faster and cost less than submerged-arc welding for two circumferential fillet welds at lap joints (Example 121)

table (Fig. 51) had to resist overloads that resulted when the outboard edge of the table was improperly used as a seat. This eccentric loading subjected the weld to a force several times greater than the weight of the seated person.

Originally, the joint was manually braze welded, but weld failures resulted because the base metal was not always properly heated. Because cold joints were difficult to detect by visual inspection, an alternative welding process was needed. Flash welding was considered, but was rejected because the production volume, which was only 150 tables per day, was too small to warrant the cost of equipment and tooling; also, a flash-removal operation would have been required.

Semiautomatic gas metal-arc welding was selected to replace braze welding. This change virtually eliminated weld failures. Also, total welding cost was reduced by 50% (see cost comparison in the table with Fig. 51), less welder skill was required, and productivity was increased.

Welding conditions for both processes are included in the table accompanying Fig. 51. The sequence of operations was similar for both types of welding. The rectangular tube was deburred and sized, and was then assembled into the formed steel plate. The assembly was clamped in a simple fixture, to maintain squareness, and was welded in the position shown in section B-B in Fig. 51. No cleaning was required following welding, because the welded joint was hidden in the final assembly to the pedestal. A visual inspection was made of each weld to control quality.

Example 126. Change From Copper Brazing to Gas Metal-Arc Welding To Eliminate Distortion (Fig. 52)

The plate assembly shown in Fig. 52 (a cover for an electrical tank) consisted principally of a cover plate and a cup, both of 1008 or 1010 steel, and two 0.312-in.-diam rods of 1112 or 1113 steel, which were joined to the plate and the cup. The four joints were required to withstand an equally distributed 800-lb pull in the direction of the axis of the rods.

At first, the rods were joined to the plate and the cup by copper brazing, because an adapter and a fitting had to be brazed on the face of the plate not visible in Fig. 52, and thus all joining could be done in a single operation. Although the brazed joints had adequate strength, the high furnace temperature for copper brazing caused distortion that exceeded tolerances on parallelism and curvature (see Fig. 52) to the extent that 50 to 75% of the brazements were rejected.

Rejections because of distortion were eliminated by the use of gas metal-arc welding for the four rod joints and low-temperature soldering for the adapter and the fitting. In spite of the normally poor weldability of 1112 or 1113 steel — because of the relatively high phosphorus and sulfur contents — the rod welds had adequate strength. Although costs for the equipment and operators for gas metal-arc welding were higher, they were offset by the elimination of rejects due to distortion. The change from brazing to welding had no significant effect on the over-all production rate of the assembly.

Gas metal-arc welding was done in two steps. First, the rods were single-bevel-groove welded to the cup (see detail A in Fig. 52) in the flat position, then the assembly was turned completely over for plug welding (see detail B in Fig. 52). The only welding-operator attention required was to turn the assembly and position the joints under the electrode holder. Conditions for gas metal-arc welding, which were the same for the groove and the plug welds, are given in the table with Fig. 52.

Safety Practice

All bulk-gas installations should be made in conformance with National Fire Protection Association Standards 51, 565 and 566, and the usual handling requirements for high-pressure gas cylinders, hoses and regulators should be followed. When gas mixtures contain oxygen, the safety requirements for oxygen cylinders should be strictly observed. The correct regulator or flowmeter, or both, should be used for each gas. Traces of grease, oil or dirt in any of the equipment that is connected to an oxygen supply can cause a violent explosion.

All welding machines should be securely grounded, to prevent accidental electric shock. Multiple-conductor line supply cables are recommended, especially for portable machines. Cables should be of sufficient size to carry the maximum current required. Insulation should be protected from cuts and abrasion, and the cable should not come in contact with oils, paints or other fluids, because deterioration may result. Damaged sections should be repaired or replaced without delay, and all connections should be tight, to prevent arcing or overheating.

Conventional fire-prevention requirements, such as removal of combustibles from the work area, should be followed. Fire prevention is particularly important when carbon dioxide is used for the shielding gas, because of danger of fire from weld spatter, which is frequently greater than when some other shielding gas is used.

Heat-resistant clothing and protective equipment are essential. For equivalent welding current, filtering lenses should be two to three shades darker than those used for shielded metal-arc welding, because the arc is brighter and ultraviolet radiation is more intense in gas metal-arc welding, especially when argon or helium is used. Depending on currents employed, lenses ranging in shade from No. 6 to No. 14 are recommended. Lenses that are too dark will cause eyestrain. For multiple-arc installations, flash goggles should be used.

Ventilation is always required, because oxygen is consumed, some ozone is generated, and toxic fumes from metal coatings or degreasing fluids may be present.

Zinc, cadmium, copper and lead coatings, and cleaning fluids such as any chlorinated compounds, should be removed before welding. The chlorinated

compounds and certain metals, such as cadmium, produce highly toxic gases under the influence of the arc. All cleaning done with volatile solvents should be isolated from welding operations, because fumes can travel a considerable distance, especially indoors.

If adequate ventilation is provided, carbon dioxide is not hazardous, even though it dissociates into carbon monoxide and oxygen in the arc. The carbon monoxide rapidly reoxidizes to carbon dioxide on cooling from arc temperatures. Tests show that the carbon monoxide concentration as close as 7 in. to the arc is not dangerous.

Careless acts such as placing the finger over the end of the welding gun to detect the electrode wire as it feeds through the contact tube, or placing the welding gun close to the ear to listen for the flow of shielding gas, should not be permitted.

Gas Metal-Arc Welding of Metals Other Than Low-Carbon Steel

Many metals other than low-carbon steel are commonly joined by gas metal-arc welding. Table 10 lists examples presented elsewhere in this volume that describe applications of gas metal-arc welding to various metals.

APPENDIX

Narrow-Gap Welding*

Narrow-gap welding is a gas metal-arc process, operating in the spray-transfer range of current densities, that was developed for making narrow welds in thick plate. The process employs a square-edge butt joint with a gap (root opening) ¼ to ⅜ in. wide, regardless of the plate thickness being joined. Feasibility studies have been conducted on steel plate up to 8 in. thick. The process is suitable for welding in all positions and has been used successfully on several carbon and low-alloy steels.

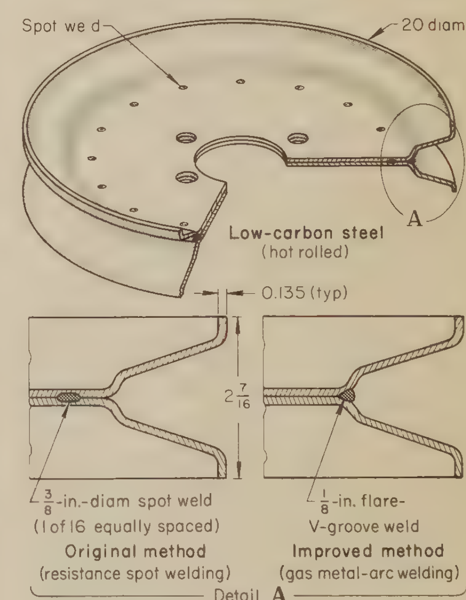
Advantages. Among the advantages claimed for narrow-gap welding are: (*a*) improved economy, because less filler metal is required for filling the joint; (*b*) good mechanical properties in the weld metal and the heat-affected zone, because the process entails relatively low heat input; (*c*) fully automatic operation in all welding positions, including overhead, when using spray-transfer welding conditions; and (*d*) improved control of distortion.

*Based on the article Narrow-Gap Welding — A Process for All Positions, by C. A. Butler, R. P. Meister and M. D. Randall, *Welding Journal*, Feb 1969.

Operating Principles. Narrow-gap welds are deposited by using special contact tubes that are inserted into the joint. In the preferred configuration, two contact tubes are used in tandem, and the electrodes are oriented so that one weld bead is directed toward one sidewall, and the other weld bead toward the opposite sidewall. Each contact tube is also guided so that it remains a fixed distance from its respective sidewall to assure proper sidewall fusion regardless of variations in gap width. Narrow-gap welding can also be done using a single contact tube centered in the joint. With this method, shielding gas is introduced into the narrow-gap joint from the plate surface by means of a special gas shield, and the weld is completed from one side of the plate.

Narrow-gap welds have been made with electrode wires ranging from 0.035 to 0.060 in. in diameter. Out-of-position narrow-gap welds are preferably deposited with the use of 0.035-in.-diam electrode wire.

Relatively high travel speeds are used because of confinement imposed by the narrow-gap joint. If slower welding speeds were used, the weld puddle would become too large to control in the narrow gap. The weld beads obtained with the high travel speeds are thin and are deposited one on top of the other to fill the joint.



Automatic Gas Metal-Arc Welding	
Joint type	Edge
Weld type	Single-flare V-groove
Power supply ..	500-amp, constant-voltage type
Electrode wire	0.045-in.-diam E70S-3

Fig. 51. Overbed table, and details of a continuous-weld T-joint at its base for which a change from braze welding to gas metal-arc welding eliminated failures and reduced cost (Example 125)

The first weld layer is deposited against a suitable backing. Approximately ten passes are required for each inch of plate thickness being joined. As a result, close control can be maintained over the composition of the narrow-gap welds.

Typical welding conditions used for welding steels with 0.035-in.-diam electrode wires are: 220 to 240 amp, 25 to 26 volts, electrode-wire feed rate of 560 to 625 in. per minute, travel speed of 40 to 45 in. per minute, and shielding gas consisting of a mixture of 80% argon and 20% carbon dioxide. These conditions provide a weld-heat input of about 7500 to 10,000 joules per inch per pass, for each electrode. A contact-tube-to-work distance of ½ in. is used. These conditions have been used for welding in the flat, horizontal, vertical and overhead positions.

The shielding gas used in narrow-gap welding depends on the metal being welded. For steel, an 80% argon – 20% carbon dioxide mixture is generally used. Premixed 75% argon – 25% carbon dioxide is also satisfactory.

Welding Equipment. Most of the equipment required for narrow-gap welding is the same as that used for conventional gas metal-arc welding. Each of the two electrodes requires its own constant-voltage direct-current power supply, welding control panel, and electrode-wire feed motor. To meet the requirements of the process, however, some special items of equipment have been developed. These include special contact tubes and a means of guiding them in the narrow-gap joint, and various devices for providing efficient gas shielding.

Because the contact tubes are inserted into the narrow gap, they must be thin. Special water-cooled copper contact tubes have been developed that are only ⅛ in. thick. The cooling-water hoses and current conductor are attached directly to each contact tube so that the whole contact tube is electrically hot. The water cooling extends to the end of the contact tube. The full-length water cooling permits the use of Teflon for electrically insulating the contact tube from the sidewalls of the joint. A 0.030-in.-wall Teflon tube is used to insulate the contact tube, so that the total thickness of the insulated tube is about 3⁄16 in. The water cooling and the Teflon also minimize the amount of weld spatter adhering to the contact tube. The contact tube is equipped with a small tip, which can be replaced when it becomes worn or if a burnback occurs. The tip is electrically insulated by a ceramic shield that also serves to extinguish the arc before it reaches the water jacket of the contact tube if a burnback occurs.

With the contact tubes inserted into the joint, a special gas shield is used that rides above the surface of the plate and introduces the shielding gas into the joint from the plate surface. On laboratory-model narrow-gap welding units this is accomplished by mounting the gas shield on a free-floating shaft in the welding head that can move perpendicularly to the plate surface. The shaft is located over the narrow gap by a self-centering tapered guide roller that also maintains the gas shield at a fixed distance above the plate surface. A flexible skirt is used on the gas shield to seal the space between the gas shield and the plate surface. The gas shield is water cooled to prevent heat buildup when welding near the surface of the plates.

At each end the gas shield has special nozzles that produce a laminar flow of gas to prevent aspiration of air into the weld region. The gas-shielding system acts to force the shielding gas to go to the bottom of the joint to escape; as a result, aspiration of air into the weld region is eliminated. The gas coverage in the welding zone is excellent: in welds made at the bottom of 8-in.-thick plates in the flat and horizontal positions, the weld beads had a bright surface as-welded.

Positioning Equipment. When the contact tubes are inserted into the narrow-gap joint and the gas shield is in place, it is difficult to see the welding arcs. Therefore, it is necessary that the contact tube be positioned accurately with respect to the sidewalls and bottom of the joint, to prevent damage

resulting from accidental contact with the sidewalls and to ensure proper fusion into the sidewalls at all times. This is accomplished by seam-tracking and proximity-sensing systems, which permit fully automatic operation of the process by compensating for variations in joint gap width and weld fill. These systems also allow more latitude in joint fit-up and alignment of the welding head with the joint.

On laboratory model narrow-gap welding units, seam tracking is done by using floating welding heads and by loading the contact tubes against the sidewalls of the joint. The welding heads are mounted to enable them to adjust transversely to irregularities in the joint while remaining parallel to the joint. Tapered roller guides locate the welding heads over the center of the narrow-gap joint and also support the gas shield. The contact tubes are spring loaded against the sidewalls and are free to adjust transversely in the joint. The contact tubes are spaced from the sidewalls by shims placed between the insulation and the tubes.

The contact-tube-to-work distance is maintained constant by the proximity-sensing system. The welding-head electrode-drive motors and wire spools of laboratory model welding units are mounted on a vertical motorized slide that moves perpendicularly to the plate surface. The motion of the slide is controlled by a roller probe that rides directly on the weld surface. The roller probe is free to move perpendicularly to the plate surface and actuates limit switches as it follows the contour of the weld. The limit switches, in turn, activate the motorized slide so that it duplicates the contour of the weld surface, thereby maintaining a constant distance between the contact tube and the work.

Out-of-Position Welding. It is necessary to maintain the distance between the contact tube and the sidewalls of the joint constant within very close tolerances when welding out of position. The floating head and spring-loaded contact tubes alone are not sufficient, because of the normal variation in the amount and direction of the cast, or curvature, of the electrode wire along the length of a coil or from coil to coil. As the cast varies, the electrode position varies with respect to the sidewalls of the joint, so that it is difficult to maintain good sidewall fusion.

The problem is solved with narrow-gap welding equipment by using a controlled-cast wire-drive system. This system decreases the final cast diameter of the electrode wire below the as-received minimum diameter and maintains both the diameter and the direction of the electrode wire constant as it exists from the contact tube. This is accomplished by introducing the electrode wire into the drive rolls at 90° from the normal position so that the wire is formed around one of the drive rolls.

By orienting the drive rolls properly, the direction of the cast in the lead and trail electrode wires can be maintained 180° apart. One electrode then can be directed toward one side of the joint, and the other electrode can be directed toward the opposite side.

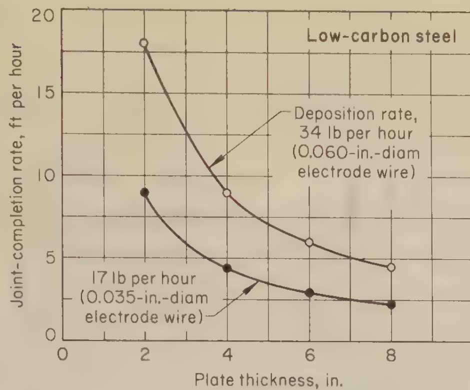

Fig. 53. Joint-completion rates for narrow-gap welding of various thicknesses of low-carbon steel plates at two deposition rates

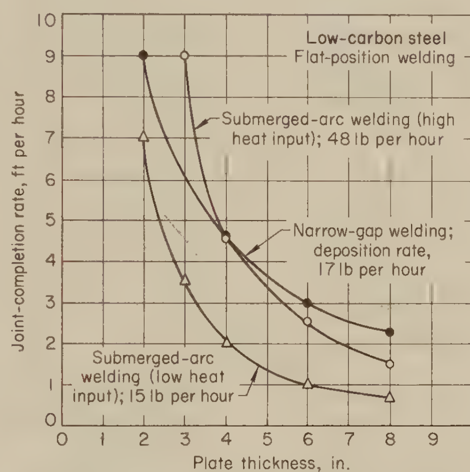

Fig. 54. Joint-completion rates for narrow-gap and submerged-arc welding of various thicknesses of low-carbon steel plates in the flat position

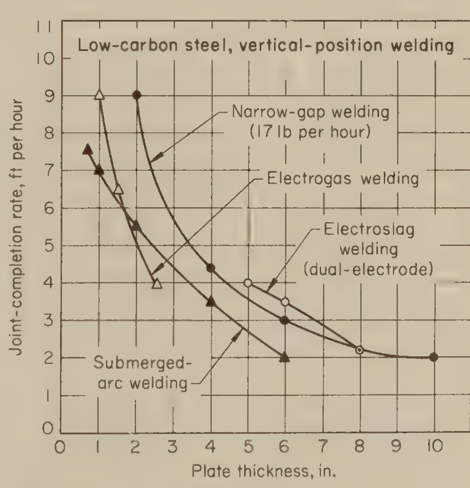

Fig. 55. Joint-completion rates for vertical-position welding of various thicknesses of low-carbon steel plates by the narrow-gap, submerged-arc, dual-electrode electroslag, and electrogas processes

Welding Applications. Narrow-gap welding systems have been proposed for both shop and field erection of large pressure vessels. One potential application, the narrow-gap welding of horizontal girth joints in large vertical steam generators, prompted a feasibility study, a part of which is described in the example that follows.

Example 127. Narrow-Gap Flat and Horizontal Welding of Steel Plates 6¾ and 8 In. Thick

As part of a feasibility study, narrow-gap welds were made in steel plates 6¾ and 8 in. thick, using a laboratory-model narrow-gap welding unit. The 6¾-in.-thick plates were of ASTM A302, grade B, steel (a manganese-molybdenum steel containing 0.20% C max, 1.15 to 1.50% Mn, and 0.45 to 0.60% Mo); the 8-in.-thick plates were of low-carbon steel. Welds in the A302 plates were made in the horizontal position; those in the low-carbon steel plates, in both the flat and the horizontal positions.

All welds were made using 0.035-in.-diam E70S-G electrode wire, and a mixture of 75% argon and 25% carbon dioxide as the shielding gas. Welding current at each of two electrodes was 260 to 270 amp at 25 to 26 volts. Welding speed, using special long contact tubes and standard gas shields, was 40 in. per minute.

Difference in plate thickness had no apparent detrimental effect on the quality of the welds. The weld beads had a bright silvery appearance, and macrosections indicated that weld soundness was satisfactory. Estimated joint-completion rate* at 100% arc operating factor was 2¾ ft per hour.

Joint-Completion Rates.* Figure 53 shows joint-completion rates for narrow-gap welding of various thicknesses of low-carbon steel plates at deposition rates of 17 and 34 lb per hour. The deposition rate of 17 lb per hour is obtained in all welding positions with the 0.035-in.-diam electrode wire normally used in narrow-gap welding of low-carbon steels or high-strength low-alloy structural steels. The 34-lb-per-hour deposition rate is obtained with larger wire (0.060-in. diam), and can be achieved only in flat-position welding.

Figure 54 compares joint-completion rates for narrow-gap welding of low-carbon steel plates with those obtained with two typical submerged-arc welding procedures. These comparisons are for flat-position welding, using a deposition rate of 17 lb per hour for narrow-gap and two deposition rates for submerged-arc — 48 lb per hour, for applications where heat-input control is not important, and 15 lb per hour, for applications where heat-input control is important. All of the curves are based on a 100% duty cycle. The submerged-arc data are for double-V grooves with a 45° included angle and a ¼-in. root face welded from both sides. The narrow-gap data are for welding from one side only. The data show that, for thicknesses greater than 2 in., narrow-gap welding compares favorably with submerged-arc welding.

Figure 55 compares joint-completion rates for vertical-position welding of low-carbon steel plates by the narrow-gap, submerged-arc, electrogas, and dual-electrode electroslag processes. Submerged-arc, electrogas and electroslag welding were done with ⅛-in.-diam electrodes. Spacing between plates was ¾ in. for electrogas welding, and 1 in. for submerged-arc and electroslag welding. All data in Fig. 55 are for 100% duty cycle. As these data show, for vertical-position welding, the joint-completion rates for narrow-gap welding are greater than for any of the other processes except dual-electrode electroslag welding (on 5-to-8-in. plate).

*Length of joint welded to full groove depth in one hour (also called joint-finishing rate).

Gas Tungsten-Arc Welding (TIG Welding)

*By the ASM Committee on Gas Tungsten-Arc Welding**

GAS TUNGSTEN-ARC WELDING (often called TIG welding) is an arc welding process in which the heat is produced between a nonconsumable electrode and the work metal. The electrode, the weld puddle, the arc, and adjacent heated areas of the workpiece are protected from atmospheric contamination by a gaseous shield. This shield is provided by a stream of gas (usually an inert gas), or a mixture of gases. The gas shield must provide full protection; even a small amount of entrained air can contaminate the weld.

Applicability

Gas tungsten-arc welding is adaptable to both manual and automatic operation, and can be used to produce continuous welds, intermittent welds (sometimes called skip welds), and spot welds. Because the electrode is nonconsumable, a weld can be made by fusion of the base metal without the addition of filler metal. A filler metal may be used, however, depending on the requirements that have been established for the particular joint.

Gas tungsten-arc welding is an all-position welding process, and is especially well-adapted to the welding of thin metal — often as thin as 0.005 in.

Metals Welded. The nature of the gas tungsten-arc welding process permits its use for welding of most metals and alloys. Metals that are gas tungsten-arc welded include carbon and alloy steels, stainless steels, heat-resisting alloys, refractory metals, aluminum alloys, beryllium alloys, copper alloys, magnesium alloys, nickel alloys, titanium alloys, and zirconium alloys.

Lead and zinc are difficult to weld by the gas tungsten-arc process. The low melting temperatures of these metals make control of the process extremely difficult. Zinc boils at 1663 F, which is far below the arc temperature, and poor welds result from vaporization of the zinc. Steels and other metals that melt at higher temperatures, but that are coated with lead, tin, zinc, cadmium or aluminum, are weldable but require special procedures.

Welds in coated metals are likely to have low mechanical properties, as a result of interalloying. To prevent interalloying in welding coated metals, the coating should be removed in the area to be welded, then repaired after welding.

Base-Metal Thickness. Gas tungsten-arc welding is applicable to a wide range of base-metal thicknesses. The process is well adapted to welding sections ⅛ in. thick or less, because of the intense, concentrated heat produced by the arc, which results in high welding speeds. Multiple-pass welding with the addition of filler metal can be done.

For base metal more than ¼ in. thick, other welding processes are generally used, although multiple-pass gas tungsten-arc welding is used for thick sections in applications where high quality is mandatory (as in aerospace work). For example, in the fabrication of a 26-ft-diam rocket-motor case with a 0.600-in. wall, longitudinal and girth welds were made by the gas tungsten-arc process, using multiple passes and filler metal. Although a slow process for metal of this thickness, gas tungsten-arc welding was used because high-quality welds were mandatory.

The gas tungsten-arc process has been successful in welding various alloys in foil thickness. Thin sheet requires accurate fixturing, and for metal of foil thickness, machine or automated welding is necessary. Plasma-arc welding, often considered as a variation of gas tungsten-arc welding, has advantages for welding thin metal (see the article on Plasma-Arc Welding, which begins on page 138).

Workpiece Shape. Manual welding is required where complex shapes preclude the use of automatic methods. Manual torch manipulation is generally used for irregularly shaped parts that require short welds, or for welding in difficult-to-reach areas. Welds can be made manually in the flat, horizontal, vertical, and overhead positions.

Automatic equipment lends itself to curvilinear and rectilinear surfaces. It has been used for special sine-wave welding of corrugated titanium to stiffeners on both ends. For this sine-wave type of weld, a mechanical tracing unit has been designed that follows a template to guide the torch. Manual control of such a weld would be extremely difficult.

Fundamentals of the Process

Because in gas tungsten-arc welding the heat is produced between the electrode and the work, edges of the workpieces are melted and are joined as the weld puddle solidifies.

To obtain welds of good quality by the gas tungsten-arc process, it is essential that all surfaces to be welded and adjacent areas be clean. Filler metal, if used, must also be clean.

Further, it is essential that the components of the assembly being welded be held firmly in the correct position relative to one another. Fixturing is necessary when fit-up is marginal, work metals are thin, shapes are complex, welding is done without filler metal, or automatic welding is used.

Arc Initiation. Some preliminary means of initiating emission of electrons and ionization of the gas is generally used for initiating (striking) the arc. Energy for this emission and ionization can be obtained by touching the energized electrode to the work and quickly withdrawing it to the desired arc length by the use of a pilot arc, or by the use of auxiliary apparatus that produces a high-frequency spark between electrode and work. Mechanical retraction of the electrode from the work is limited to mechanized welding with a direct-current power supply. Pilot arc starting, however, is applicable to both manual and mechanized welding, but is similarly limited to use with direct-current power supplies as is mechanized retraction of electrodes. High-frequency spark starting is applicable to manual welding with either alternating or direct-current power supplies. Many power supplies incorporate an apparatus that produces a high-frequency spark to initiate and stabilize the arc.

When beginning to weld, if the electrode is started (or "warmed") on a piece of copper, the arc may be started on the work metal with greater ease. Prewarming also reduces the amount of tungsten that may be lost as the result of forcing the tip of a cold electrode to support maximum current.

An ultraviolet-ray lamp, aimed at the torch tip, was used to facilitate arc initiation in Example 137.

Electrode and filler-metal positions in manual gas tungsten-arc welding are shown in Fig. 1. Once the arc is started, the torch is held so that the electrode is positioned at an angle of about 75° to the surface of the workpiece and points in the direction of welding, as shown in all views in Fig. 1. To start welding, the arc usually is moved in a circular fashion until enough base metal melts to produce a weld puddle

The assistance of E. B. LaVelle in the preparation of this article is gratefully acknowledged. The examples presented in this article were contributed by members of other Metals Handbook welding committees. A total of 108 examples of gas tungsten-arc welding appear in other articles in this volume, as recorded in Table 12, on page 138.

of suitable size (Fig. 1a). As adequate fusion is achieved, a weld is made by gradually moving the electrode along the adjoining edges of the parts to be welded, so as progressively to fuse the parts together. Filler metal, when added manually, is often held at an angle of about 15° to the surface of the work and is slowly fed into the weld puddle (Fig. 1c). Filler metal must be fed carefully, to avoid disturbing the gas shield or touching the electrode, and thereby causing oxidation at the end of the filler rod or contamination of the electrode. The filler metal may be added continuously from a rod, or the rod may be dipped in and out.

Filler metal can be added continuously by holding the filler rod in line with the weld (as is often done in multiple-pass welding of V-joints), or by oscillating the rod and the torch from side to side, with the filler rod feeding into the weld puddle (a technique often used in surfacing).

To stop welding, first the filler metal is withdrawn from the puddle (Fig. 1d), but is momentarily kept under the gas shield to prevent oxidation of the filler metal; then the torch is moved to the leading edge of the puddle (Fig. 1e) before the arc is extinguished. The arc can be extinguished by raising the torch just enough to extinguish the arc, but not enough to cause contamination of the weld crater and the electrode. Preferred practice is to decrease the current gradually with a foot control without raising the torch.

Arc length equal to about 1½ times the electrode diameter is used in many applications of gas tungsten-arc welding, but it may vary for specific applications and, particularly, according to the welder's preference. The greater the arc length, the higher is the heat dissipation into the surrounding atmosphere. Also, long arcs ordinarily interfere, to an extent, with steady progression of the weld. One exception is the bell-and-spigot joint in piping or tubing welded with the pipe axis in the vertical position; here, a long arc will produce a fillet weld of smoother contour than will a short arc.

Manual and Automatic Operation. There is a distinction between manual and fully automatic gas tungsten-arc welding. Manual welding is done by a welder; fully automatic welding, by an operator. Refinements of manual welding such as foot controls for welding current and on-off switching are first steps toward automatic welding. The use of equipment that holds and drives the torch at constant or programed speed, that automatically adjusts arc voltage (arc length), and that has provision for automatic starting and stopping constitutes fully automatic welding (see section on Automatic Welding, page 134).

Table 1. Suitability of Types of Current for Gas Tungsten-Arc Welding of Various Metals

(E = Excellent; G = Good; NR = Not recommended)

Metal welded	Alternating current(a)	Direct current: Straight polarity	Direct current: Reverse polarity
Low-carbon steel:			
0.015 to 0.030 in.(a)	G(b)	E	NR
0.030 to 0.125 in.	NR	E	NR
High-carbon steel	G(b)	E	NR
Cast iron	G(b)	E	NR
Stainless steel	G(b)	E	NR
Heat-resisting alloys	G(b)	E	NR
Refractory metals	NR	E	NR
Aluminum alloys:			
Up to 0.025 in.	E	NR(c)	G
Over 0.025 in.	E	NR(c)	NR
Castings	E	NR(c)	NR
Beryllium	G(b)	E	NR
Copper and alloys:			
Brass	G(b)	E	NR
Deoxidized copper	NR	E	NR
Silicon bronze	NR	E	NR
Magnesium alloys:			
Up to ⅛ in.	E	NR(c)	G
Over 3/16 in.	E	NR(c)	NR
Castings	E	NR(c)	NR
Silver	G(b)	E	NR
Titanium alloys	NR	E	NR

(a) Stabilized. Do not use alternating current on tightly jigged assemblies. (b) Amperage should be about 25% higher than when straight-polarity direct current is used. (c) Unless work is mechanically or chemically cleaned in the areas to be welded.

Welder Skill. Selection and training of operating personnel depend greatly on the degree of automation used. Since gas tungsten-arc welding is most frequently used for joining sheet-metal parts in applications where one welder can readily manage the relatively light, small components to be welded, the welder often spends part of his time in cleaning, assembling, fixturing and tacking. Aside from the high degree of manual dexterity, patience and training required for producing quality welds, the welder sometimes must have the mechanical skills needed for properly assembling and fixturing the components to be welded.

The specific welding skills required vary from one process to another; for instance, a welder skilled in manual shielded metal-arc welding (stick electrode) will need additional training to qualify for gas tungsten-arc welding. In addition, special skills are involved in some applications, such as the placement and welding of consumable backing rings, and repair welding.

Inspection. The inspection of gas tungsten-arc welds can encompass the full range of nondestructive techniques — from surface inspection of sheet-metal weldments, to radiographic and ultrasonic techniques for heavier weldments in which subsurface defects are more likely to occur.

Welding Current

Current is one of the most important operating conditions to control in any welding operation, because it is related to the depth of penetration, welding speed, deposition rate, and quality of the weld.

Fundamentally, there are but three choices of welding current: (*a*) direct current, straight polarity (dcsp); (*b*) direct current, reverse polarity (dcrp); and (*c*) alternating current (ac). Certain desirable effects can be obtained by superimposing high-frequency current on all three. A guide to selection of the type of current for welding various metals is presented in Table 1.

Direct current, straight polarity (dcsp), is the type of current most widely used for gas tungsten-arc welding. It can produce satisfactory welds in almost all the common weldable metals and alloys.

In welding with dcsp, the electrode is negative and the work metal is positive, so that electrons flow from the electrode to the work metal. Because in all direct-current arcs 70% of the heat is generated at the positive, or anode, end of the arc, an electrode of a given size will support more straight-polarity than reverse-polarity current. Consequently, dcsp is the type of current to use if the hottest arc for a specific size of electrode is desired.

Straight-polarity direct current produces a deep, narrow weld bead, with penetration superior to that provided by the two other types of current. The narrow bead and deeper penetration, however, may cause difficulty when thin metal is welded with dcsp. Unlike dcrp or ac, dcsp will not remove surface oxides on aluminum, magnesium, or beryllium copper, but aluminum may be welded with dcsp by the use of specialized welding techniques, plus mechanical or chemical cleaning prior to welding (see Table 1).

More skill is required when using dcsp than when welding with high-frequency-stabilized alternating current, principally because of the normal absence of a high-frequency pilot discharge when starting the arc with dcsp. High-frequency current can be superimposed on dcsp by adding special apparatus to standard machines.

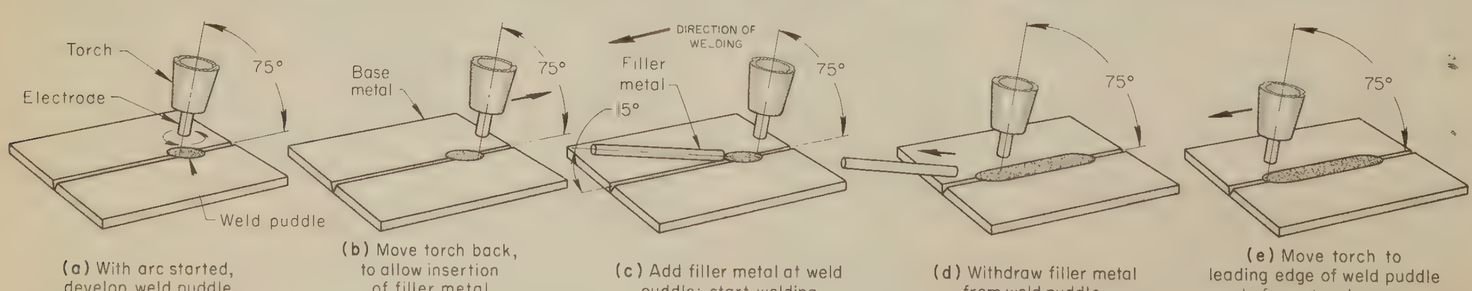

Fig. 1. Positions of the torch and filler metal in manual gas tungsten-arc welding. See text for discussion.

Direct Current, Reverse Polarity (dcrp). In welding with dcrp, the electrode is connected to the positive terminal of the power supply, and the work metal to the negative terminal. Thus, electrons flow from the work to the electrode, generating high heat in the electrode and low heat in the workpiece. At the same amperage and arc length, the arc voltage of a dcrp arc is somewhat higher than that of a dcsp arc, so that the dcrp arc has more total energy.

Reverse-polarity direct current is the least used of the three types of current, because it produces a flat, wide bead with shallow penetration. Welding with dcrp requires great skill and, because of the large size of electrode that must be used with a comparatively low level of welding current, is not generally recommended. Reverse-polarity direct current has the coldest *effective* arc of the three types of current, but it does provide superior removal of oxides from the surface of the work metal.

Aluminum is particularly difficult to weld with dcrp, because the weld puddle is readily attracted to the tip of the electrode, which becomes contaminated when touched by the aluminum. However, dcrp may be effectively used for joining thin aluminum sheet (up to about 0.025 in. thick). Magnesium, on the other hand, appears to be repelled by the arc action inherent to dcrp, and thus contamination is not a problem; dcrp may be used for welding magnesium in thicknesses up to ⅛ in.

Oxide Removal by Dcrp. Several theories have been advanced to explain the cleaning action whereby reverse-polarity direct current removes oxides from the surface of some base metals, but the generally accepted explanation is:

> When the electrode is positive, argon or helium ions travel to the surface of the base metal. Positively charged gas ions are produced through action of the arc on the surrounding inert-gas atmosphere. The gas ions have considerable mass and hence acquire large amounts of kinetic energy while speeding to the surface of the base metal. When these ions collide with the surface, they clean it by tearing away particles of oxide in a manner somewhat analogous to grit blasting. The ions produce little heating of the base metal, in comparison with the heating that occurs at the anode end of the arc; as a result, the amount of penetration is slight. If the electrode is negative and the work positive (straight polarity), the ions travel to the electrode and exert no cleaning action on the work metal, and electrons bombard the metal being welded, thus producing considerable heat and penetration of the work metal.

Metals such as stainless steel, carbon steel, and copper do not form oxide coatings that interfere appreciably with gas tungsten-arc welding.

Determining Polarity of the Welding Machine. In automatic gas tungsten-arc welding, there is little danger of starting the welding operation with the wrong polarity, because of the repetitive nature of the operation. In manual welding, however, polarity may accidentally be reversed through changing of the welding-machine leads, and it is well to test the polarity before starting to weld. This will avoid possible damage to the electrode, which would occur if a high reverse-polarity current were imposed on a small electrode.

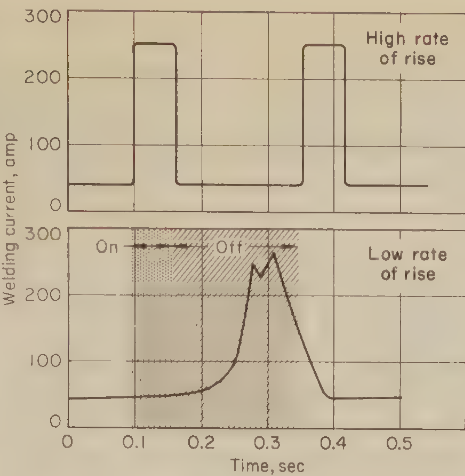

Fig. 2. Representative shapes of current pulses with high and low rates of rise

To test for polarity, a hookup for a metal-arc (stick) electrode holder can be incorporated in the circuit, and, using this holder, an arc is struck with a reverse-polarity, all-position, general-purpose shielded metal-arc welding electrode (class E6010). If the polarity is straight, the arc will have a strong, energetic hissing sound, not the energetic crackling sound of a true reverse-polarity E6010 arc.

Alternating current (ac) may be represented as a series of alternate pulses of dcsp and dcrp, and it reverses direction 120 times per second. With alternating current, the voltage varies from a maximum positive value to a maximum negative value during each cycle, and the arc is extinguished each time this occurs. A conventional arc welding transformer does not produce voltage high enough for positively re-establishing the arc after it has been extinguished when welding in an inert atmosphere; consequently, high-frequency current must be superimposed on the arc to re-establish the welding arc at each half cycle, unless the transformer used has a sufficiently high inherent voltage characteristic to render it unnecessary.

Alternating current gives good penetration and surface-oxide reduction, and the form of the gas tungsten-arc weld bead it produces when filler metal is added is more nearly that of a satisfactory shielded metal-arc deposit but with slightly less reinforcement. The bead produced in gas tungsten-arc welding with ac is wider and shallower than a dcsp bead, but narrower and deeper than a dcrp bead, and it has more reinforcement than either a dcsp or a dcrp bead. Alternating current is therefore preferred for the welding of aluminum, magnesium, and beryllium copper.

Prevention of Rectification in Alternating Current. Rectification, a phenomenon characterized by an unbalanced current sine wave caused by the unequal resistance to current flow during the positive and negative half-cycles of voltage across an alternating-current arc, may produce direct-current voltage components in the ac arc high enough to cause arc fluttering and instability. Rectification is more likely to occur in older transformers used for gas tungsten-arc welding; modern balanced-wave units are free of this.

Rectification occurs because the electrode and the weld metal emit unequal quantities of electrons. It is affected by the current density of the arc at the electrode and the workpiece, which controls the temperature of each. To some extent it is affected also by arc length and the shielding gas used. Rectification may produce dc voltage components as high as 12 volts. In the welding of aluminum, when the dc component is high the bright puddle of molten aluminum will darken and film over with oxide — the extent being proportional to the magnitude of the dc component.

Rectification, and its adverse effects, can be eliminated by the use of a balanced-wave transformer. This unit incorporates into the welding-current circuit a series capacitor (condenser) of a capacity that will permit the alternating welding current to flow efficiently but will block the direct-current component. These units are usually designed for open-circuit voltages in the range of 100 to 150 volts, require high-frequency current for arc starting only, and are used extensively in welding aluminum alloys and magnesium alloys.

Pulsed-Current Welding. Pulsed-current gas tungsten-arc welding employing a high rate of current rise and decay and a high pulse-repetition rate is widely used in the joining of precision parts. Pulsed current with slower rates of current rise and slower current-pulse rates is used in mechanized pipe welding and some other applications of mechanized welding.

Circuits have been developed that permit automatic precise control of the arc voltage of a pulsed-current tungsten arc. These circuits use the arc voltage produced by the high current pulse and lock the control during the remainder of the cycle. In sophisticated pulsed-current welding power supplies, the following may be set independently: pulse length at low current, pulse length at high current, amplitude of low-current pulse, amplitude of high-current pulse, and beginning of pulses. Figure 2 illustrates representative shapes of current pulses with high and low rates of rise, correlated with a scale of time in seconds.

The advantages of pulsed-current gas tungsten-arc welding are:

1. **Increased Depth-to-Width Ratios of Weld Beads.** By using a short-duration, high-current welding pulse with a small, blunt thoriated tungsten electrode, the arc force generated will produce weld beads in stainless steel that have depth-to-width ratios approaching two to one.
2. **Elimination of Drop-Through.** High-current, short-duration pulses will melt through root passes or thin work metal and solidify before the weld puddle becomes large enough to sag.
3. **Minimal Heat-Affected Zone.** The heat-affected zone can be minimized by proper proportioning of the high pulse height and pulse-on time and the low pulse height and pulse-on time. It is sometimes desirable to set the low pulse height at zero while holding a finite space between high-current pulses.
4. **Stirring in the Weld Puddle.** The high pulse of current develops arc and electromagnetic forces much greater than those developed with constant-

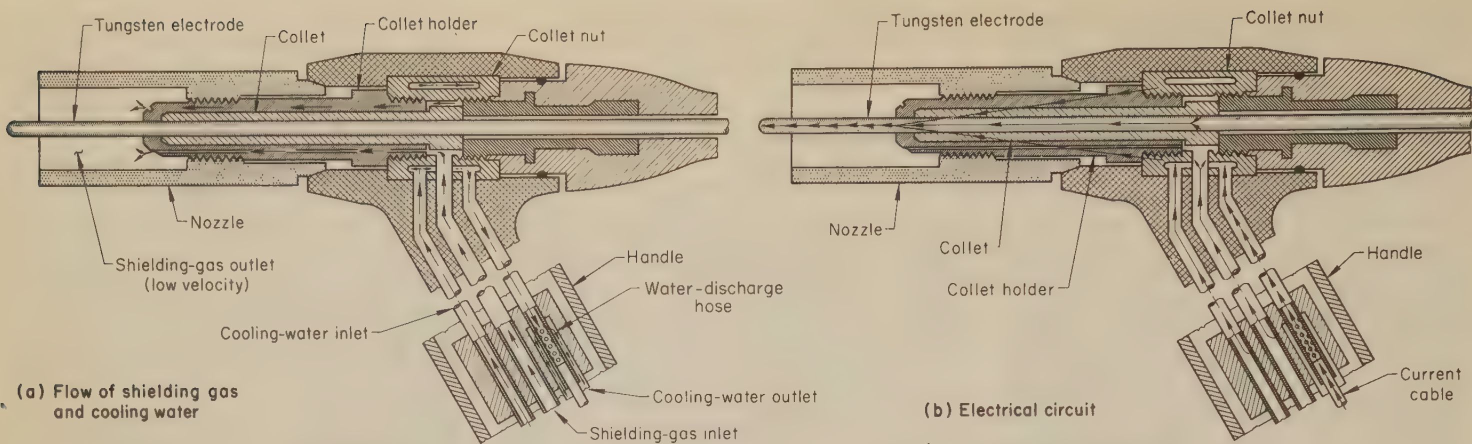

Fig. 3. Sectional views of a typical water-cooled torch for manual gas tungsten-arc welding

current welding. These high forces produce agitation of the weld puddle that reduces the porosity and incomplete fusion that may occur at the bottom of the joint. The pulsing also produces substantial arc stiffness when used for low-current welding, eliminating the arc wander associated with a low-current constant-current arc.

Power Supply

Power-supply units for gas tungsten-arc welding are: (*a*) transformer-rectifiers, for direct-current output; (*b*) transformers, for alternating-current output; and (*c*) power-driven generators — either electric-motor-driven (for dc output only) or engine-driven (for either ac or dc output).

Transformer and rectifier power supplies have several advantages over power-driven generators: low initial cost, no current dropoff during warmup, quiet operation, low maintenance and operating costs, no rotating parts, and low power input while idling.

The advantage of engine-driven generators is that they can be used in areas where electricity is unavailable.

High-Frequency (HF) Stabilization. Spark-gap or tube-type oscillators are incorporated into the circuitry of welding transformers for the purpose of starting the arc, and in some instances may be used continuously. In most early gas tungsten-arc welding done with high-frequency-stabilized alternating current, the radio interference that was generated created considerable difficulty. At present, however, vibrating relays, electron tube triggering circuits, and proper phasing of the high-frequency transformer furnishing a spark, supply a weaker discharge that interferes with radio reception to a lesser degree.

To adapt some older transformers equipped with HF-stabilized circuits to touch starting, they may be provided with a magnetic contactor in the ac power supply to be energized by a foot switch. With this setup, the welder can rest the electrode point at the desired starting location, drop his face shield, and then depress the foot switch. The arc starts when the electrode is raised from the work. This procedure is less tiring than others, and when the welder desires to stop the welding current he merely releases the foot switch.

The required intensity of HF pilot discharge depends on joint design, electrode extension, and the welder's ability to start the arc with the minimum of HF pilot-discharge current. If the weld is to be made in a deep groove joint, the HF-current intensity must be lower; otherwise, the arc will bridge the width of the groove rather than go to the root of the joint.

Excessive high-frequency stabilization may have the following undesirable effects:

1 Greater possibility of electric shock to operating personnel
2 Welding-arc instability
3 Crossfiring to metal nozzles (if they are being used)
4 Decreased life of the welding cable, because of high-frequency penetration of the insulation
5 Increased radio-reception interference.

When a high-frequency circuit is superimposed on the welding current, it is essential that the power be shut off before attempting to install or adjust electrodes, or before placing the hands on or near the metal parts of the welding head. Otherwise, a severe shock may result, particularly if the operator comes into contact with moisture that may be present near the work.

When welding with high-frequency-stabilized alternating current, a purple corona appears at the tip of the electrode while the electrode is hot after the arc is extinguished. As the electrode cools, the corona fades in intensity, and when the electrode reaches a certain temperature, the corona abruptly disappears. While the corona is visible, the arc will fire at a relatively great distance as the electrode approaches the work, and so great care must be taken to avoid accidental arc firing and arc burns at unwanted locations while the corona is visible.

"Hot Start" Devices. For certain welds it is desirable to furnish a surge of current substantially above the normal welding current, to initiate the weld with less time lag. This is particularly beneficial in automatic or semiautomatic welding. A "hot start" device incorporated into the circuitry provides this initial surge of current. Ordinarily, the device can be preadjusted to furnish the degree of additional current desired, and for the time span required.

Reduction of Power Surge. When welding at high current levels of short duration and with frequent starting, line surges can be reduced by connecting an induction motor across the line lead to the welding machine and running the motor without an external load. The horsepower rating of the motor should be in excess of the kilovolt-ampere rating of the welding machine, so that there will be enough kinetic energy in the rotating armature to return a substantial amount of power to the line when the line voltage drops because of the surge of current due to the short circuit set up in starting the arc. A sharp drop in line voltage will cause the motor to slow down, and rotational energy in the motor will be converted into electrical energy, which will help to hold the line voltage up. A careful cost study should be made before attempting an installation of this type, unless it is done on an emergency basis to reduce line-voltage drop at arc starting.

Reduction of Current for Crater Filling. In some applications, it is desirable to make a symmetrical closure of the end of the weld bead, and to avoid abrupt sagging or recession in the crater of the weld at the point of arc extinction. To do this in the welding of aluminum alloys and magnesium alloys, it is necessary to start reducing the welding current just before closure. However, some metals, such as some nickel-base and cobalt-base alloys, are so sensitive to thermal shock that crater cracks or "checks" invariably result unless the arc is extinguished with *gradual* reduction, assisted by the *over*-deposit of filler metal (which also quenches the heat from the weld puddle). The weld pass must continue beyond the end of the weld bead, and the current must be reduced to the point where the metal is no longer molten, in order to avoid a dimple or depression in the crater when the arc is extinguished. Otherwise, a trough or arc scar will be formed in the workpiece material when the arc is swung off. Such scars, and the microcracks that may be present in them, increase susceptibility to corrosion.

There are several methods of accomplishing gradual current reduction with the various welding machines: (*a*) by excitation control on motor-generators, (*b*) by variable-reactor control on rectifiers, and (*c*) by using a motor or an air cylinder to separate the primary and secondary coils on movable-coil or saturable reactors used to control transformers.

Welding Torches

A torch for manual gas tungsten-arc welding should be compact, lightweight, and fully insulated. It must provide a handle for holding it, a means for conveying the shielding gas to the arc area, and a collet, chuck or other means for securing the tungsten electrode and conducting welding current to it. The torch assembly normally includes various cables, hoses and adapters for connecting the torch to sources of power, gas and water (if water is used for cooling). A typical water-cooled manual torch is shown in Fig. 3. The shielding-gas passage through the entire system must be leakproof. Leaks in the hose or connections result in loss of valuable shielding gas and insufficient shielding at the weld puddle. Inspiration of air into the gas system is often a major problem. Careful maintenance is required to ensure a leakproof gas system.

Torches for gas tungsten-arc welding are available in a variety of sizes and types weighing from as little as three ounces to almost one pound. The different sizes of torches are rated in accordance with the maximum welding current that can be used. In addition, they will accommodate different sizes of electrodes and different types and sizes of nozzles. The head angle, or angle of the electrode with the handle, also varies on different torches. The most common angle is approximately 120°. However, torches with 90° head angles, straight-line (pencil-type) torches, and even adjustable-angle torches are available. Some torches have auxiliary switches and gas valves built into their handles.

The major distinction among torches for gas tungsten-arc welding is whether they are air cooled or water cooled. Air-cooled torches might more correctly be called gas-cooled torches, because much of the cooling is achieved by the flow of shielding gas; the only true air cooling is by radiation into the surrounding air. On the other hand, for water-cooled torches, some cooling is provided by flow of shielding gas, but it is supplemented by water that is circulated through the torch (Fig. 3a).

Air-cooled torches are usually lightweight, small, compact, and less expensive than water-cooled torches. However, they are generally limited to a maximum welding current of about 125 amp. They are normally used for welding thin metal and for limited duty cycles. The tungsten electrode operates at higher temperatures in air-cooled torches than in water-cooled torches, and this may cause tungsten particles to slough off into the weld puddle when pure tungsten electrodes are being used at or near current-carrying capacity.

Water-cooled torches are designed for continuous high-current welding. They will operate continuously with welding current up to 200 amp. Some are designed for a maximum welding current of 500 amp. They are heavier and more expensive than air-cooled torches.

The water hose and associated connectors are normally supplied with the torch. Generally, the power cable bringing the welding current from the power supply to the electrode is enclosed in the water-discharge hose (Fig. 3). This provides for cooling the cable and allows the use of a small-diameter, lightweight, flexible conductor. Adapter blocks, and sometimes flow switches and fuses, also are included. Water leaks in the torch or moisture contamination of the gas system will contaminate the weld and render the process inoperable.

Table 2. Typical Characteristics of Torches Used for Gas Tungsten-Arc Welding

Torch characteristic	Torch size: Small	Medium	Large
Maximum current usable (continuous duty), amp	100	200 to 300	500
Cooling method	Air(a)	Water	Water
Diameters of electrodes accommodated, in.	0.010 to 3/32	0.040 to 5/32	3/32 to 1/4
Nozzle-orifice diameters accommodated, in.	1/4, 5/16	1/4, 5/16, 3/8	3/8, 1/2, 3/4

(a) "Air-cooled" nozzles actually are cooled by the flow of shielding gas, and by radiation.

General characteristics of air-cooled and water-cooled torches are presented in Table 2.

Types of Nozzles. Several types of nozzles are used in gas tungsten-arc welding: ceramic, metal (cooled by radiation and the shielding gas, or water-cooled), fused quartz, and dual-shield nozzles. Ceramic nozzles cost the least and are the most popular, although water-cooled metal nozzles have longer service life, if properly used.

Ceramic nozzles become brittle after continued use and must be replaced when the lip of the nozzle becomes rough and uneven. A rough, uneven lip will interfere with the flow of shielding gas and cause nonuniform gas coverage of the weld area. Currently (1970), ceramic nozzles by one major manufacturer cost about 90¢ each in all orifice sizes (1/4-in. to 1/2-in. diameters). When welding with high-frequency current, ceramic nozzles must be used whenever possible, to prevent crossfiring to the gas nozzle (which often occurs when metal nozzles are used). However, crossfiring to the gas nozzle can be offset to a degree by using the largest-size nozzle that is practical for the application.

Sleeve-type, or slip-on, metal nozzles are very limited as to current-carrying capacity and, being delicate, are much more easily damaged and misused than the water-cooled types. Also, under the stress of continued use they run so hot that crossfiring destroys them immediately when it occurs.

Water cooling of metal nozzles makes it possible to use welding current as high as 500 amp, which is about the maximum practical for manual gas tungsten-arc welding (although automatic operations have used current well above 500 amp).

Fused-quartz nozzles are preferred by some welders, who maintain that superior vision of the weld operation is achieved by their use. Others, however, are dazzled by the brilliant light from the electrode, which is visible through the side of the nozzle up to the point where it emerges from the holding collet. Also, at the slightest contamination of the electrode, the violent ejection of metallic vapors away from its surface dulls the inside of the quartz nozzle, and visibility of the weld is thereafter severely impaired. In addition, even when the nozzle wall is clear, the vision aberration through it is so great that it is questionable that an advantage actually does exist.

Metal nozzles cooled by radiation and shielding gas ("air-cooled" nozzles) cost about $3.50 each; water-cooled metal nozzles cost about $12 each and range up to 3/4 in. in orifice diameter.

The substantial difference in cost between ceramic nozzles and water-cooled metal nozzles is sometimes offset by the rapidity with which ceramic nozzles are spent by welders who fail to give them reasonable care in the course of operation. Several ceramic nozzles may be used in a single shift by one welder if they are subjected to careless use.

The dual-shield nozzle permits a relatively small flow of argon or helium around the electrode to shelter the immediate weld puddle, while an annular grooved section around the central nozzle sends down an atmosphere of nitrogen or carbon dioxide to exclude air from contact with the central inert-gas column.

All gas nozzles, of whatever material, should be kept clean at all times, because an accumulation of foreign material on the inner surface — and, particularly, on the lip of the orifice — will eventually interfere with, or set up turbulence in, the gas column or may begin to pass vaporized metal down into the weld puddle.

Size of Nozzle. When choosing a ceramic nozzle for a specific job, an attempt should be made to use the smallest nozzle whose lip will not melt under the concentrated heat of the arc. A small nozzle will assist in maintaining a more stable and positive arc, permit welding in more restricted areas, and give better vision of the weld. Smaller nozzles provide some "compression effect" around the arc, which acts to make the arc more forceful, direct and concentrated. Larger nozzles, however, will give better atmosphere blankets at a slower gas-discharge rate than is provided by smaller nozzles. For metals such as titanium that are sensitive at elevated temperature to contamination from the ambient atmosphere, larger nozzles are safer.

Shape of Nozzle. The common form of gas nozzle is either cylindrical or tapered in the inner surface. Because commercially available nozzles are almost invariably round, however, does not necessarily mean that they are the most economical for all applications. Greater economy can ordinarily be achieved by using a nozzle designed for a specific production application.

Nozzles to which elongated trailing sections have been added have proved helpful for shielding welds made in metals with high susceptibility to gas contamination at elevated temperature. Nozzles have been made that have a section flared out or shaped in such a manner that the gas flow is altered to achieve a special effect, such as maintaining protection over the finished weld area for a longer period than will a conventionally shaped nozzle. This permits reducing the gas flow to the *welding* nozzle by a factor of two or three from the flow that would be required without a trailing shield, in order to achieve only a part of the protection offered by the special shield.

Although additional gas is directed into the trailing shield, the gas flows slowly and is ordinarily liberated through a porous metal baffle onto the heated metal surface that is to be protected. The purposes of the porous baffle are to avoid turbulence and to economize on gas. Some metals and alloys susceptible to gas contamination at elevated temperature could not be welded without such devices. The "trailing" nozzles should be of a form that will follow well behind the arc location itself (see Fig. 7 on page 380 in the article on Arc Welding of Titanium and Titanium Alloys).

Other nozzles have been designed so as to direct the gas flow *forward,* to offset a draft effect from the ambient atmosphere caused by a high speed of welding-head traverse over the work surface.

When it is necessary to weld in extremely restricted locations, special torches should be fabricated, if practical. When welds must be made where there is considerable interference, long, narrow nozzles are available or can be made. Round nozzles made from very thin copper brought down to a knife edge have been effective at exceptionally low gas flows.

Gas Lenses. Laminar flow has also been achieved by the introduction of a special screen inside the gas nozzle. This device, known as a "gas lens", permits projection of an uncontaminated column of inert gas to a considerable distance beyond the nozzle orifice.

Size of Gas Orifices in Torch Collets. In some older torches, many of which are still in wide use in industry, the gas orifices in the electrode-holding collet are so small that considerable turbulence is created in the gas column issuing from the torch nozzle. This distorts the coverage pattern of the gas over the weld. Enlarging the orifices by drilling and reaming overcomes this difficulty, and is worth considering should turbulence be encountered while an older torch is being used. When enlarging the orifices, it is important not to remove so much material that the collet will be weakened to the extent that it might fail structurally to hold the electrode securely.

Less turbulence and mixing with surrounding air will occur if the gas column issues from the nose of the gas nozzle with a minimum of deflection.

Electrode sizes (diameters) for torches with various sizes of nozzle-orifice diameters are typically as follows:

No. 4 (¼-in. orifice)	Electrode, 0.020 in.
No. 5 (5⁄16 in.)	0.040 in.
No. 6 (⅜ in.)	1⁄16 or 3⁄32 in.
No. 7 (7⁄16 in.)	⅛ in.

In general, a metal nozzle should have a slightly larger orifice than a ceramic nozzle for the same electrode size. When the diameter of a metal nozzle is too small, overheating occurs and the nozzle deteriorates rapidly.

Nozzles are attached to the torch by tapered friction fit or by internal or external screw threads. Electrodes are clamped inside the torch by collet or chuck, or by other means. Separate collets are required for each size of electrode. The various sizes of collets within the size range of the torch are made to hold the electrode securely by a threaded cap fitting. The electrode should be inserted in the collet so that the end extends beyond the end of the nozzle. The permissible amount of extension depends on the type of weld joint, the electrode size employed, and the type of torch used (see "Electrode Extension", on page 121). The collet assembly also carries the current from the torch body to the electrode.

The design of the cap on the torch governs the length of electrode that can be used. (No cap is shown on the torch in Fig. 3.) Cap extensions allow the use of electrodes as long as 7 in.

Centering of the electrode in the torch nozzle orifice is important, because a deflection will cause the arc to be offset from the center of the issuing stream of shielding gas. If the electrode is slightly bent, it may be straightened by pressing against it laterally after it has been heated and is red hot. Axial alignment of the electrode is easily checked by looking straight into the gas nozzle; it is unnecessary to apply a gage or similar device to attain precision in centering.

Collets are of either the split type or the draw type. Both types are effective in making positive electrode contact if properly adjusted. The bodies of most collets are made of a copper alloy, to obtain the efficiency of heat transfer and electrical conductivity offered by copper, although some collet bodies are made of 80-20 nickel-chromium alloy.

The inner surface of a collet should be smooth. Before a collet is placed in service, it should be thoroughly checked for burrs, which might decrease the efficiency of electrode contact. Poor contact contributes to poor current-carrying capacity.

The position of most electrode collets with relation to the end of the electrode is a compromise between being immediately adjacent to the heated end (which would be most efficient from the standpoint of heat withdrawal) or being withdrawn far into the gas nozzle (where it would offer least resistance to the flow of shielding gas, and thus would minimize turbulence in the issuing stream of inert gas).

Electrodes

The use of a nonconsumable electrode — that is, an electrode that does not supply filler metal — constitutes the major difference between gas tungsten-arc welding and other metal-arc welding processes.

Tungsten, which has the highest melting temperature of all metals (3410 C, or 6170 F), has proved to be the best material for nonconsumable electrodes. In addition to having an extremely high melting point, tungsten is a strong emitter of electrons, which stream across the arc path, ionize it and thus facilitate the maintenance of a stable arc.

Table 3. AWS Classifications and Composition Limits for Tungsten Arc Welding Electrodes (AWS A5.12-69)

AWS classification	Tungsten, % min(a)	Thoria, %	Zirconia, %	Other, % max(b)
EWP	99.5	...	...	0.5
EWTh-1	98.5	0.8-1.2	...	0.5
EWTh-2	97.5	1.7-2.2	...	0.5
EWTh-3(c)	98.95	0.35-0.55	...	0.5
EWZr	99.2	...	0.15-0.40	0.5

(a) By difference. (b) Total. (c) EWTh-3 is a tungsten electrode with an integral lateral segment throughout its length that contains 1.0 to 2.0% thoria; average thoria content of the electrode is as shown in this table.

Tungsten of commercial purity (99.5% W) and tungsten alloyed with either thoria or zirconia are the electrode materials used in virtually all applications of gas tungsten-arc welding. Pure tungsten electrodes cost about 25 to 35% less than the thoriated types, depending on finish.

Table 3 gives AWS classifications and compositions for tungsten and tungsten alloy electrodes.

Finish and Surface Condition. The two main types of finish with which tungsten arc welding electrodes are commercially available are a ground finish and a chemically cleaned finish. Electrodes with a chemically cleaned finish cost about 15 to 30% less than those with a ground finish, as shown by the following comparison of typical costs for pure tungsten and thoriated tungsten electrodes 1⁄16 in. in diameter by 2 in. long, with the two finishes:

Pure tungsten, ground	$0.50
Pure tungsten, chemically cleaned	0.42
Thoriated tungsten, ground	0.80
Thoriated tungsten, chemically cleaned	0.57

The arc is more stable when electrodes with a ground finish are used. The relative smoothness of the surface of a ground electrode has considerable effect at high current levels; the resistance offered by the rougher surface of a chemically cleaned electrode may reduce the maximum current-carrying capacity. Ground electrodes maintain maximum contact with torch collets. The smooth finish of a ground electrode ensures that a uniform surface is exposed to the arc, the gas stream, and the inner holding surface of the collet.

Electrodes made by drawing with the use of graphite as a lubricant may retain a slight coating of graphite and thus present a black or blue-black appearance. The graphite coating does not affect the arc or welding characteristics. Any other discoloration on the surface of a tungsten electrode, however, indicates the presence of tungsten oxide or some type of contamination. This will result in dirty welds and rapid consumption of the electrode, and may cause a wild and unstable arc.

If the electrode is discolored after use but has not been contaminated with filler metal or base metal, the discoloration is caused by oxidation. Ground or chemically cleaned electrodes will remain bright and shiny if properly protected from air contamination. The one exception is the graphite-drawn electrode, which will always be dark before and after use.

Electrodes having seams, cracks, pipes, slivers, or nonmetallic segregated inclusions should not be used. Any of these structural imperfections will substantially reduce the maximum current density that the electrode will tolerate. Also, irregularity on the surface of the electrode may cause the arc stream to "backfire" and attach itself to the electrode at some distance back from the tip; this results in a welding difficulty that need not have occurred.

Electrodes should be stored in a clean container until they are needed. Grease or dirt on the surface of tungsten electrodes will interfere with good electrical contact when they are inserted into the torch, and may cause damage to the torch through arcing to the collet. Also, dirty electrodes can contaminate the weld metal while welding is in progress.

Size. Standard commercial diameters and lengths of tungsten electrodes are given in Table 4. Table 5 lists typical ranges of current within which the various diameters of tungsten or tungsten alloy electrodes are used when welding with argon as the shielding gas.

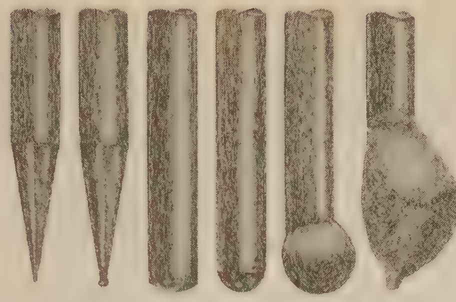
Generally the electrode size should be chosen so that the electrode will operate at near-maximum current-carrying capacity. At such a current level, the heat of the arc is more concentrated. This ensures maximum penetration, a stable arc, high welding speed, and minimum width and convexity of weld bead. The electrode size must be chosen for the current required and the speed desired for the specific application.

Authorities differ as to the electrode size that should be used for a specific current. Most agree that the smallest electrode that will maintain the arc without losing metal from the electrode tip in the form of molten drops or solid pieces should be selected for the unit current. Many users of pure tungsten electrodes grind a needle point on a much larger electrode than would ordinarily be used, and permit the electrode tip to "find" its normal current-density diameter upon the first striking of the arc. This practice, which is applicable *only* to pure tungsten electrodes, will automatically give an ideal electrode tip diameter.

The most stable arc for any particular electrode will be that which supports the maximum amperage without failing. Because of the high current-carrying capacity of tungsten electrodes and the large end-area differential existing between any electrode and the next larger or smaller size, it is not possible to attain an ideal current density merely by changing electrodes.

End Profile. Tungsten electrodes may have an end profile that is pointed, partly or completely hemispherical, or a bulbous mass of greater diameter than the electrode (see Fig. 4). A pointed end is ideal for welding in restricted locations, such as narrow joints in stainless steel piping, and it permits current density to be maintained at an extremely high level. An electrode with a hemispherical end profile will have the greatest current density, since less of the electrode end will be in contact with the arc. The thoriated and zirconiated tungsten electrodes will maintain their prepared end section over an extensive heat range, but pure tungsten electrodes will change their end profile according to the current density at which they are operating.

There is a method, previously mentioned, by which the end diameter of pure tungsten electrodes can automatically be adjusted to the specific job. In this method, after the heat required for the specific joint, metal, and welding position has been determined, an electrode is chosen that is in the general current range for the job. The electrode is then ground to a sharp point, with a taper three to six diameters long. When the pointed electrode is applied to the work, the point will melt back on itself until the tendency of the electrode mass to cool the molten tip balances the heat from the arc tending to melt it (see Fig. 4b). Thus, the molten section on the end of the electrode will have the ideal diameter for the specific job, and the diameter of this end section will rarely be identical with any available electrode size.



(a) (b) (c) (d) (e) (f)

(a) Thoriated tungsten electrode with pointed end, which will be maintained at a maximum current level for the entire electrode. (b) Pointed pure tungsten electrode that has attained ideal end diameter by method described in text. (c) Pure tungsten electrode with partly hemispherical end. (d) Pure tungsten electrode with fully hemispherical end. (e) Pure tungsten electrode with bulbous end. (f) Electrode contaminated with aluminum base metal or filler metal.

Fig. 4. End profiles of tungsten electrodes

Table 4. Standard Diameters and Lengths of Tungsten Arc Welding Electrodes (AWS A5.12-69)

Standard diameters, in.	Tolerance on diameter, in.	Standard lengths, all diameters(a), in.	Tolerance on length, in.
Diameters		Lengths	
0.010	±0.001	3, 6, 7	±1/16
0.020	±0.002	12, 18, 24 ...	±1/8
0.040, 1/16, 3/32, 1/8, 5/32, 3/16, 1/4	±0.003	(a) 0.010-in. electrodes also are available as coils.	

This method of preparing an electrode will add greatly to the ease of operation in executing any specific weld. It also avoids a difficulty that attends the use of a blunt-end electrode (particularly when welding in a deep groove) — that of the arc running up the side of the electrode. Several pure tungsten electrodes should be pointed before a job is begun. Then, if the electrode strikes the workpiece or the filler rod, it will be necessary only to change electrodes, instead of waiting for time-consuming regrinding of the point on the electrode being used.

When extremely thin and delicate sections are to be joined, it may be necessary to grind the smallest available electrode to a needle point in order to help stabilize the arc at extremely low current. If welding is to be done automatically, the grinding should be done by machine, so that the end profile is duplicated from electrode to electrode for repetitive use under closely controlled welding conditions.

Current-Carrying Capacity. Polarity, electrode holder, torch design, and the skill and ability of the welder all have great influence on the maximum current that an electrode will withstand. The surface finish of the workpiece also has some effect; the radiation from a mirrorlike workpiece surface will reduce the current-carrying capability of the electrode because of heat reflection, whereas a dull surface will permit the current to be increased. When the work metal has been preheated, the radiation of heat from the work will considerably reduce the current-carrying capacity of the electrode — although less current will be required for obtaining a given depth of penetration.

If the current range is too low for the electrode being used, the arc will wander over the end of the electrode. Excessive current values will cause the tip of a pure tungsten electrode to "ball up" and vibrate at high frequency, at which point the tungsten begins to transfer across the arc in the form of small particles and metallic vapor. Excessive current may also cause arc instability. When this occurs, there is a strong possibility that the large molten globule suspended from a pure tungsten electrode will drop into the weld puddle, contaminate it, and require mechanical removal before welding can proceed. Ideal arc conditions result when the molten tip of a pure tungsten electrode assumes the shape of a hemisphere. Stability of the arc will be promoted by using the smallest electrode at the maximum current value that will form the molten hemisphere at the tip.

Figure 5(a) shows the ends of pure tungsten electrodes after being used for welding at 300, 250 and 150 amp, with argon shielding. Note the erosion on the end of the electrode used at 150 amp, and the small projection on that electrode where the arc was concentrated but wandered over the surface of the electrode end. This wandering

Table 5. Typical Ranges of Current Used in Gas Tungsten-Arc Welding With Tungsten Electrodes of Various Diameters (AWS A5.12-69) (a)

Electrode diameter, in. 3/32	150-250	15-30	100-160	140-235	100-235	60-130	100-180	60-180
1/8	250-400	25-40	150-210	225-325	150-325	100-180	160-250	100-250
5/32	400-500	40-55	200-275	300-400	200-400	160-240	200-320	160-320
3/16	500-750	55-80	250-350	400-500	250-500	190-300	290-390	190-390
1/4	750-1000	80-125	325-450	500-630	325-630	250-400	340-525	250-525

(a) Ranges are based on the use of argon as the shielding gas. Other current values may be employed, depending on the shielding gas (lower values would be used with helium as the shielding gas), type of equipment, and application. (b) These combinations are not commonly used.

sometimes leads to erratic following of the weld seam if mechanized welding is being used.

Figure 5(b) shows the ends of pure tungsten electrodes after being used for welding at 300, 250 and 150 amp, with helium shielding. The undercut appearance of the electrode used at 150 amp may result from both low amperage and low gas-flow rate.

Under extended periods of use in automated applications where only the molten hemisphere was permitted to form, no measurable usage of tungsten could be detected after 200 hr of continuous welding. When this form of electrode tip is presented to the work, not only is the current density the greatest, but also the arc gap may be the longest for any specific application.

Heating of the Electrode Tip. More heat is liberated on the positive side of a welding arc than on the negative side, because the impact of the electrons on the positive terminal heats it more than the negative. Consequently, when the polarity is reverse (electrode positive), the electrode becomes hotter than the workpiece, whereas with straight polarity (electrode negative), the workpiece becomes hotter. For example, to withstand the heat of a 125-amp current, a tungsten electrode must be ¼ in. in diameter if reverse polarity is used, but only $\frac{1}{16}$ in. in diameter with straight polarity.

Greater penetration into the work metal can be obtained using straight polarity, because about 70% of the heat of the arc is concentrated on the positive end of the arc stream, and only about 30% on the negative. Thus, straight-polarity current provides the most satisfactory heat transfer. However, when the arc is changed to reverse polarity, with the electrode positive, the current-carrying capacity of the electrode is reduced so much that continuous welding is maintained only with great manual skill and dexterity.

Excessive heating of an electrode can be avoided by changing to a larger electrode. Increasing the contact surface of the collet may also prove of some benefit. A non-water-cooled pure copper gas nozzle may be substituted for a ceramic nozzle; water-cooled nozzles will further assist.

The flow of inert gas has a certain cooling effect on the electrode, although if the welder attempts to use higher amperage by employing an abnormally high gas flow, the cost of doing so will be excessive.

Consumption of tungsten electrodes while welding is in progress is so small that it can be detected only by elaborate methods. A tungsten electrode loses material by inclusion into the weld metal, by condensation on the surface of the work, and by vaporization into the atmosphere.

The greatest consumption of electrodes results from striking the workpiece or the filler rod. Another cause of electrode consumption is improper shielding of the electrode after the arc has been extinguished. Also, the introduction of a contaminating atmosphere into the gas nozzle along with the inert gas causes tungsten oxide to be passed down from the oxidizing tungsten electrode.

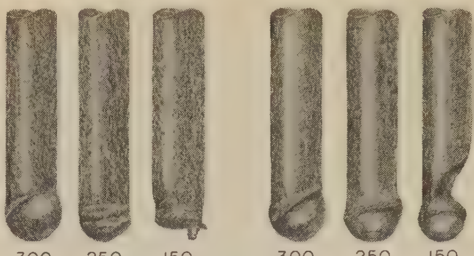

Fig. 5. Ends of pure tungsten electrodes after welding at three levels of current, with argon or helium shielding

If a tungsten electrode has been oxidized because the shielding gas was shut off too soon after welding was completed, when next the arc is restruck tungsten oxide will be thrown onto the work surface in the form of brilliant white particles, which pass through the arc with great speed. This throwdown, or "spitting", of tungsten oxide across the arc, coincidental with "missed cycles", may result also from instability of the welding transformer. To avoid tungsten spitting, it is necessary, after extinguishing the arc, to permit argon or helium to flow until the tungsten electrode becomes bright, silvery and shiny. Any discoloration on the surface of the electrode is caused by penetration of oxygen into the surface of the metal, and this oxidation may increase tungsten consumption by as much as twenty to thirty times.

If a large rate of consumption of electrodes is anticipated, it is best to use holders that will accommodate long electrodes, in order that the unusable electrode stub will be short in relation to the original length. For example, the unusable stub on a 3-in.-long electrode represents a much greater percentage of the original length than the stub on a 7-in. electrode.

Tungsten Contamination of Weld Puddle. When a pure tungsten electrode strikes the weld puddle, tungsten will be deposited in the weld metal. Because the contaminating tungsten may impair the strength and corrosion resistance of the welded joint, if the weldment is critical the welding operation should be stopped when such a strike has been made, and the tungsten should be mechanically routed out of the weld.

To remove the tungsten inclusions, carbide burrs must be used; an ordinary grinding wheel is likely to push the embedded particles even farther into the work as the wheel goes down into the material. For critical weldments, it may be necessary to radiograph the area to ascertain that all of the tungsten has been routed out before resuming welding. Tungsten particles show up as white flecks in weld radiographs.

Contamination of Tungsten Electrodes. During welding, the tip of a pure tungsten electrode reaches a temperature of at least 6200 F, which is above the melting point. Any filler metal or base metal that strikes the molten tip is vaporized to a degree. It also chills the molten tip enough so that the tungsten will combine with the filler or base metal to form an alloy. If welding is continued, the arc will be wild and unstable. When this occurs, there are two alternatives: (*a*) to break off the contaminated section of electrode and start welding with a clean section, or (*b*) to hold the arc on a section of copper or other material until the electrode has been cleared of contaminating metal through its vaporization. It can be seen through the filter lens that at the instant of clearing, the arc will stabilize itself and regain a normal welding condition.

The contamination of tungsten electrodes results not only in defacing of the workpiece, but also in loss of several minutes of welding time while the electrode is being cleared of the base metal plated on its surface or alloyed with it. When the electrode is being used at or near its maximum current capacity, if the torch is given a quick flip instantly after the electrode strikes the base metal or filler metal, most of the contaminating metal will slide down and off the end of the electrode. However, it may still be necessary to hold the arc for a short time on a piece of copper or other material, in order to clean the electrode completely. A considerable amount of electrode can be saved by this technique.

When welding stainless steel, if a pure tungsten electrode is contaminated with the base metal or filler metal, it is possible to maintain the welding arc without clearing the electrode, despite the wildness of the arc. This is not good practice, however, because contamination of the weld metal is almost certain to result. The arc instability results from the unusual shape of the contaminated electrode tip (see Fig. 6), and also from the passing of metallic vapors across the arc as the base metal or filler metal adhering to the electrode is vaporized. The electrode will not regain its proper form until the contaminated section is removed and readjusted to its proper extension beyond the nozzle orifice.

Once put into use and heated, a tungsten electrode is brittle a short distance back from the point. If the end of an electrode is to be removed, it should be gripped tightly with a pair of pliers and snapped off suddenly in the brittle area, generally within ⅜ in. from the end. If an attempt is made to break the electrode farther away from the point, the electrode will probably be bent rather than broken, thus causing subsequent difficulty in realigning it with the nozzle orifice.

Protection Against Oxidation. If electrodes are not protected by continued flow of the inert gas after the arc is extinguished, the usage of electrode may be up to 25 times as much as when protection against oxidation of the hot electrode is complete. However, it costs about six times as much for protective gas as it does for the wasted (or oxidized) tungsten. In addition, the cost of the welder's time must be considered.

The shielding gas may be shut off immediately upon completion of welding, without the necessity of permitting the tungsten to cool below oxidizing temperature, if the nose of the torch is introduced into a small ceramic crucible or metal hood at the moment the gas is shut off. The crucible will hold

enough argon to protect the tungsten while it is cooling.

If an electrode (other than one that has been graphite drawn) fails to attain a silvery color when the gas is permitted to flow until the electrode has cooled, there is air leakage into the gas system or the gas is impure.

Electrode Extension. Ordinarily, the distance an electrode extends beyond the orifice of the gas nozzle should equal the diameter of the electrode. The longer the electrode extension, the more danger there will be of striking the work metal or filler rod and contaminating the electrode. The farther the electrode tip is withdrawn into the gas nozzle, the less current the electrode will accommodate — probably because more arc heat is reflected back from the gas nozzle onto the electrode.

Ordinarily, the amount of electrode extension is dictated mainly by the profile of the joint to be welded. An inside fillet weld requires the greatest electrode extension, in order that the electrode may approach the root of the joint and yet permit some vision of the weld puddle. At the opposite extreme is an upstanding edge-flange weld, for which only a very slight extension is required, or no extension at all.

In some applications of welding with high-frequency-stabilized current, it is practical to withdraw the end of the electrode entirely within the nozzle nose. This has been done, for example, in welding an edge-flange joint between two 0.081-in.-thick sheets of aluminum alloy, wherein high-frequency-stabilized alternating current was used and the electrode was retracted 1/32 in. within the gas-nozzle nose. This practice makes it impossible for the electrode to become contaminated by touching the work surface. It does, however, interfere with weld visibility, and demands a high degree of welder skill. Also, when the electrode is retracted inside the gas nozzle and there is no possibility of contaminating atmosphere reaching the weld puddle, a black or gray material may appear in the center of the puddle if the arc is too long. This phenomenon has occurred while using unbalanced alternating-current transformers, and may have been caused by direct-current component passing across the arc.

For metals that require a very short welding arc, electrode extension should be greater than normal, to provide the welder with better vision and to assist control of the arc. However, the farther the electrode is extended, the greater must be the volume of gas flow to compensate for the greater distance of the gas nozzle from the workpiece surface.

As the inclination of the torch varies from one joint to another, some variation in electrode extension must accompany it. It is seldom necessary to extend the electrode farther than ½ in., although under special conditions of inert-atmosphere control, electrode extensions of as much as 3 in. have been used successfully.

In order to conserve gas and provide adequate shielding of the weld puddle, the electrode should be extended no farther than absolutely necessary. Also, any misalignment of the electrode axis within the gas nozzle will place the arc in improper relation to the shielding gas and may lead to insufficient coverage of the weld puddle. When welding with high current and a ceramic gas nozzle, if the electrode is slightly off center, the nozzle lip nearest the electrode may begin to melt and vaporize and thus contaminate the shielding gas.

Fig. 6. Typical shapes of pure tungsten electrodes, 1/16 in. in diameter, after contamination with stainless steel base metal or filler metal during welding

Thoriated tungsten electrodes contain up to 2.2% thoria (see Table 3). Unlike pure tungsten electrodes, thoriated tungsten electrodes do not melt at the usual current levels. For example, one ⅛-in.-diam thoriated tungsten electrode ground back ¾ in. from a needle point held a 450-amp dcsp arc for 12 min, at which time the grinding-wheel marks had disappeared from the surface of the ground portion only in the first 1/32 in. Failure of thoriated tungsten electrodes from excessive current is characterized by the sudden dropping off of a large length, rather than by the melting off of droplets as occurs with pure tungsten electrodes.

If high frequency is used in striking the arc, the arc will start instantly at lower current values than are required for touch starting. Also, the arc may be started at much greater arc lengths with complete arc stability, which is of prime importance when welding expensive materials that may have to be surface-finished to a high degree.

Touch starting with thoriated tungsten is free of the sputtering and flashing that may occur when pure tungsten is used. The best conditions for easy touch starting are high open-circuit voltage, thoriated tungsten electrodes, and argon shielding. The type of work metal also has a considerable influence on the comparative ease with which touch starting is accomplished; stainless steel is one of the easier alloys from this standpoint, whereas aluminum requires high open-circuit voltage for successful touch starting.

Climbing of the arc up the side of the electrode at reduced current values, which often occurs when pure tungsten electrodes are used, is not encountered with thoriated tungsten electrodes except after long periods of use.

The degree to which thoriated tungsten electrodes are superior to pure tungsten in current-carrying capacity when welding with alternating current may range from 0 to 50% (Table 5), and apparently depends on the amount of direct-current component and the amount of rectification in the arc. Current-carrying capacities of the larger thoriated tungsten electrodes are considerably higher with helium shielding than when pure argon is used. Compared with pure tungsten electrodes, thoriated tungsten electrodes provide somewhat greater arc stability.

The higher current density that can be tolerated by thoriated tungsten electrodes, and the ability of these electrodes to hold a point without melting, contribute to an extremely stable and "stiff" arc stream. The consumption of thoriated electrodes in manual welding is only 10 to 20% as great as that of pure tungsten electrodes, and in mechanized applications the advantage is many times greater.

At a given current level and arc length, less penetration is obtained when welding with thoriated than with pure tungsten electrodes, because arc voltage is from 3 to 5 volts less when thoriated electrodes are used. However, the much greater current-carrying capacity of thoriated tungsten electrodes more than compensates for the decreased arc voltage.

When a thoriated tungsten electrode is dipped into a molten puddle of stainless steel weld metal, ordinarily neither the weld metal nor the electrode will be contaminated, particularly if the welding is being done in the flat position. In the vertical, horizontal and overhead positions, however, a portion of the molten metal in the puddle often will adhere to the electrode and create a deformed outer profile. It is common practice to break off the section so contaminated, rather than to grind off the contaminating material, because of the difficulty of determining whether all the adhering material has been ground off before welding is resumed.

The pointing of thoriated tungsten electrodes is particularly beneficial for the welding of piping, or of joints with deep grooves. With a pointed electrode, there is extreme concentration of the arc force and the welding technique is assisted by the arc "stiffness".

It has been reported that there are certain low-current automatic welding applications for which pure tungsten electrodes are more satisfactory than the thoriated type. After a period of use, some thoriated tungsten electrodes permit the arc to attach itself to a part of the electrode other than the extreme tip. With continued use, the thoria inclusions may become segregated, and the arc may direct itself to these areas on the surface of the electrode, thus becoming unstable.

Zirconiated tungsten electrodes, which contain 0.15 to 0.40% zirconia (see Table 3), are well suited for applications in which contamination of the

weld with tungsten must be minimized. They retain a balled end during welding and are highly resistant to contamination; thus, they perform well when used with alternating current. Zirconiated tungsten electrodes are in common use, but are less widely used than thoriated tungsten electrodes. Both types are comparable in performance and applicability.

Effect of Tip Angle. In "The Effect of Electrode Geometry in Gas Tungsten-Arc Welding" (*Welding Journal*, Nov 1965, p 489s-496s), W. F. Savage, S. S. Strunck and Y. Ishikawa report that in gas tungsten-arc welding with straight-polarity direct current, the included angle at the conical tip of the tungsten electrode has a significant influence on (*a*) the voltage-current characteristics of the arc, (*b*) the penetration characteristics and the width of the weld puddle, and (*c*) the distribution of temperature along the length of the electrode.

For 2% thoria tungsten electrodes, centerless ground, the width of bead-on-plate welds decreased by a factor of nearly two when the vertex angle at the conical tip was increased from 30° to 120°. For the same increase in vertex angle, the depth of penetration increased by as much as 45%, while the cross-sectional area of the weld remained essentially unchanged.

From this investigation, it is evident that the vertex angle at the conical tip of a thoriated tungsten electrode should be specified and controlled if reproducible results are to be obtained with automatic gas tungsten-arc welding.

Shielding Gases

The main requirement of a shielding gas is that it exclude air from the weld puddle, the electrode, and the heated end of the filler rod (if used), to avoid contamination of the weld deposit. Shielding gas does not directly add heat to the weld. The gases ordinarily used in gas tungsten-arc welding are:

- Argon
- Helium
- Argon-helium mixtures
- Argon-hydrogen mixtures

The choice of shielding gas can significantly affect weld quality as well as welding speed. Argon, helium, and argon-helium mixtures will not react with tungsten or tungsten alloy electrodes and have no adverse effect on the quality of the weld metal.

Argon vs Helium. There is considerable difference of opinion about the relative merits of argon and helium for welding purposes. Each gas possesses characteristics that make it more suitable than the other for certain applications (see Tables 6 and 7).

Argon is more widely preferred, because it provides a "softer" arc, which is smooth and stable. Helium-shielded weld puddles are very hot and fluid, the weld metal is difficult to handle when pipe must be welded in the horizontal fixed position, and welding becomes more susceptible to manipulative errors. Argon is better for welding aluminum alloys, magnesium alloys, and beryllium copper; helium is less efficient in the surface-oxide cleaning characteristic that is essential when these metals are gas tungsten-arc welded. Greater penetration is achieved when using helium, and helium is used to good effect when fast, hot welding is desired for stainless steel.

Table 6. Characteristics and Comparative Performance of Argon and Helium as Shielding Gases

Argon

Low Arc Voltage. Results in less heat; thus, argon is used almost exclusively for manual welding of metals less than 1/16 in. thick.

Good Cleaning Action. Preferred for metals with refractory oxide skins, such as aluminum alloys, or ferrous alloys containing a high percentage of aluminum.

Easy Arc Starting. Particularly important in welding of thin metal.

Arc stability is greater than with helium.

Low Gas Volume. Being heavier than air, argon provides good coverage with low gas flows, and it is less affected by air drafts than helium.

Vertical and Overhead Welding. Sometimes preferred because of better weld-puddle control, but gives less coverage than helium.

Automatic Welding. May cause porosity and undercutting with welding speeds of more than 25 in. per min. Problem varies with different metals and thicknesses, and can be corrected by changing to helium or a mixture of argon and helium.

Thick Work Metal. For welding metal thicker than 3/16 in., a mixture of argon and helium may be beneficial.

Welding Dissimilar Metals. Argon is normally superior to helium.

Helium

High Arc Voltage. Results in a hotter arc, which is more favorable for welding thick metal (over 3/16 in.) and metals with high heat conductivity.

Small Heat-Affected Zone. With high heat input and greater speeds, the heat-affected zone can be kept narrow. This results in less distortion and often in higher mechanical properties.

High Gas Volume. Helium being lighter than air, gas flow is normally 1½ to 3 times greater than with argon. Being lighter, helium is more sensitive to small air drafts, but it gives better coverage for overhead welding, and often for vertical-position welding.

Automatic Welding. With welding speeds of more than 25 in. per min, welds with less porosity and undercutting mav be attained (depending on work metal and thickness).

Argon is used more extensively throughout industry than is helium. Argon is 1.4 times as heavy as air, but it will mix with air in confined spaces. Also, it is about ten times as heavy as helium and thus is better suited to welding in certain positions than helium, which rises rapidly from a weld after release from the torch nozzle.

Helium has only about one-seventh the weight of air and will mix with air only slowly. For welding of a given joint, a greater amount of helium than of argon must be used for shielding, because it is not feasible to confine helium to the weld area with dams and baffles, as must be done when welding gas-sensitive metals and alloys. The one exception is when welding is being done in the overhead position; then, baffles and dams can be used effectively to confine helium to the weld area and thus to achieve a beneficial shielding effect as well as to conserve gas.

Helium is ideal for welding in the overhead position, and for shielding the bottom side of joints welded in the flat position. In a vessel, helium will rise to the top. This constitutes a health hazard if the welder is working inside the vessel. In contrast, argon will sink to the bottom, and this must be considered if personnel are to enter and work near the bottom of a vessel.

Schlieren shadowgraphs show that the weight of the gas (whether argon or helium) has little effect on the immediate shield of the arc and weld puddle, and that adequate coverage is offered by either argon or helium. There is less entrainment of air into the issuing stream of helium than occurs with argon. Increasing the flow of argon after the necessary coverage has been established brings about an increase of turbulence without increased effectiveness of coverage. With helium, however, which induces almost no turbulence, additional coverage of area *is* attained by increasing the amount of flow. When welding aluminum with helium, a sootlike deposit forms adjacent to the weld. It has been determined that this deposit is condensed aluminum of submicron particle size. However, this deposit is not harmful, and it can be readily wiped away after the welding operation is completed.

Experimental work on thin sections of heat-resisting alloys has shown argon to be superior to helium for most applications of manual welding. The use of argon permits more latitude in joint fit-up, whereas a helium atmosphere requires a precisely fitted joint; otherwise, melt-through and irregular welds are certain to occur. It is customary to use argon for welding very thin sections because of the easily controllable arc argon provides and because minor variations in joint makeup and process adjustment assume greater relative importance in metals less than 0.062 in. thick when helium is used.

Manual welders may have difficulty in manipulating a helium-shielded tungsten arc because of the intensity of penetration and the greater heat liberated by this arc than by an argon-shielded tungsten arc. The use of helium requires considerably more skill than the use of argon, because argon permits a wide variation in arc length with a relatively small difference in heat input.

A helium-shielded arc emits about one-third more heat than an argon-shielded arc at the same current setting, because of the higher arc voltage of the helium arc. Some authorities state that about 10 to 20% more helium than argon is required for effective shielding of the weld puddle. However, 30 to 40% greater welding speed will be attained with helium because of the hotter and more intense arc it provides.

In one application of welding aluminum with argon shielding, gas consumption was 15 cu ft per hour, welding current was 350 amp, and welding speed was 16 in. per minute. When helium was substituted as the shielding gas, gas consumption was 19 cu ft per hour, but it was possible to reduce current to 250 amp and to increase welding speed to 26 in. per minute. Also, narrower weld beads with deeper penetration and higher reinforcement were attained than when argon was used.

With straight-polarity direct current, high-quality welds cannot be made in aluminum when argon shielding is used, but when high-purity helium is used, thoroughly acceptable weave beads and stringer beads can be made.

Argon-helium mixtures are used when the greater penetration of helium is desired but the arc-softening action of argon is helpful from the standpoint of control. A mixture of (by volume) 80 parts of helium and 20 parts of argon has been effective in such applications. If a hotter arc is desired when welding aluminum with argon, helium can be added until the desired penetration is obtained. Combinations of argon and helium are widely used for automatic welding, and are obtainable in various percentages in cylinders.

Argon provides greater coverage of the weld puddle at low flow rates, whereas helium gives maximum coverage at high flow rates. Experiments indicate that the 80-20 helium-argon mixture provides coverage almost midway between the two extremes.

Argon-hydrogen mixtures have been used for the welding of various metals with which the occurrence of porosity is a constant problem; Monel and silver are two examples. In one critical application of welding nuclear miniature tubing made of "A" Nickel, a mixture of argon with 2% hydrogen was used effectively when no other shielding gas or combination of gases could overcome the porosity problem encountered.

Mixtures of argon with 10 to 15% hydrogen have been used successfully for welding stainless steel. Argon-hydrogen mixtures should not be used for welding carbon or low-alloy steel.

When an argon-hydrogen mixture is used, the gas is caused to flow, then ignited and brought down on the work, continuing to burn during the welding operation. When hydrogen gas is used for any purpose, there is always the danger of encountering an explosive mixture unless precise procedures are used. Cases are on record in which considerable effort was expended by welders to manufacture fittings to permit the use of hydrogen for purposes for which it was not intended and serious explosions resulted. Although pure hydrogen will not explode (it will only burn), when combined with even a small percentage of air, hydrogen *will* explode.

The use of argon-hydrogen mixtures is probably less than 1/10 of 1% of total gas usage in welding. The purpose of argon-hydrogen mixtures is to increase arc heat as well as to offer some measure of control of weld-bead profile. Helium-hydrogen mixtures have been tried, with no significant advantage.

Oxygen-Bearing Argon Mixtures. Argon mixed with 1 to 5% oxygen is for use only with the gas metal-arc process, which uses a *consumable* electrode. If oxygen-bearing argon is used with the gas tungsten-arc process, the oxygen in the gas will cause very rapid deterioration of the electrode.

Nitrogen in a shielding-gas mixture is always detrimental to arc stability, because of the inherent steady attack on, and deterioration of, the electrodes. However, nitrogen markedly increases the voltage and attendant heat in the welding of copper and copper alloys, for which an extremely hot arc is essential.

If high-purity nitrogen is used as the shielding atmosphere for welding deoxidized copper, the higher arc voltage obtainable will permit higher current to be used with standard equipment. The efficiency of heat transfer is much higher than when argon or helium is used, and this will result in substantial economy. Nitrogen costs so much less than either argon or helium that its use would be favored for this reason alone. If thoriated tungsten electrodes are used, the electrode contamination by nitrogen will be so low as to be negligible.

Nitrogen is used in Britain for welding deoxidized copper, because of the shortage of argon and helium there; but this usage is unknown in the United States.

Argon-nitrogen mixtures are laboratory curiosities, with no practical use yet found for production welding.

Table 7. Suitability of Argon and Helium for Use as Shielding Gases in Gas Tungsten-Arc Welding of Various Metals

(Welding with direct current, straight polarity, unless noted otherwise)

Aluminum Alloys. Argon (with alternating current) preferred; offers arc stability and good cleaning action. Argon plus helium (with alternating current) gives less stable arc than argon, but good cleaning action, higher speed, and greater penetration. Helium (with dcsp) gives a stable arc and high welding speed on chemically clean material.

Aluminum Bronze. Argon reduces penetration of base metal in surfacing (for which aluminum bronze is used).

Brass. Argon provides stable arc, little fuming.

Cobalt-Base Alloys. Argon provides good arc stability, is easy to control.

Cupro-Nickels. Argon provides good arc stability, is easy to control. Used also in welding cupro-nickels to steel.

Deoxidized Copper. Helium preferred; gives high heat input to counteract thermal conductivity. A mixture of 75% helium and 25% argon provides a stable arc, gives lower heat input than helium alone, and is preferred for thin work metal (1/16 in. or less).

Inconel. Argon provides good arc stability, is easy to control. Helium is preferable for high-speed automatic welding.

Low-Carbon Steel. Argon preferred for manual welding; success depends on welder skill. Helium preferred for high-speed automatic welding; gives more penetration than argon.

Magnesium Alloys. Argon (with alternating current) preferred; offers arc stability and good cleaning action.

Maraging Steels. Argon provides good arc stability, is easy to control.

Molybdenum-0.5Ti Alloy. Purified argon or helium equally suitable; welding in chamber preferred, but not necessary if shielding is adequate. For good ductility of the weld, the nitrogen content of the welding atmosphere must be kept below 0.1%, and the oxygen content below 0.005%.

Monel. Argon provides good arc stability, is easy to control.

Nickel Alloys. Argon provides good arc stability, is easy to control. Helium is preferred for high-speed automatic welding.

PH Stainless Steels. Helium preferred; provides more uniform root penetration than argon. Argon and argon-helium mixtures also have been used successfully.

Silicon Bronze. Argon minimizes hot shortness in the base metal and weld deposit.

Silicon Steels. Argon provides good arc stability, is easy to control.

Stainless Steel. Helium preferred. Provides greater penetration than argon, with fair arc stability.

Titanium Alloys. Argon provides good arc stability, is easy to control. Helium is preferred for high-speed automatic welding.

Purity of Shielding Gases

Only welding-grade gases should be used in gas tungsten-arc welding. If commercial-grade gases are used, difficulties will occur.

For welding reactive metals such as titanium, tantalum and zirconium, which are penetrated at elevated temperature by detrimental gases present in the ambient atmosphere, gas of absolutely predictable purity must be used, in order to avoid difficulty during welding. Assurance that gas purity is being maintained can be obtained by periodically testing cylinders before use on production work. Relative coloration of the surfaces of welds made in inert-gas chambers has been used as a test criterion for purity.

The dew point of shielding gas should be −75 F or lower (11.4 ppm water vapor, by volume). Water vapor in impure helium dissociates in the arc and yields hydrogen and oxygen. The presence of hydrogen in the inert atmosphere causes porosity, and the oxygen forms a film over the weld puddle, which may impair the ease of welding and result in poor fusion, together with inclusions. The presence of nitrogen as a contaminant, in any concentration, will impair the speed of weld progression. Helium of less than 99.8% purity will contain excessive water. If welding is attempted with helium of such purity, difficulty may be encountered when the cylinder pressure drops below 50 psi. It may be necessary to discontinue use of the cylinder at this point unless the water is removed by use of a drying agent, such as magnesium perchlorate, in the venting system.

Cylinder Gas Contamination. To prevent contamination of inert-gas cylinders with other gases, an arrangement is generally entered into between the customer and the supplier, whereby the user is requested to leave a certain residual pressure in the cylinder at all times. This will assure the supplier that he will be freed of the necessity of purging any contaminating gases from the returned cylinder. The customer is permitted a price adjustment on the basis of the volumes of gas returned to the supplier. Usually, a residual pressure of 25 psi is sufficient to ensure against contamination of the cylinder prior to recharging.

Welding difficulty is often attributed to impurity of the shielding gas, but experience has shown that of all possible sources of trouble, the gas in the cylinder itself is least likely to be contributing to the difficulty.

Hoses and connections must be thoroughly checked against leakage, which can readily cause contamination of the inert atmosphere flowing to the torch. Every possible care should be taken to ensure that the pure gas from the cylinder is conveyed to the weld puddle through a system that is completely leakproof.

If commercial-grade argon or helium is used for welding, the residual gases in the cylinders will contaminate the weld puddle, resulting in weld porosity. Purity of gas must be considered for critical applications, although the purity of welding-grade argon and helium as now produced (99.995% purity) is generally satisfactory for almost all

applications. Passing the gas through a small chamber containing incandescent "getter" metals is one way of reducing impurities in inert gases to only a few parts per million.

Removal of Air From Argon. Figure 7 shows that four volume changes of argon in a 70-cu-ft atmosphere chamber can reduce air content to about 0.1% (which is adequate for welding most reactive metals), if the argon is introduced slowly (at 80 cu ft per hour), through a porous bronze or similar diffusing plate. If, on the other hand, the argon is introduced directly (without diffusion through a porous plate) at a *higher* flow rate (350 cu ft per hour, as shown in Fig. 7), and perfect mixing of the gases is assumed, a proportion of 0.1% air in argon will be reached after ten volume changes.

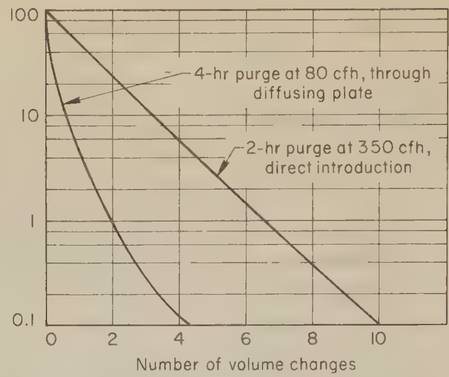

Fig. 7. Typical relation of purging times and gas-flow rates to number of volume changes required for removal of air from argon in a 70-cu-ft chamber

Gas Flow

Only enough shielding gas to exclude air from the weld location (and the heated area, for reactive metals and alloys) should be used. Excessive gas flow not only unnecessarily increases cost, but also may cause undercutting and arc instability.

The cost penalty for failure to give adequate consideration to economy of gas usage may be severe. In welding aluminum pipe, for example, gas-flow rates range from 25 to 45 cu ft per hour; at an approximate average cost of 10¢ per cubic foot for argon or helium in cylinders, the cost penalty for wasting gas is obvious. (The cost penalty is less with bulk gases; for example, bulk quantities of argon may be obtained for as little as 1.8¢ per cu ft.)

The minimum flow of gas required for maintaining adequate and effective coverage of the welding area is influenced by the following variables:

- Shielding gas used
- Distance of gas-nozzle orifice from the work surface
- Design of the weld joint
- Size of gas nozzle
- Shape of gas nozzle
- Size of weld puddle
- Amount of welding current
- Presence of drafts or wandering air currents
- Inclination of the torch
- Arc length
- Welding speed
- Position of the workpiece
- Metal or alloy being welded.

The list of variables above is in the general order of relative importance for most jobs, although specific applications may alter the relationship of these factors. In still atmospheres, effective shielding has been obtained with gas flows as low as 6 cu ft per hour for helium and 4 cu ft per hour for argon. These flow rates are only about half the rates normally used for average welding conditions, but they indicate the economy that is possible when all factors are under good control.

Shielding gas issues from the torch nozzle at relatively low velocity — about 10 ft per second — and thus the gas column is comparatively easy to disturb with drafts and air currents. The use of excessive gas flow to prevent the disturbance, however, not only is wasteful but also may be detrimental to the weld metal and the welding operation. Excessive flow also may cause an unstable arc at low welding-current values, and can result in undercutting of the work surface adjacent to the weld bead.

Only enough gas flow is required to exclude the surrounding air from the weld location; for argon, a flow rate of 8 to 12 cu ft per hour should usually be ample. If substantially greater flow than this is required to provide ample coverage, consideration should be given to the possibility of interference from drafts in the weld area, incorrect nozzle size for the specific job, or improper jig design.

Some flowmeters are calibrated in cubic feet per hour; others, in liters per minute. To facilitate correlation between gas flows, the conversion equivalents in Table 8 may be used.

Supply and Control of Shielding Gases

Shielding gases may be distributed from single cylinders containing gas or liquid, from portable or stationary manifold systems, or by pipelines that are connected to bulk storage tanks.

Supply. Single cylinders of gas or gas mixtures provide an adequate supply for operations consuming limited quantities. Single cylinders of liquid provide about three times as much gas as gas cylinders. Single cylinders have the advantage of maximum portability.

When the volume of gas required exceeds that which can be obtained from single cylinders, two or more cylinders may be joined together to form either a portable or a stationary manifold system. Portable manifold systems, of which there are two types, are extremely flexible and permit the manifolded cylinders to be located near the welding operation. In one type of portable manifold, the cylinders (usually from two to five) are connected by means of leads, called pigtails, to a common coupler block, from which they are connected to a single, common, pressure-reducing regulator. In the other type, which generally is used for more than five cylinders, the cylinders are joined successively by T's attached to the cylinder valves and by pigtails that successively join T to T. The gas from each cylinder passes through its T and flows into the main gas stream to a single regulator, which serves the entire group of cylinders. Both types of manifold systems can be assembled rapidly.

A stationary manifold system may be installed where large volumes of gas are regularly required or where a centralized gas supply is desired. This type of manifold consists of an adequately supported, stationary, high-pressure header to which a number of cylinders are connected with pigtails. One or more permanently mounted regulators serve to reduce and regulate the pressure of the gas flowing from the manifold into the piping system.

When stationary manifolds, truck trailers, or bulk supply systems are used as a source of gas, the gases are distributed by pipelines to the welding locations. The pipelines should be designed to handle and distribute the gases in sufficient volume and purity, and without undue pressure drop. Pipelines should incorporate all necessary safety devices (such as relief valves and bursting disks) to protect the system in case of mishap. Proper flushing procedures are necessary to achieve quickly the high purity available from distribution of liquefied gas. With the use of pipelines, an ample, uninterrupted supply of gas is available at all times.

Hoses and Fittings. It is essential to use plastic hoses for transporting helium, because at 20 psi, helium will diffuse through the walls of rubber or rubber-fabric hoses. The safer procedure is to standardize on plastic hoses for both helium and argon, to guard against possible gas diffusion. Vinyl chloride plastic, such as Tygon, has been used extensively for this purpose.

When setting up a gas tungsten-arc welding operation, it is best to use only new hoses and fittings, because old hoses may have been used for purposes that would have contaminated them. When old hoses are used for argon or helium, they may continue for a long time to contaminate the inert gas transmitted through them.

When argon or helium lines are disconnected, both male and female connections should be closed with pressure-sensitive tape or with plastic plugs, to prevent water or moisture, or other contaminants, from entering the gas passages. This is an important precaution; even the slightest deposit of water in the line will contaminate the inert atmosphere to the extent that the equipment cannot be used until considerable time and effort have been expended to remove the moisture.

Moisture contamination of the shielding atmosphere is indicated when the surface of the weld puddle loses its shiny, mirrorlike appearance (goes "cloudy") and visible masses of oxide or solid material float in the puddle. Also, the solidified weld metal will have a rough, irregular appearance. In the welding of aluminum, the slightest trace of moisture in an argon line causes the oxide to float on the surface of the weld puddle and a soft, sooty deposit to form around the puddle and along the sides of the weld deposit. Also, a brilliant indigo-blue color will appear outside the sooty deposit. This is caused by tungsten oxide thrown down on the material. Some welders

have been seen blowing into an argon line. This will cause condensation of moisture from the breath in the tube, and result in the difficulties mentioned earlier in this paragraph.

A systematic procedure should be used for installing or altering inert-gas systems to prevent damage to the work, loss of time, and unsafe practices. It is essential that all argon or helium connections be tight at all times; loose connections not only permit the loss and wasting of expensive inert gas, but also may draw air into the gas line and thus contaminate the atmosphere at the weld location, with consequent damage to the work. The tungsten electrode should be silvery in color on cooling; a bluish to green color denotes air leakage.

Regulators. A gas regulator is a mechanical device for reducing pressure automatically and controlling the volumetric flow of compressed gases. The four principal elements of a pressure-reducing regulator are:

1 A valve element consisting of a nozzle and a mating seat member
2 An adjusting screw, which controls the thrust of the bonnet spring
3 A bonnet spring, which transmits to a diaphragm the thrust created by the adjusting screw
4 A diaphragm connected with the mating seat member.

The bonnet spring holds the valve open until the gas pressure created on the underside of the diaphragm is equal to the thrust of the bonnet spring. The seat member then closes, or partly closes, against the nozzle, thus automatically throttling the flow of gas that is being withdrawn from the outlet of the regulator. A given set of conditions, such as constant inlet pressure, constant volumetric rate of flow, and constant outlet pressure, will produce a balanced condition whereby the nozzle and its mating seat member will remain in a fixed relationship to each other.

There are two basic types of pressure-reducing regulators: the stem type (sometimes referred to as inverse or negative type) and the nozzle type (sometimes referred to as direct-acting or positive type). These two types may be used in combination in a system as two-stage regulators.

Stem-Type Regulators. In the stem type of regulator, the inlet pressure acts to close the seat member against the nozzle. The outlet pressure of this type of regulator increases somewhat as the inlet pressure decreases. This increase is caused by a decrease in the force produced by the gas pressure against the seating area, as the inlet pressure decreases.

Nozzle-Type Regulators. In the nozzle type of regulator, the inlet pressure acts to move the seat member away from the nozzle. The outlet pressure of this type of regulator decreases somewhat as the inlet pressure decreases. The reason for this decrease of outlet pressure is that the force that moves the seat member away from the nozzle is reduced as the inlet pressure decreases. A smaller outlet pressure on the underside of the diaphragm is all that is necessary to close the seat member against the nozzle. The opening between the seat member and the nozzle is reduced, which results in less gas flow.

Two-stage regulators were developed to meet the need for more accurate regulation over a wide range of varying gas pressures. A two-stage regulator is a combination of two single-stage regulators in series, and it reacts as one unit.

Table 8. Conversion Equivalents of Gas Flow Rates

Liters per min	Liters per hr	Cu ft per hr	Life of 244-cu-ft cylinder, hr
1	60	2.1	116.2
2	120	4.2	58.1
3	180	6.4	38.1
4	240	8.5	28.7
5	300	10.6	23.0
6	360	12.7	19.2
7	420	14.8	16.5
8	480	16.9	14.4
9	540	19.1	12.8
10	600	21.2	11.5
11	660	23.3	10.5
12	720	25.4	9.6
13	780	27.5	8.9
14	840	29.7	8.2
15	900	31.8	7.7

The outlet pressure, from the first stage, is usually preset to deliver a specified inlet pressure to the second stage. By delivering a relatively low and very nearly constant inlet pressure to the second stage, an almost constant delivery pressure can be obtained from the outlet of the regulator, even though the supply pressure may vary.

There are several combinations of nozzle-type and stem-type regulators incorporated in one body that are used to make up a two-stage regulator. Regardless of the combinations, the increase or decrease in the outlet pressure is usually so slight (and apparent only at very low inlet supply pressures) that, for all practical purposes, the variation in delivery pressure is disregarded in welding operations.

Many kinds of regulators are produced for various applications. When single cylinders are used, the regulators need not have high capacities; a maximum of 1500 cu ft per hour is usually sufficient. When gas cylinders are manifolded, or a bulk system is used, regulators may have to accommodate a flow of 50,000 cu ft per hour, or more. Regulators at distribution-line stations are normally low-pressure types (up to 500-psig inlet pressure), and are available in various sizes depending on the volume demand at the particular station.

The outlet connections on gas cylinders are of different sizes and shapes to ensure against the possibility of connecting the wrong cylinder. Thus, regulators are made with different inlet conditions to fit the cylinders. The Compressed Gas Association has formulated a complete set of noninterchangeable cylinder-valve outlet connections. Regulator outlet fittings also differ in size and thread, depending on the gas and regulation capacity.

Flowmeters are used to control the flow of shielding gases. A flowmeter is equipped with a manual throttle valve for gas-flow adjustment. The flowmeter tube is calibrated for the specific gas being used, and the operator can set the rate of flow required. The flowmeter tube is calibrated at a positive pressure, which normally exceeds any back pressure produced by the apparatus and thus makes possible a time reading of the gas flow.

Regulator-flowmeter combinations step down the high pressure in the cylinder, or in manifolded cylinders, to a lower working pressure. This lower pressure is then received by the flowmeter. The required gas flow is controlled by the manual adjustment of a throttle valve. The flow is indicated on a flowmeter tube. In operations where the gas consumption is high, a central manifolded-cylinder system can be installed and the gas piped to the various welding stations. Manifold regulators maintain a constant delivery pressure in the piping system. At the welding location, a station flowmeter can be attached to the piping system.

Mixers. When a mixture of two or more gases is used, the mixture is made by metering the separate gases into a mixing chamber. Here the gases are combined and mixed, after which the mixture exits through a single port. Gas mixtures are also available in cylinders.

Maintenance of Adequate Shielding. Protection of the heated and welded surface is often not complete if the weld progresses too fast. To obtain satisfactory shielding at high welding speed, one or more of the special measures discussed here are required. Insufficient shielding may be corrected in some instances by inclining the torch in the direction of welding, by directing it backward over the finished weld, or by increasing the gas flow. Ordinarily, when reactive metals such as titanium and zirconium are being welded, special gas nozzles are used that direct the atmosphere back over the heated and welded surface (see the discussion under "Shape of Nozzle", on page 117 in this article). For these metals and alloys, which are subject to gaseous contamination in the solid state at elevated temperature, separate means of protection by inert atmosphere furnished from a separate source must often be provided. Sometimes even this is not wholly effective, and the entire operation may have to be done within an inert-atmosphere chamber. (See pages 375 to 382.)

Drafts and Air Currents. To avoid contamination of the shielding atmosphere brought to the weld area by the torch, the ideal location for gas tungsten-arc welding is a draftless area. If conditions of disturbed air exist, suitable baffle screens should be set up around the operation. If work is to be done in the open, a portable framework of convenient size may be erected around the work area. This may be covered by canvas, leaving an opening for entry. When welding with any gas-shielded process is done in the field, much time, effort and difficulty will be avoided by providing some method of proper protection against drafts.

Conditions of disturbed air can be overcome to a degree by delivery of a greater volume of inert gas to the work, but ordinarily this is inadvisable because of the much greater expense involved per unit weld, as well as the fluctuations in shielding obtained under such conditions. Inclining the torch toward the direction from which the draft is coming will help somewhat, but this will hinder the welding operation and make it more difficult to perform.

Accessory Equipment

Jigs or restraining fixtures should be used whenever possible, to hold workpieces in alignment and to exert pressure at the proper point so that the

work cannot move during heating and cooling. If alignment, or joint fit-up, is not maintained, expansion and contraction may cause distortion or mismatch of the welded joint. Principles of fixturing for gas tungsten-arc welding are generally the same as for other welding processes (see the sections on fixtures in the articles on Shielded Metal-Arc Welding, page 11, and Gas Metal-Arc Welding, page 90). However, fixturing is frequently more critical for gas tungsten-arc welding, because the workpieces are often made of thin metal and thus are more susceptible to deformation than heavy structural parts.

Tack welding may be used in manual welding operations in which the shape of the workpieces prevents the use of fixtures, or in which production quantity is too small to warrant the cost of fixtures. However, in semiautomatic or automatic welding, tack welds may impair control of arc voltage and of filler-wire feeding.

Weld backing improves the uniformity, appearance and contour of a weld. Thin work metal is usually backed to protect the underside of the weld from atmospheric contamination, which may result in weld porosity or poor surface appearance. Backing bars also absorb some of the heat generated by the arc and can lend support to the assembly and the weld puddle. A weld can also be backed up with inert gas, which serves to control penetration and maintain a bright, clean undersurface, but does not function as a support. Sometimes, metal backing bars and an inert gas are used in combination.

Nitrogen has been used effectively to back stainless steel welds, but caution is necessary to prevent contamination of the arc atmosphere with nitrogen, which will cause arc instability. The use of nitrogen for backing can contribute substantially to the economy of the operation.

In applications where the final weld composition must conform to extremely rigid specifications, particular care must be taken to exclude all atmospheric gases from the underside of the weld. This is accomplished by introducing an atmosphere of shielding gas into the relief groove of a backing bar (as shown in Fig. 8).

Automatic Welding. Fixtures for automatic gas tungsten-arc welding must be designed to permit rapid assembly of parts and easy removal of the weldment after completion. Where high-volume production welding is required, automated welding equipment in various combinations can be used. This equipment is composed of the machine head, control panel, and motorized carriages or work positioners that are employed to move the welding torch along the welding seam. The machine head contains the torch body and a wire-feed mechanism to supply the filler metal at a regulated speed. The control panel contains indicating meters for current and voltage; components that determine arc-starting time; time-delay relays for gas and water supplies; controls for current increase (upslope) or current decay (downslope); and controls for wire-feed starting, delay and stop. (See also the discussion under

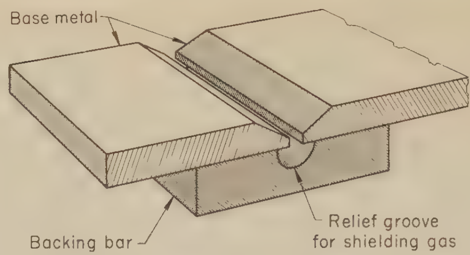

Fig. 8. Use of a backing bar with a relief groove for shielding gas, to exclude atmosphere from underside of weld

"Equipment" in the section on Automatic Welding, page 134.)

Longitudinal seamers, often called stake welding fixtures, are designed to locate and clamp both sides of a straight butt joint, as shown schematically in Fig. 9. The butt joint may be between two plates or be the longitudinal seam of a flat, conical, circular or rectangular workpiece. A longitudinal seamer consists of a base, which contains a weld backing bar to which the work is clamped by hold-down fingers, and an upper beam structure (not shown in Fig. 9), which supports a traveling carriage and track carrying the welding head, wire-feed mechanism, and clamping fingers. The upper beam structure is cantilevered, being secured to the base and hinged at one end for support, and with the opposite end remaining open to permit loading and unloading of the workpieces. A pivoted locking latch is provided at the loading end to restrain the cantilevered upper beam when the clamping force is applied.

The clamping mechanism is composed of two rows of hold-down fingers, which firmly hold the workpiece during welding. Each row may be independently actuated by means of manual or foot-operated valves that control mechanical, magnetic, hydraulic or pneumatic pressure systems. The intensity of clamping force may be controlled by means of a pressure-regulating device.

The backing bars are removable to permit the use of variously contoured groove openings for different thicknesses and types of metal. The bars may also contain relief grooves that permit flow of shielding gas to the underside of the weld (as in Fig. 9), and they may have provision for thermostatically controlled heating or cooling.

Pedestal boom manipulators can be used for rapid positioning and welding in any direction to produce internal or external longitudinal or circumferential (girth) welds. This equipment is suitable for use with power rolls or headstock-tailstock welding positioners on tanks, vessels, pipes and similar weldments. Rotating positioners, to which fixtures or other workholding tooling devices are mounted, are readily adapted to use with pedestal boom manipulators for small production runs or special fabrications.

Power supplies, filler-metal supplies, portable coolant tanks, automatic welding heads, and remote controls can be mounted on a pedestal boom manipulator. A typical pedestal boom manipulator that includes some of these features is shown in Fig. 10.

Pedestal boom manipulators can be moved manually, on integral wheeled bases, to work locations, or they can be powered to travel at welding speeds on rails.

Rotating positioners (see Fig. 16 in the article on Shielded Metal-Arc Welding) are probably the most adaptable type of fixtures for manual or automatic welding. The positioner worktable is a circular or square plate that has been machined to a flat surface and is fitted with T-slots for bolting down various jigs or workholding tools. The worktable can be rotated for 360° circumferential welds in any plane from flat to 10° past vertical. Variable rotational speeds and provision for smooth starting and stopping are mandatory for automatic welding operations. Pedestal boom manipulators are used to position the automatic welding head over the joint, and the positioner worktable may be started manually or sequenced to start automatically.

Skate welders are lightweight motorized travel carriages on which seam-tracking positioners, a wire-feed system and the automatic welding head are mounted. A skate welder enables precision welding of massive structures that cannot be handled by conventional rotating positioners and longitudinal seamers. Straight or curved track sections are attached directly to the workpiece by bolting or suction cups, permitting movement of the welding carriage in a continuous path along the weld seam. The skate carriage can be operated in horizontal and vertical directions to enable making out-of-position welds.

In skate welding of large assemblies, a mobile service carriage, which contains the power supply, the gas supply, all the control elements, and the operator, is synchronized to travel with the moving skate carriage during welding. Such equipment is satisfactory for long duty cycles on large assemblies.

Cables must be kept to a minimum length, and must be of ample size to handle the welding current. Excessively long cables or undersize cables will cause loss of current and voltage. Long cables should never be coiled up; rather, the proper length of cable should be obtained. Welding cables must not be operated at currents in excess of their rated capacity, or overheating and rapid deterioration of the insulation will result. Frayed or worn cables should be replaced or repaired immediately, to prevent short circuiting.

For welding with high-frequency arc stabilization, cables should be as short as practical, to prevent high-frequency attenuation. The cable between the high-frequency unit and the torch should be suspended from insulated hangers and not be taped or looped with other cables. In automatic welding operations where a jig or holder is used, all metallic parts containing the workpiece must be grounded, to prevent arc-over or burning.

Interfering radiation can escape in four distinct ways from an installation for machine welding by the gas tungsten-arc process in which high-frequency stabilization is used:

1 **Direct radiation from the welding machine.** This may be minimized if the

cover case of the welding machine is properly grounded.

2 **Direct feedback to the primary power line.** This may be prevented by enclosing the line in solid metallic conduit for at least 50 ft away from the welding machine in an unbroken line.

3 **Direct radiation from the welding cables.** High-frequency attenuation may be minimized by keeping the welding cable as short as possible.

4 **Pickup and reradiation from power lines and unshielded wiring.** Telephone wires, electric wires and ungrounded metallic objects up to 50 ft away from the welding machine may pick up high-frequency radiation and conduct it for some distance before reradiating a strong interference field in another area as a radiating antenna.

Water hoses should have a large diameter and be short, to minimize pressure drop in the flow of cooling water. Water flowing at about one quart per minute will provide adequate cooling of the torch. To maintain proper flow, a hose 12½ ft long must have a line pressure of at least 25 psi, and a hose 25 ft long should have a pressure of 35 psi. A pressure regulator may be required if supply pressure exceeds 35 psi; otherwise, the hoses may be damaged.

Cooling Water. Water-cooled torches must have a continuous supply of cool, clean water. In areas where the water supply has a high mineral content and contains excessive amounts of particles, it may be necessary to filter the water, to prevent clogging of the torch cooling passages. An alternative is the use of a water-recirculating system, as is required for portable equipment systems.

For portable installations, a water tank with a 10 to 40-gal capacity, equipped with an electrically driven pump, is usually adequate. The water tank should be filled with distilled, demineralized or deionized water. A bactericide or fungicide may also be added to further ensure its quality.

Equipment Location

Because welding cables, shielding-gas hoses, and water hoses must be short, the welding equipment and power supply must be near the work location. The following aids to equipment location have been used successfully:

1 **Portable carts** with integral water tanks, which will accommodate a power supply and gas-supply cylinders, and have racks for storing hoses and cables.

2 **Pedestal boom manipulators,** which have a tracked, car-type base that can be moved manually or by power. The base usually is large enough for one or more power supplies, gas-supply cylinders, and water tanks, and may be equipped with an operator's control station.

3 **Overhead track-type carts,** which may be equipped like the portable carts described above but with the primary electrical power supplied from a moveable slider contact on a bus bar. These units are difficult to maintain, but they provide a high degree of mobility for the welder and maximum utilization of floor space.

Filler Metals

The selection of a filler metal for gas tungsten-arc welding depends primarily on the base metal being joined.

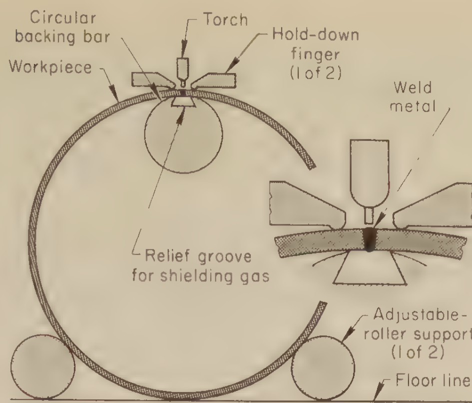

Fig. 9. Setup for automatic welding of longitudinal butt joints (see text)

Other influencing factors are: required mechanical and physical properties, joint design, and required finish or appearance of the welded part. To accommodate varied requirements, filler metals in a wide range of compositions are available for each group of alloys; Table 9 lists applicable AWS specifications. These specifications identify and give compositions for filler metals normally used for gas tungsten-arc welding; other compositions are available to meet more specialized requirements.

Forms, Sizes and Use. Filler metals are available in the form of rods, spooled wire, and consumable inserts.

For straight rods, standard diameters range from 0.030 to 0.25 in.; nominal length is 36 ± 0.375 in. Straight rods are available in 1, 5, 10, 25 and 100-lb packages. Wire diameters range from 0.020 to 3⁄16 in.; spools range in outside diameter from 4 to 12 in. Consumable inserts are designed to meet size and shape requirements of specific joints; some types of consumable inserts have been standardized.

Table 9. AWS Specifications on Filler Metals for Use in Gas Tungsten-Arc Welding of Various Metals

Metal welded	AWS specification on filler metals
Aluminum alloys	A5.10
Copper alloys	A5.7
Magnesium alloys	A5.19
Nickel alloys	A5.14
Steel, carbon	A5.18
Steel, stainless	A5.9
Titanium alloys	A5.16

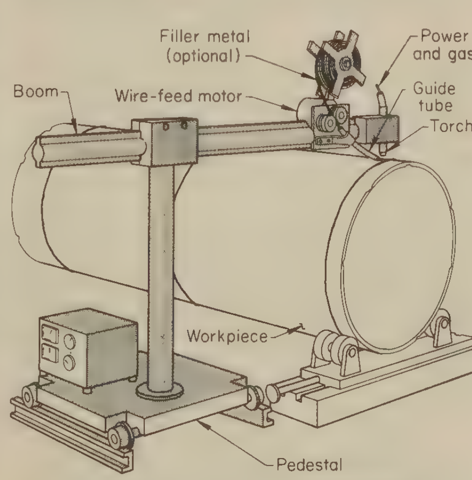

Fig. 10. Use of a pedestal boom manipulator for making a circumferential (girth) weld

Filler metals are added either manually or automatically during welding, or are added as preplaced consumable inserts. Manual additions are made by hand-feeding a filler rod to the weld puddle. Automatic feed systems supply filler metal, normally as spooled wire, to the weld puddle at a predetermined rate. Consumable inserts are placed in the weld zone before the arc is started, and are consumed in the weld puddle during welding (see also "Use of Consumable Inserts", page 128).

Storage and Preparation. Manufacturers of filler metals employ elaborate techniques to ensure that rod or wire is clean prior to packaging. Storage under improper conditions will very likely result in contamination of the filler metal. Any oil or other organic material on filler metal, or a heavy oxide film, will interfere with the deposition of sound weld metal.

Filler metal should be stored where condensation will not contaminate it. Normally, an area that has reasonably constant temperature and low humidity, and that is protected from oily shop atmospheres, is adequate. More elaborate facilities may include temperature and humidity controls or inert-gas chambers designed to remove air and moisture.

For most welding applications, filler metal that has been properly stored requires no specific preparation prior to welding. When necessary, straight rods may be degreased, cleaned chemically by etching, or rubbed with steel wool or abrasive to remove traces of oxide. These techniques may also be used to clean coiled filler metals, but uncoiling and recoiling is a time-consuming chore.

Joint Design

The five basic types of joints — butt, lap, corner, edge and T — are all used in gas tungsten-arc welding. Variations of these joints can be made to meet special requirements. Selection of the proper design for a particular application depends primarily on:

1 Mechanical properties desired
2 Cost of preparing the joint and making the weld
3 Type of metal being welded
4 Size and configuration of the components to be welded.

Edge and joint preparation are critical to the obtaining of sound welds, because proper joint fit-up is necessary — particularly for square-groove butt joints and any other joint to be made without adding filler metal.

Butt Joints. A square-groove butt joint is the easiest to prepare, and can be welded with or without filler metal, depending on the composition and thickness of the pieces being welded. A single-V-groove butt joint is used where complete penetration is required on work metal more than 3⁄16 to ⅜ in. thick. (The maximum thickness of square-groove butt joint that can be penetrated from one side depends greatly on composition of the metal being welded. For instance, the maximum practical thickness for stainless steel is approximately 3⁄16 in., whereas for an aluminum alloy this limit is about ⅜ in.) Filler metal must be used

for a V-groove weld. The included angle of the V-groove should be approximately 60°. The root face will be ⅛ to ¼ in. high, depending on the composition and thickness of the pieces being welded.

A double-V-groove butt joint is generally used on stock thicker than ½ in., when design of the weldment permits access to the back of the joint. Butt joints of special design are sometimes used for very thick work metal, which may require many welding passes (often by other processes in addition to gas tungsten-arc welding). However, the shape and dimensions of the portion of these joints where welding begins are usually close to those described above.

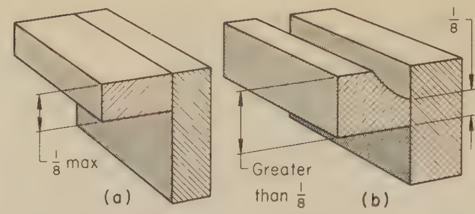
Butt joints of special design are used also in welding with consumable inserts (see Fig. 13 and the discussion under "Joint design" on this page).

Lap Joints. A lap joint has the advantage of eliminating the need for edge preparation. The only requirement for making a good lap weld is that the plates be in close contact along the entire length of the joint to be welded. This requirement is difficult to meet for thin base metal unless jigs and fixtures of appropriate design to provide adequate clamping are available. Otherwise, closely spaced tack welds may be necessary. Lap joints are difficult to repair, finish or clean, and they frequently have root defects.

Corner joints are used for fabricating boxlike structures. Two designs of corner joints are illustrated in Fig. 11. Assuming that the work metal is stainless steel, if the metal is no thicker than ⅛ in., the corners can be butted as shown in Fig. 11(a), and a satisfactory weld can be produced without filler metal; if the metal is thicker than ⅛ in., one of the corner members must be beveled or shaped as shown in Fig. 11(b).

Edge joints do not usually require the addition of filler metal. Three common types of edge joints are illustrated in Fig. 12; a feature common to all three types is that the thickness of the two components at the point of being joined is approximately the same. For joining thin turned-up edges, such as are illustrated in Fig. 12, some sort of backing for a heat sink is usually required to obtain uniformly fused edges.

T-joints require the addition of filler metal to provide the necessary buildup of fillet-weld size. The number of passes that must be made on each side of the joint depends on work-metal thickness and required weld size.



The thickness limits shown apply to stainless steel, or to metals with thermal conductivity similar to that of stainless steel.

Fig. 11. Corner joints for thin and thick metals

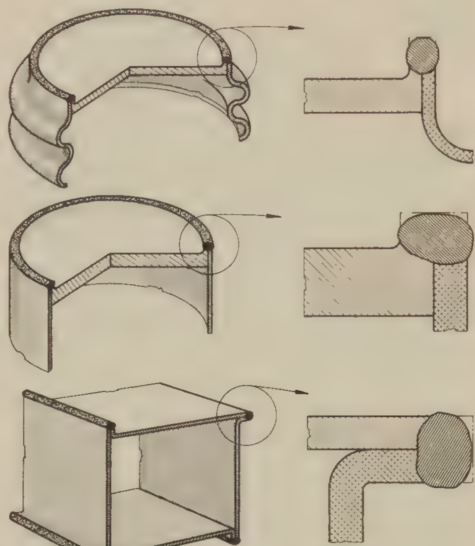


Fig. 12. Typical designs of edge joints

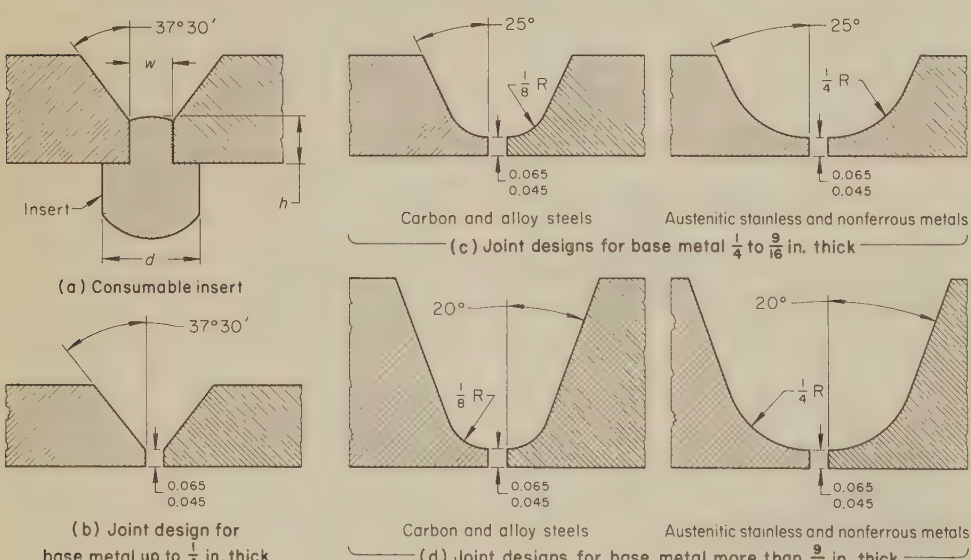


Nominal dimensions, *d*, *w* and *h* as shown in (a), for two sizes of inserts, are as follows: **⅛-in. inserts:** *d*, 0.125 in.; *w*, 0.047 in.; *h*, 0.055 in.; **5/32-in. inserts:** *d*, 0.156 in.; *w* and *h*, 0.063 in.

Fig. 13. (a) *Shape of one type of consumable insert placed between two pipe sections prior to welding.* (b), (c) and (d) *Joint designs for consumable inserts.*

Use of Consumable Inserts

The consumable-insert method of root-pass welding was originally developed for use in the fabrication of nuclear-powered submarines, for which the highest-quality joints are essential. This method is intended primarily for applications in which (*a*) accessibility is limited to one side of the joint; (*b*) smooth, uniform, crevice-free inner weld surface contours are essential; and (*c*) the highest quality attainable in the root pass is mandatory.

This method involves the use of an insert that is completely fused by a gas tungsten arc. The insert permits the deposition of a root-pass bead that is smooth and uniform even though welding is done from one side only. It provides full penetration to the root of the joint from the top side of the joint. The insert method is especially useful in butt welding of pipe, although there are no particular restrictions on its application. However, consumable inserts must be precisely fitted. Consumable inserts serve as backing rings, and are frequently specified in pipe welding.

Typical Insert. A cross-sectional view of one type of consumable insert is shown in Fig. 13(a); nominal dimensions of two common sizes of these inserts are noted below Fig. 13. Inserts of this type are available in a variety of compositions, including carbon, alloy, heat-resisting and stainless steels, and nickel and copper alloys.

The insert shown in Fig. 13(a) is placed between two pipe sections prior to welding. The inside diameters of the pipe sections at the root-face intersection may differ or be eccentric with misalignment of as much as 1/32 in. without any adverse effect on quality of joint or internal weld contour.

Joint design for use with consumable inserts of the type shown in Fig. 13(a) depends on the thickness and composition of the base metal, as illustrated in Fig. 13(b), (c) and (d). The single-V groove with shallow root faces (Fig. 13b) is satisfactory for base metal up to ¼ in. thick. For thicker metal, the design should be altered to U-grooves as shown in Fig. 13(c) and (d).

Welding Procedure. In most applications of joining with consumable inserts, gas tungsten-arc welding is used only for tacking and for the root pass. Other welding processes that are capable of depositing metal faster than gas tungsten-arc welding are ordinarily used for completing the weld. A typical procedure for using a consumable insert for making a high-quality weld that joins two pipe sections with the axis of the pipe in the horizontal-fixed position consists of the following:

1 Place an insert (ring form), with its overlap, on one pipe end that has been prepared (usually by machining).
2 Using a gas tungsten-arc torch, make small tack welds appropriately spaced to obtain a close fit, starting at one end of the insert and continuing halfway around the circumference.
3 Using a hacksaw or hand shears, cut off the overlapping ends so that the ends of the insert are butted together and the gap between the ends of the insert does not exceed 1/32 in.
4 Tack weld the remainder of the insert to the pipe end. One of the tack welds

should be at the splice where the insert ends are butted together.

5 Butt the second pipe against the insert that has been tacked to the first pipe end. The fit-up tolerance should not exceed $1/32$ in.

6 Midway between the original tacks, tack weld the second pipe to the insert and continue the tack across the insert to include the first pipe section.

7 From the top of the joint, weld upward first on one side, and then on the other, fusing the insert with the pipe ends to complete the root pass.

8 Complete the joint by any welding process, using filler metal.

For highest-integrity welds it may be necessary to use a backing of inert gas while welding the root pass. This is done by placing a cap over the end of the pipe and purging with an inert gas.

Although the procedure described above was developed primarily to produce high-integrity welds, it may also prove to be less costly than other methods, as in the following example of an improved joint design.

Example 128. Joint Redesign That Reduced Cost by Permitting a Root Pass To Be Made by Gas Tungsten-Arc Welding With a Consumable Insert (Fig. 14)

The longitudinal butt joints in 20-ft-long sections of SA-106, grade B, carbon steel pipe used for power-boiler headers were originally designed as shown at lower left in Fig. 14. With this design, the root pass and the second pass were made by shielded metal-arc welding using a backing bar, and then the weld was completed by the submerged-arc process.

To reduce cost, the joint design was changed to that shown at lower right in Fig. 14. This permitted making the root pass by gas tungsten-arc welding, using a consumable insert, instead of by shielded metal-arc welding with a backing bar. Then, as with the original joint design, the second pass was made by shielded metal-arc welding and the weld was completed by the submerged-arc process. The shielded metal-arc process was used for the second pass to provide a deposit thick enough to ensure against melt-through by the submerged-arc process.

Welding conditions for the improved joint design are given in the table that accompanies Fig. 14, together with a comparison of welding costs for both designs. As the comparison shows, the improved joint design and change in welding procedure resulted in a 25% saving in cost (material, labor and overhead) per foot of seam welded.

Cleaning the Work Metal

Welds made by the gas tungsten-arc process are extremely susceptible to contamination during the process. Therefore, the work metal must be free of grease, oil, paint, marking-pencil inscriptions, cutting lubricants, plating, dirt and oxides, or any other foreign material. It is possible, for instance, to pick up enough sulfur from soil contaminants to introduce brittleness in some joints. Heavily soiled workpieces (except those made of titanium alloys) are usually cleaned by immersion in emulsion or solvent cleaners followed by vapor degreasing with trichlorethylene. Phosphorus, lead, zinc, cadmium, and low-melting alloys, and iron contamination from metal stamping dies, also must be removed prior to welding.

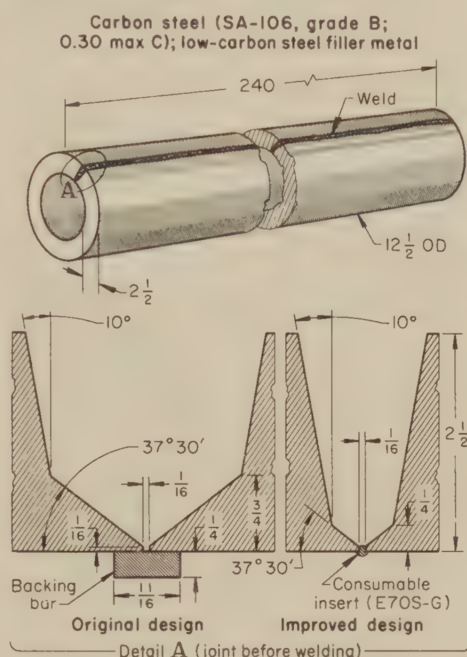
Simple degreasing is enough preparation for metals that have oxide-free surfaces. For metals with a light oxide coating, acid pickling treatments are generally used. Heavy oxide scales are removed by mechanical cleaning operations, such as grinding and abrasive blasting. When a plate having an oxide coating is sheared, the oxides may become embedded in the sheared edge. These oxides cannot be removed by chemical means, but must be removed by grinding or filing. Cleaning processes that should be used for various work metals are discussed briefly in the following paragraphs. (For more detailed information on cleaning of specific metals, see Volume 2 of this Handbook.)

Aluminum Alloys. Exposure to the atmosphere quickly causes the formation of a self-protective oxide coating on aluminum surfaces. This oxide coating, which is highly refractory and has considerable electrical resistance, must be removed by deoxidation with a hot alkaline cleaning solution, followed by rinsing in demineralized or deionized water.

Nickel alloys and stainless steel may be chemically cleaned by pickling to remove sand-blast residue or iron and other contaminants. The pickling solutions usually are composed of 5 to 20% nitric acid plus 0.5 to 2% hydrofluoric acid in water, and are used at 130 to 160 F; treatment time is 5 to 30 min, depending on the thickness of the contamination or oxide on the surface.

Carbon and low-alloy steels may be chemically cleaned in solutions of 50% hydrochloric acid in water; the acid treatment is followed by desmutting with an electrolytic chromic acid dip and by a cold-water rinse.

Titanium alloys may be descaled in molten salt baths or by abrasive blasting (see the article on Arc Welding of Titanium Alloys, which begins on page 375). Chlorinated solvents, such as trichlorethylene, should not be used for degreasing titanium alloys, because the chlorine residues cause intergranular attack in subsequent heating operations. Chemical cleaning may be performed by pickling for 1 to 20 min in solutions containing 20 to 47% nitric acid plus 2 to 4% hydrofluoric acid in water, or about a 10-to-1 ratio of nitric acid to hydrofluoric acid; bath temperature is 80 to 160 F.



Item	Original design(a)	Improved design(b)
Comparison of Costs per Foot Welded		
Weld metal	\$ 3.22	\$ 2.15
Labor and overhead	18.00	13.75
Total cost per foot	\$21.22	\$15.90
Saving with improved design		\$ 5.32

Welding Conditions for Improved Design

Welding process:
- Root pass .... Gas tungsten-arc
- Second pass .... Shielded metal-arc
- Remainder .... Submerged-arc

Power supply:
- Gas tungsten-arc and shielded metal-arc .. 200-amp transformer-rectifier(c)
- Submerged-arc .. 600-amp motor-generator(d)

Edge preparation .... Machined
Preheat .... 250 F min

Filler metal (mild steel):
- Gas tungsten-arc (argon shielding) ...... E70S-G, consumable insert
- Shielded metal-arc E7018
- Submerged-arc EL12

Power setting:
- Gas tungsten-arc ...... 90 amp, dcsp; 12 volts
- Shielded metal-arc .... 120 amp, dcrp; 23 volts
- Submerged-arc .... 450 amp, dcrp; 30 volts

Interpass temperature .... 500 F max
Postheat .... Stress relieve at 1150 ± 25 F(e)

(a) With the original joint design, the root and second passes were made by shielded metal-arc welding using a backing bar. Weld was then completed by submerged-arc welding. (b) With the improved joint design, the root pass was made by gas tungsten-arc welding using a consumable insert (no backing), the second pass by shielded metal-arc welding, and the remainder by submerged-arc welding. (c) With high-frequency start, and slope control. (d) Welding head on boom-type manipulator; workpiece supported on power and idler rolls for turning. (e) In furnace; 1 hr per inch of section.

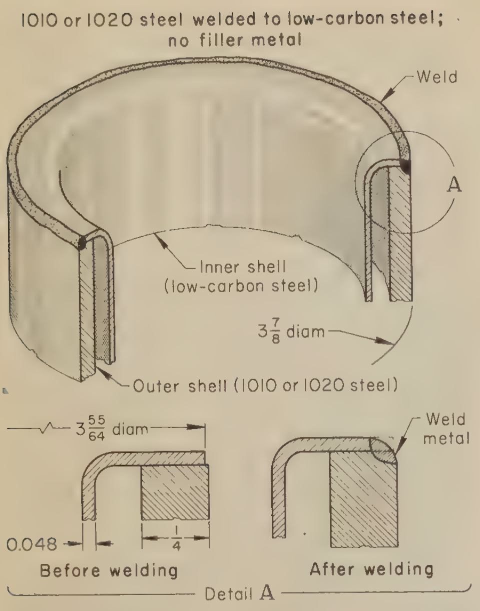
Fig. 14. Revision of joint design, entailing the use of a consumable insert, that permitted change to a lower-cost method of welding boiler-header pipes (Example 128)

Welding of Carbon and Alloy Steels

Carbon Steel. The weldability of carbon steel, for a given thickness and joint design, depends mainly on carbon content, and it is essentially the same for gas tungsten-arc welding as for other arc welding processes. As carbon content increases, difficulty in welding also increases — generally, in the form of cracking in the weld or in adjacent base metal. Thus, the requirements for preheating and postheating increase as carbon content increases, as in any other welding process. Other elements in carbon steel, however, such as sulfur, phosphorus and oxygen, generally have greater influence on weld quality in gas tungsten-arc welding than in other arc welding processes, such as shielded metal-arc or submerged-arc welding.

When gas tungsten-arc welding was first applied to carbon steels, the filler-metal compositions were selected on the basis of weld-deposit compositions obtained with the older, well-established processes. The result was that high-quality welds could not be produced consistently. Base-metal composition proved to be a major variable. For instance, rimmed steels were more susceptible to porosity in the weld than similar steels that were fully killed (see Example 139). Further, it was found that shielding gas, current density and other operating variables also had a marked influence on weld porosity in welding of carbon steel and must be kept under close control to obtain successful welds consistently.

For further information on welding carbon steels having higher carbon content (generally, more than 0.25% C), see page 187 in this volume.



Joint type	Corner
Weld type	Corner fillet
Process	Manual gas tungsten-arc
Electrode	$\frac{1}{16}$-in.-diam EWTh-2
Welding torch	250-amp, water cooled
Filler metal	None
Shielding gas	Argon, 8 to 10 cfh
Welding position	Horizontal or vertical
Current	120 amp, dcsp
Voltage	14 v
Arc starting and stabilization	High open-circuit voltage
Power supply	250-amp transformer-rectifier
Welding speed	25 to 30 ipm
Fixturing	Centering and hold-down clamps; variable-speed drive for rotation

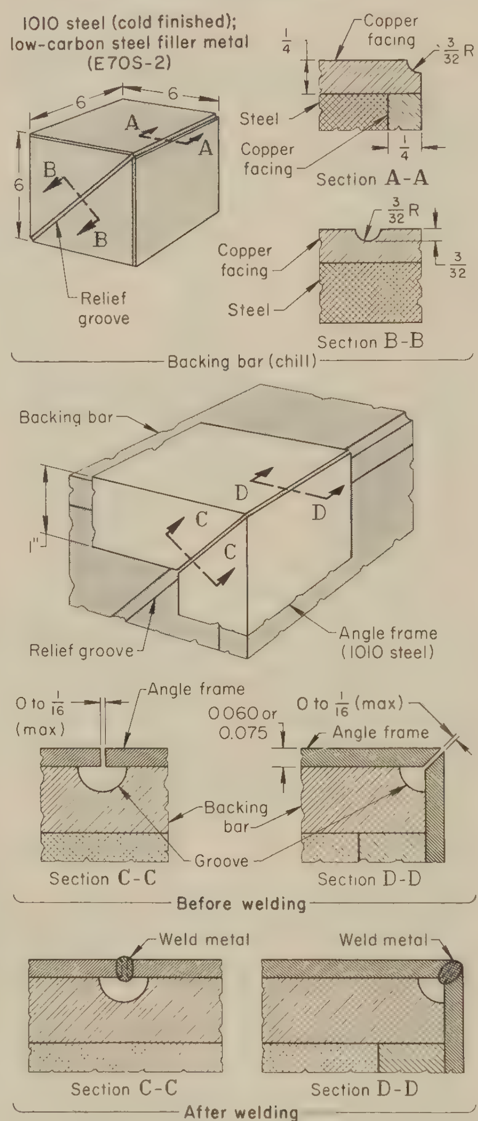
Fig. 15. Double-wall bearing mold welded by the gas tungsten-arc process at three to four times the speed obtained in gas welding (Example 129)

Alloy steels of all types are successfully welded by the gas tungsten-arc process. Alloy steels, however, particularly those that contain more than about 0.20% carbon, are far more susceptible to cracking than plain low-carbon steels. For this reason, all aspects of the welding practice must be under more careful control for alloy steels than is usually necessary for plain low-carbon steels. For instance, it is even more important that welds be located as far as possible from points of maximum stress. Joint design should be such that full penetration can be obtained and thorough inspection of the weld is possible. (For detailed information, see "Arc Welding of Alloy Steels", page 200.)

High-strength structural steels, also known as high-strength low-alloy steels, are welded by virtually all welding processes, including gas tungsten-arc. As with other alloy steels, susceptibility to cracking in the heat-affected zone is the most common problem in welding of these steels. However, some of these steels have specific properties or contain elements in amounts that intensify cracking difficulties during or after welding. For instance, some high-strength low-alloy steels contain relatively high percentages of phosphorus. Since phosphorus and sulfur increase susceptibility to cracking, it is desirable to keep the total content of phosphorus and sulfur well below 0.30%. Silicon contributes to cracking in some grades.

In welding these steels, inert gases with leading and trailing shields are often used to prevent weld contamination from the atmosphere. Preheating or postheating, or both, are often used to prevent cracking and to assist in attaining specified mechanical properties. In most applications, the use of gas tungsten-arc welding on these steels is restricted to the root pass; another process, such as shielded metal-arc or submerged-arc welding, is used for the remaining passes.

For further information on welding these steels, see the article that begins on page 200 in this volume.



Joint types	Butt, and mitered corner
Weld type	Square groove
Process	Manual gas tungsten-arc
Power supply	250-amp motor-generator
Electrode	$\frac{1}{16}$-in.-diam EWP
Arc length	$\frac{1}{8}$ in., approx
Filler metal	$\frac{1}{16}$-in. diam, same as E70S-2
Number of passes	One
Shielding gas	Argon, 20 cfh
Welding torch	150-amp, air cooled
Edge preparation	None (as-sheared)
Current	65 amp, dcsp
Voltage	Low-range setting
Welding position	Horizontal and vertical

Fig. 16. Use of a grooved backing bar in gas tungsten-arc welding of an angle frame, which reduced welding time and finishing time required when frame had been gas welded (Example 130)

Production Examples of Welding Low-Carbon Steel

Partly because of the difficulty in obtaining consistent results, and partly because gas tungsten-arc welding was generally considered a high-cost process compared with gas welding, shielded metal-arc welding or submerged-arc welding, there has been some hesitation in adapting the gas tungsten-arc process to the welding of low-carbon steels. However, consistent results can be obtained by close control of the steel being welded and the welding operation. Further, the cost of using gas tungsten-arc welding for carbon steels is not necessarily higher than the cost of competitive processes; in many applications, the finished weldment has cost less because production rate was higher, because control was better, or because the better appearance made possible by gas tungsten-arc welding eliminated, or at least reduced, post-weld operations. The four examples presented in this section describe specific applications for which gas tungsten-arc welding was used in preference to another process for one of the above reasons.

Gas Welding vs Gas Tungsten-Arc Welding. Although manual gas tungsten-arc welding differs greatly from gas (oxyacetylene) welding, the two processes are similar as regards manipulation. Both processes can be used with or without the addition of filler metal. (When filler metal is used, the welder has both hands occupied.) Although gas tungsten-arc welding allows less freedom of movement, filler metal can be added as needed, at the option of the welder. However, the tungsten arc produces a higher temperature, resulting in deeper, narrower welds made at higher welding speeds, generally with lower total heat input and narrower heat-affected zones. Both processes are used effectively on thin work metals. These similarities and differences suggest that manual gas tungsten-arc welding can be substituted for gas welding for higher productivity in selected applications, as described in the next three examples.

Example 129. Change From Gas Welding to Gas Tungsten-Arc Welding That Increased Productivity 300 to 400% (Fig. 15)

Double-wall steel cylinders of the design shown in Fig. 15 were used as molds for sleeve and journal bearings. The inner shell was a 0.048-in.-thick sleeve flared over at one end to a diameter $\frac{1}{64}$ in. less than the outside diameter of the outer shell. When properly centered, the sleeve could be slipped into the outer shell so that the flared edge could be welded to form a concentric annular closure (Fig. 15). The major welding problem was to obtain a leakproof weld without burning through the thin sleeve.

Gas welding, which was originally used for this application, produced satisfactory welds. For gas welding, the inner and outer shells were positioned in a plug-type fixture that centered the sleeve and permitted the flare to rest concentrically on the outer shell. With the assembly in the vertical position (Fig. 15), welding was done in the horizontal position. Because the flare edge was set back from the outside of the outer shell, a conventional fillet weld could have been used to make the joint, but it would have been too time-consuming. Instead, a slightly reducing flame was used to melt the

two edges of the joint, with the flame directed chiefly at the exposed corner of the outer shell. This technique not only avoided burning through the thin sleeve, but also provided the desired weld puddle. Filler metal — a high-tensile-strength (75,000 to 90,000 psi) steel rod of proprietary composition designed for fast deposition — was used only as required. Nevertheless, this procedure appeared to be too slow compared to the possibilities offered by manual gas tungsten-arc welding, and a change was therefore effected.

To take advantage of the higher welding speed of the gas tungsten-arc process, a new welding fixture was required. This fixture consisted of a centering device that clamped the shells in concentric alignment from the open end, and a spring-loaded clamp that held the flared end of the sleeve in positive contact with the outer shell. The unit was rotated by a variable-speed (0.10 rpm) drive actuated by a foot switch, and was additionally gimbal mounted to permit welding in either the vertical or the horizontal position.

Gas tungsten-arc welding was done in a single pass, entirely without filler metal. No change in the design of the shells was required, since the welding technique was essentially the same as that described for gas welding. To attain high speed with the new process, however, welders required special practice sessions. Welding speed was three to four times greater than that obtained in gas welding; the assemblies were gas tungsten-arc welded at the rate of 40 per hour. Additional conditions for gas tungsten-arc welding are given with Fig. 15.

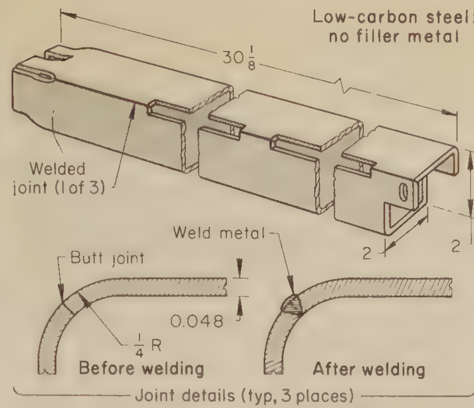
Examples 130 and 131. Change From Gas Welding to Gas Tungsten-Arc Welding, To Reduce Welding and Finishing Time

Example 130 — Angle Frames (Fig. 16). In the welding of butt joints and mitered corner joints in angle frames (see joint details in the lower views in Fig. 16), satisfactorily smooth appearance and freedom from distortion were more difficult to obtain than adequate strength. Formed from cold finished (rimmed) 1010 steel 0.060 or 0.075 in. thick, the angles varied from 1 by 1 in. to 1 by 3 in., and the welded frames varied from 3 by 3 ft to 4 by 8 ft over-all, with varying corner angles. Appearance was critical because the frames were assembled on the sides and ends of finished office equipment.

To minimize grinding and dressing, it was important to control weld buildup and heat input, as well as to avoid porosity and surface defects. Adhesive fillers could not be used to smooth surface imperfections, because they were not compatible with the phosphate coating and the high baking temperature of the enamel finish. Since the weld depended to some extent on the accuracy of forming and mitering, joint design called for a close-fitting square butt and corner joint with no overlap. Maximum permissible root opening was 1/16 in.

Originally, single-pass welds were made by manual gas welding. However, because of the weld-metal buildup, and the distortion and oxidation due to the heat input, considerable grinding and dressing were required. Changing to manual shielded metal-arc welding for six months resulted in only slight improvements, and a six-month trial using semiautomatic gas metal-arc welding with E70S-2 electrodes produced but a small improvement in finishing time. Then gas tungsten-arc welding was tried, and weld quality improved significantly.

Two particular requirements for gas tungsten-arc welding were: (*a*) the use of a backing bar, which served also as a chill; and (*b*) the selection of a filler metal designed to avoid porosity. The backing bar (see upper view in Fig. 16) consisted of a block of steel faced with 1/4-in.-thick copper shaped to fit the inside contour of the angle joints, with a groove 3/16 in. wide by 3/32 in. deep cut in the copper face to allow for underside weld reinforcement. The filler metal was of the same composition as the E70S-2



Joint type	Butt

Current	180 amp, dcsp
Voltage	16 v
Arc starting	High frequency
Power supply	300-amp motor-generator linked with high-frequency generator
Welding speed	75 ipm

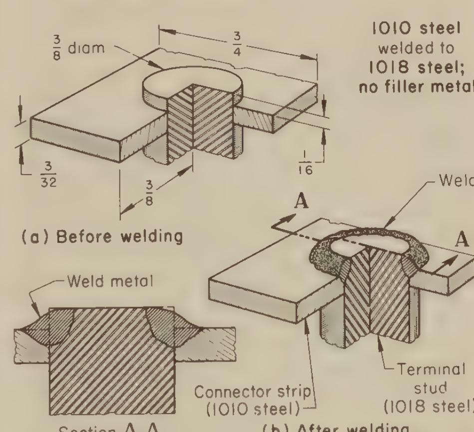
Fig. 17. Furniture leg for which welding time was reduced, and postweld cleaning eliminated, by change from gas welding to gas tungsten-arc welding (Example 131)

electrodes used in gas metal-arc welding. These are multiple deoxidized wires containing 0.40 to 0.70% silicon and a combined total of 0.20% zirconium, titanium and aluminum. Other welding details are summarized with Fig. 16. The benefits realized by gas tungsten-arc welding as compared with gas welding were as follows:

1. Grinding and finishing time were reduced by half.
2. Welding time was reduced 20%.
3. Porosity repair, which had run as high as 25%, was negligible.
4. Distortion and oxidation due to excessive heating were negligible.

Example 131 — Furniture Legs (Fig. 17). A furniture leg, consisting of a 2-in.-square tube 30⅛ in. long, was blanked and formed from cold rolled 0.048-in.-thick low-carbon steel, with a longitudinal seam that required welding in three places, as shown in Fig. 17. Good appearance was the major weld requirement. To keep costs down, a minimum of cleaning and finishing time was desired before painting. Originally, the welds were made by gas welding; the workpiece was clamped in a fixture, to form a close-fitting corner joint, and the edges were fused by means of an oxyacetylene torch without filler metal. Because the combined times for welding, and cleaning the welds for painting, appeared excessive, a change was made to gas tungsten-arc welding. No filler metal nor backing was used, no postweld cleaning was required, and welding time was greatly reduced.

For easy arc starting, a high-frequency generator circuit, timer controlled, was linked into the welding-current circuit of the motor-generator power supply. Another special feature of the equipment was an air-cooled torch, which was fitted with a copper alloy cup having a magnetic ring to prevent arc blow. Conditions for gas tungsten-arc welding are given in the table that accompanies Fig. 17.



Joint type	T
Weld type	Circumferential fillet
Process	Manual gas tungsten-arc
Electrode	0.060-in.-diam EWTh-2
Welding torch	150-amp, air cooled
Filler metal	None
Shielding gas	Argon, 10 cfh
Welding position	Horizontal
Fixtures	Locating jig and foot-operated turntable
Current	70 amp, dcsp
Voltage	10 to 12 v
Arc starting	High frequency
Arc length	0.06 in., approx
Power supply	200-amp transformer-rectifier (constant-current type)
Welding speed	4 to 6 ipm, approx

Fig. 18. Terminal stud gas tungsten-arc welded to a strip for connection to a helical resistor (Example 132)

Gas Tungsten-Arc vs Other Arc Welding Processes. In speed and cost, gas tungsten-arc welding is not competitive with other arc welding processes for most joining of carbon and low-alloy steels, provided acceptable results can be obtained by shielded metal-arc, gas metal-arc or submerged-arc welding. There are, however, some applications in which the degree of control afforded by gas tungsten-arc welding makes it the most efficient process. The example that follows describes an application in which shielded metal-arc welding was changed to gas tungsten-arc welding to obtain the desired results. (Two other applications, involving the welding of low-carbon steel to dissimilar metals, are described in Examples 134 and 135. In Example 135, the change to gas tungsten-arc welding also permitted a substantial cost saving.)

Example 132. Change From Shielded Metal-Arc to Gas Tungsten-Arc Welding for Better Control of Weld Deposit (Fig. 18)

Short lengths of cold rolled 1010 steel strip 3/32 in. thick formed the connections between the turns of a helical resistor and seven 3/8-in.-diam cold finished 1018 steel terminal studs of varying length. Because of the heat and stresses developed during operation of the resistor, the joint between connector strips and studs was welded (see Fig. 18), rather than being soldered or brazed. Originally, these assemblies were shielded metal-arc welded in a simple fixture. However, difficulty in maintaining control over the small weld deposit and the necessity for slag removal prompted a change to the gas tungsten-arc process.

The new method employed a special holding fixture mounted on a foot-operated turntable. Studs were inserted vertically through holes in a horizontal plate so that their lower ends rested on locating pins, which were adjustable to the several stud lengths. When properly located, each stud projected above the plate surface sufficiently to allow the connector strip to be placed over the stud leaving a 1/16-in. projection for a fillet weld (Fig. 18a).

Welding was done manually, without added filler metal. The arc was started at the center of the stud and moved to the edge, at which point the welder rotated the fixture by foot, while holding the torch 30° from vertical. After fusing the edge of

the stud to form a 1/16-in. fillet through one complete revolution, the arc was again brought to the center of the stud and extinguished.

Five of the seven studs required for each assembly were welded in this manner, under the conditions listed with Fig. 18. The two other studs, which were connected to the extreme ends of the resistor, had a joint design different from that shown in Fig. 18(b). For these studs, the connector strips were larger and were formed with a semicylindrical shape at one end, so that the stud nested in the shaped portion. These joints were also made with a 1/16-in. fillet weld, but a 0.040-in.-diam mild steel rod (E70S-3) was used as filler metal. One of these studs was welded on the special fixture described above; the other was welded manually without a fixture, after all other components had been assembled and welded.

Joining of the connector strips to the helical resistance coil is described in Example 134.

Welding of Stainless Steel

Gas tungsten-arc welding is used extensively for the various grades of stainless steel. It is used for welding of very thin sheet or strip, with or without the addition of filler metal, as well as for critical applications on material 1 in. or more in thickness. Welding equipment, gas shielding, tooling, and other processing conditions must be closely controlled for sound weldments. Filler metal compatible with the base metal must be used. For further details on the application of gas tungsten-arc welding to stainless steel, together with examples of production practice, see the article that begins on page 245 in this volume. (Table 12, in the present article, lists examples given elsewhere in this volume that deal with gas tungsten-arc welding of stainless steel.)

Welding of Heat-Resisting Alloys

Gas tungsten-arc welding is used for most grades of iron-base, nickel-base and cobalt-base heat-resisting alloys (Hastelloy D is an exception). Section thicknesses varying from thin sheet to about 1 in. are readily welded by manual or automatic methods. Direct current, straight polarity, is recommended for use when welding these alloys. Alternating current can be used for automatic welding where close control of arc length is possible. Appropriate selection of electrodes and filler-metal composition is especially important. Filler metal differing from base-metal composition may sometimes be used to control porosity or hot cracking. Close control of current, voltage, travel speed, shielding gas, and tooling is mandatory for producing sound welds. For further details on the application of gas tungsten-arc welding to heat-resisting alloys, together with examples of production practice, see the article that begins on page 277 in this volume. (Table 12, in the present article, lists examples given elsewhere in this volume that deal with gas tungsten-arc welding of heat-resisting alloys.)

Refractory Metals. Metallurgical characteristics of the refractory metals (molybdenum, tungsten, columbium and tantalum) preclude the use of any welding process that affords less protection to the hot metal than does the gas tungsten-arc process with the inert

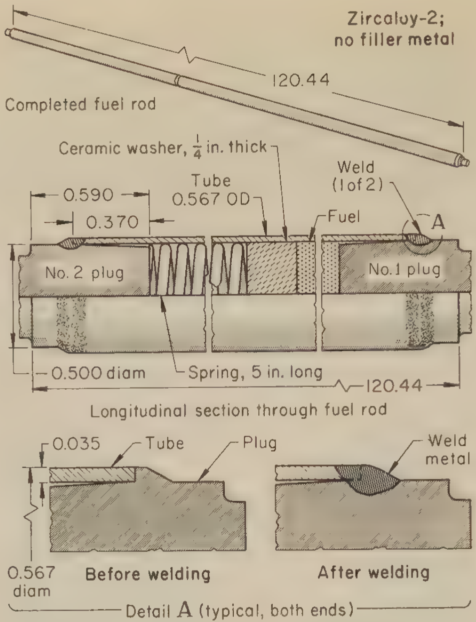


Fig. 19. Zircaloy-2 nuclear fuel-rod assembly joined by automatic gas tungsten-arc welding in a vacuum-purge chamber (Example 133)

gas shield. These metals must be protected from the oxidizing atmosphere. Under certain conditions it is possible to weld in the open with provisions for careful control by inert-gas shielding. Torch gas flow and backup shielding must be closely controlled. Usually, purged chambers containing high-purity inert gas are used. Close control of equipment and process, coupled with careful material handling for preparation and cleanness, is essential for welding the refractory metals.

Welding of Nonferrous Metals

Aluminum alloys, beryllium, copper alloys, magnesium alloys, nickel alloys, titanium alloys and zirconium alloys are all welded by the gas tungsten-arc process. The application of gas tungsten-arc welding to these alloys is discussed briefly in the paragraphs that follow. For more complete information and details of production practice, see the articles in this volume that deal individually with the welding of specific metals. (See also Table 12, in the present article, which lists examples given elsewhere in this volume that deal with gas tungsten-arc welding of nonferrous metals.)

Aluminum Alloys. Most gas tungsten-arc welding of aluminum alloys is accomplished with alternating current. Arc stability and length must be controlled. Control of the arc penetration and bead contour, to prevent any problems with undercutting, is also extremely important. Selection of the appropriate welding current and the correct electrode size for the specific joint is essential. Either argon or helium shielding gases may be used. Argon is generally used. Filler metal may or may not be used, depending on joint design and work-metal thickness. Good joint fit-up, cleanness of joint and filler metal, and close control of process variables are requisites for obtaining sound welds. Detailed information on welding of aluminum alloys is given in the article beginning on page 296 in this volume.

Beryllium can be welded by the gas tungsten-arc process. However, because of inherent characteristics of beryllium, the welds are brittle. Special precautions in handling beryllium are required because of its toxicity. Beryllium should be welded in a hooded enclosure, preferably a glove box. Techniques such as described for titanium alloys (see below) also are applicable to welding of beryllium.

Copper Alloys. Copper, copper-zinc alloys, copper-silicon alloys, copper-tin alloys, copper-aluminum alloys and copper-nickel alloys are all weldable by the gas tungsten-arc process. Each group of copper alloys requires special considerations.

Direct current, straight polarity, is normally used, but alternating current is satisfactory for some alloys. Both argon and helium shielding gas can be used, depending on the material to be welded. When welding material thicker than thin sheet, joints must have wide groove angles (60° to 90°), to permit proper manipulation of the torch and to obtain adequate penetration at the root of the joint. Root openings should be used to facilitate complete penetration. Detailed information is given in the article beginning on page 337.

Magnesium alloys are readily welded by the gas tungsten-arc method. Reverse-polarity direct current and alternating current are used to obtain different weld characteristics in various thicknesses of different alloys. (See the article beginning on page 358.)

Nickel alloys, as discussed in the preceding section "Welding of Heat-Resisting Alloys", are readily welded by the gas tungsten-arc process. (See also the article on Arc Welding of Nickel Alloys, beginning on page 366.)

Titanium Alloys. Titanium is highly reactive and in welding must be carefully shielded to prevent the absorption of oxygen, nitrogen, hydrogen or carbon. The absorption of these impurities will adversely affect mechanical properties of the weld and the base metal. In addition to the gas flow at the torch, shielding-cup leading and trailing gas shields are used. The trailing shield must provide protection for the weld area until the weld area cools below 1000 F. Leading shields should be used when the metal ahead of the weld is above 1000 F. Flow-purged chambers and vacuum-purged chambers are used to provide the most desirable inert-gas atmosphere. For quality welding, base metal and filler metal must be clean and shielding gas must be of high purity. Welding procedures must be specific for each individual setup.

Additional information on gas tungsten-arc welding of titanium alloys is given in the article on page 375.

Zirconium Alloys. The principal difficulty encountered in the welding of zirconium alloys is the contamination of the heated metal surface by oxygen and nitrogen. These impurities increase the hardness of the metal, and decrease the ductility and resistance to corrosion. Production of ductile, corrosion-resistant welds in zirconium alloys requires protection of the welded surface

by a rigidly controlled inert-gas atmosphere, often necessitating welding inside a chamber filled with inert gas. Zirconium alloys are also sensitive to traces of chemical contaminants, and to obtain high-quality welds, all joining areas must be carefully cleaned before welding.

Zircaloy-2 is commonly used for cladding fuel elements and end-closure joints of nuclear fuel rods. Welds for joining end plugs to tubing of fuel rods used in commercial (boiling water) nuclear reactors must be virtually defect-free, to avoid costly and often dangerous failure in service. In-plant specifications require close monitoring of all welding conditions and careful inspection of all welds. An automatic procedure developed for gas tungsten-arc welding in a vacuum-purge chamber is described in the next example.

Example 133. Joining Zircaloy-2 End Closures in Nuclear Fuel Rods by Automatic Gas Tungsten-Arc Welding (Fig. 19)

Figure 19 shows a nuclear fuel rod consisting of two end plugs and a tube, all of Zircaloy-2, which were joined by automatic gas tungsten-arc welding.

Equipment for welding included a cylindrical vacuum-purge welding chamber, about 15 ft long and 4 ft in diameter, specially designed to accommodate a batch of 100 fuel-rod assemblies, a rotatable chill-block fixture to clamp the tube in the horizontal position, and a 110-amp air-cooled torch rigidly mounted to hold the electrode in the vertical position for welding.

Before welding, a batch of tubes and end plugs was degreased, cleaned with detergent, dried, and loaded into the welding chamber. The tubes were placed in the horizontal position and handled by means of supporting trays. After being evacuated, the welding chamber was backfilled with a mixture of 92% helium and 8% argon; then each tube, manually fixtured, was inserted with a No. 1 end plug through glove ports in the chamber. The tube-and-plug assembly was rotated at a speed of 8 rpm for welding. Current at high frequency was used to start the arc, and the square-groove butt joint between the end plug and tubing (see Fig. 19) was welded in a single pass without added filler metal. Welding was done at 50 to 60 amp, dcsp, with no inert-gas flow at the torch; welding speed was 14.25 in. per minute. A 300-amp transformer-rectifier was the power supply; the welding electrodes were 1⁄16-in.-diam EWTh-2.

After welding of the No. 1 end plugs, each joint was subjected to visual, liquid-penetrant and radiographic inspection, and to corrosion tests. After inspection, acceptable tubes were loaded with uranium oxide pellets, a ceramic (Al_2O_3) washer ¼ in. thick, and a 5-in.-long spring. Then the tubes were assembled to No. 2 end plugs, fixtured, inserted through glove ports into the chamber, which had been evacuated and backfilled as before, and the No. 2 end plugs were welded to the tube, using the same procedure as for the No. 1 end plugs.

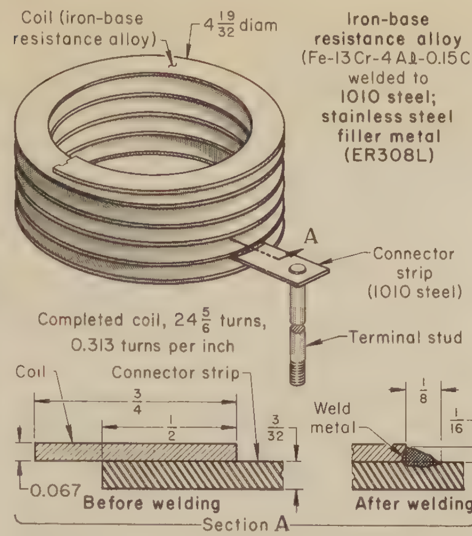
The completed fuel rods were subjected to a final leak test. Since helium had been sealed in the rods during final welding, a helium mass spectrometer was used for leak detection. The rods were loaded in a vacuum chamber equipped with a "snifter" probe. The chamber was evacuated, and a leak-rate measurement was taken. If a failure was detected, the rods were removed and tested in smaller lots until the defective rod was sorted.

Welding Dissimilar Metals

Various combinations of dissimilar metals are welded by the gas tungsten-arc process. Combinations commonly welded are carbon steel to stainless steel, and carbon steel to copper alloys.

Selection of filler metal generally is more critical for welding of dissimilar metals than for welding of similar metals (note Example 134). In welding steel to a copper-base alloy, the welding is started on the steel, which then serves to preheat the copper alloy (Example 135).

The two examples that follow describe applications in which shielded metal-arc welding was replaced by gas tungsten-arc welding, to obtain better control of weld deposit and less distortion in joining of dissimilar metals.



Joint type	Lap
Weld type	Single fillet
Process	Manual gas tungsten-arc
Electrode	0.060-in.-diam EWTh-2
Welding torch	150-amp, air cooled
Filler metal	0.045-in.-diam ER308L wire
Shielding gas	Argon, 10 cfh
Welding position	Horizontal
Fixtures	Coil-supporting jig with stud-locating template
Current	50 amp, dcsp
Voltage	10 to 12 v
Arc starting	High frequency
Power supply	200-amp transformer-rectifier

Fig. 20. Resistor assembly with detail of weld joining coil of iron-base resistance alloy and terminal connector strip (1 of 7) of low-carbon steel (Example 134)

Examples 134 and 135. Change From Shielded Metal-Arc to Gas Tungsten-Arc Welding

Example 134 — Better Control of Weld Deposit (Fig. 20). Resistor assemblies of the type shown in Fig. 20 required dependable joints between the resistance coil and seven terminal connector strips for stepped resistances. (Example 132 describes welding of these strips to terminal studs.) The coil consisted of 24⅚ turns of edge-wound flat wire 0.067 in. thick by ¾ in. wide, made of a 13Cr-4Al-0.15C iron-base alloy; connector strips were of cold rolled 1010 steel 3⁄32 in. thick by ¾ in. wide. Welding, rather than soldering or brazing, was used to make the joints, because of the heat and stresses developed in operation. At first, shielded metal-arc welding was used, but the procedure was changed to manual gas tungsten-arc welding because of difficulty in controlling the unequal-leg (1⁄16 by ⅛ in.) fillet weld (see Fig. 20).

Gas tungsten-arc welding was done with ER308L stainless steel filler metal, which was selected on the basis of laboratory tests to determine the most economical filler metal for the dissimilar-metal combination, and with the aid of a specially built fixture. This consisted of an L-shape bracket that permitted the coil to be held in the vertical position by a spring-loaded leather strap. The base of the bracket was drilled in seven locations to accept the stud end of respective connector strips. With the stud located in its proper hole, the end of the connector strip lapped under the edge of the resistor coil at the designated number of turns. The lap was then made snug by adjusting an elevating screw. To tighten the lap joint for welding, the two members were clamped by a vise-grip pliers modified with small tabs at the grips.

Welding was done by starting the arc approximately 1⁄16 in. from the edge of the strip, moving back to the edge and then carrying the puddle across the joint to the opposite edge. The torch was held at a 45° angle. After a momentary break in the arc, the weld was carried around the edge of the strip to prevent cracking at this point. This procedure was followed in sequence for the seven joints. Other welding conditions are given in the table with Fig. 20.

Example 135 — Improved Results, Lower Cost (Fig. 21). The boxlike weldment shown in Fig. 21 consisted of two naval brass bars to which were welded side plates of 1018 or 1020 steel. Used as a sliding ram, the assembly was installed in the front end of a lift truck to push the load forward off the truck. Tolerances on width and height (see Fig. 21) were important, because the assembly was not machined after welding.

Originally, the four corner joints were continuously fillet welded using shielded metal-arc welding with a phosphor bronze electrode. This procedure came under review because of the amount of time spent in straightening (to correct distortion), in grinding and cleaning the welds, and in removing spatter.

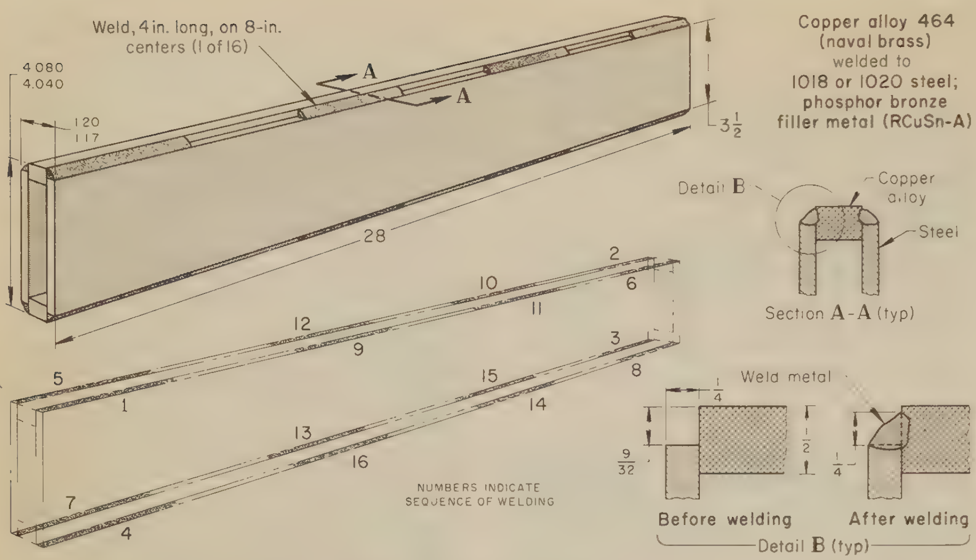
To eliminate the problems, the process was changed to gas tungsten-arc welding, using a revised procedure. Before welding, joint surfaces were cleaned by sanding and wiping with clean rags. The components were assembled in a fixture (jig) and mounted on a positioner to orient the assembly for flat welding. Joints were then tack welded, using the gas tungsten-arc process with argon shielding and phosphor bronze filler metal. (Although tack welding had not been used in the original procedure, it was specified here to help maintain alignment of the pieces during welding.) Then the joints were welded, using the same process and filler metal as for tack welding. Because of the large difference in melting temperature between the steel and the brass, the welding was started on the steel. This preheated the brass. Filler metal was then fed in at 6 to 8 in. per minute.

In the gas tungsten-arc process, instead of continuous fillet welds (as in the previous method), 16 intermittent fillet welds, 4 in. long on 8-in. centers, were deposited in a staggered sequence. The use of intermittent welds did not impair the strength of the assembly, because the service load on the welds was quite low. On the other hand, the intermittent welds greatly reduced heat input and distributed it favorably — both of which helped eliminate distortion. Also, the use of gas tungsten-arc welding eliminated the need for grinding and cleaning welds and removing spatter.

Details of the improved welding procedure are given in the table that accompanies Fig. 21, along with a comparison of time and cost for the original and the improved methods. As shown, gas tungsten-arc welding saved approximately two-thirds of the time and cost of shielded metal-arc welding, in addition to eliminating the distortion problem. Although part of the time and cost saving with gas tungsten-arc welding resulted because of the change from continuous to intermittent welds, the major portion was due to the elimination of the postweld cleaning and straightening operations.

Automatic Welding

Automatic gas tungsten-arc welding is used extensively. The degree of mechanization varies from the simple



Item	Shielded metal-arc	Gas tungsten-arc
Labor Time per Piece, Hr		
Welding	0.67	0.45
Grinding and cleaning	0.26	...

mounting of the welding torch in a bracket that moves over the workpiece (or in a stationary bracket, with the workpiece being moved under the torch), to a fully automatic operation that accomplishes the complete welding cycle (see Example 133). The degree of mechanization is usually determined by the number of identical welds to be made, and by the speed and quality desired. The aerospace industry uses automatic gas tungsten-arc welding extensively, not necessarily because of large quantities of production parts, but because the quality required for aerospace designs often can be achieved only with the control inherent in automatic welding. A typical example of this is the fabrication of large-diameter rocket-motor cases, in which longitudinal and girth welds are made by automatic welding techniques.

Mechanized welding is usually employed for metals that must be welded in a chamber, because it provides greater ability to manipulate the work within the chamber, compared with manual welding (see Example 133).

Equipment. Semiautomatic torches for gas tungsten-arc welding were introduced about 1952, but were never widely used. Essentially, a semiautomatic torch is an assembly of a hand-held water-cooled torch with an attachment that brings the filler metal (wire) into the arc area. The filler metal is fed to the torch through a flexible conduit by means of a motor-driven wire feeder. The wire feeder is controlled by a trigger switch on the torch. In theory, the filler wire fed from the torch helps propel the torch and establish travel speed. The wire is then melted by the arc and deposited in the joint. The introduction of gas metal-arc welding interrupted the full development of the semiautomatic gas tungsten-arc welding system, and it is now little used.

For automated welding systems, the torch is mounted in a mechanism for moving the work or the torch relative to one another. Specially designed torches are used; two types are available. One, the heavy-duty barrel type, is of metal construction and water cooled. It is equipped with a rack and is long enough to be adjusted and carried in a holder similar to that used for machine gas cutting. Barrel-type holders are fully insulated, can be used with various types of nozzles, and accommodate electrodes up to 18 or 24 in. long, with diameters of 0.040 to 1/4 in. Welding current may be up to 600 amp.

The second type of torch is also water cooled, but will not fit automatic gas-cutting equipment. These torches are usually made to accommodate shorter (7-in.-long) electrodes in a slightly smaller size range (0.020 to 3/16 in.). Welding current for these torches may be up to 500 amp. In addition, metal or ceramic nozzles can be used. These shorter holders require a special offset bracket for mounting.

Mechanized or automatic gas-cutting carriages are often used for moving the automatic torches. Special hardware and adapters are readily available. Automatic head controllers are also available. They will electronically maintain a preset arc voltage even though the surface of the work being welded varies substantially.

For completely automatic production-line welding of joints requiring the addition of filler metal, a wire feeder is added. An adjustable bracket is mounted at the torch to direct the "cold" (electrically neutral) filler metal into the arc area. This equipment is used for welding with direct current, straight polarity. The wire feed is adjusted to provide the amount of filler metal required — which is based on joint design, travel speed, welding current, and filler-wire size.

Examples of Practice. Changing from manual to mechanized welding usually requires a good knowledge of welding, a high degree of skill in machine design, and a high initial investment. These requirements necessarily increase with the degree of automation desired. Because of the availability of a wide variety of mechanical and electrical controls, operations of seemingly great complexity can often be automated. Because of its inherent arc stability, gas tungsten-arc welding is readily adapted to this type of control. Usually, if a repetitive operation can be manually fixtured and manually welded, it can be mechanized. And if the welding machine is used frequently, the initial investment often can be recovered in a short time, as in Example 136, which follows. Examples 137 and 138 in this section describe applications for which automatic gas tungsten-arc welding was advantageously employed. An application of automatic welding in a vacuum-purge chamber is described in Example 133. See also Examples 252 to 255 in "Arc Welding of Stainless Steel".

Example 136. Change From Manual to Automatic Welding for Increased Productivity (Fig. 22)

The four legs that constituted the supporting members of swivel-chair bases were made by blanking, forming and welding 0.057-in.-thick low-carbon steel sheet. Figure 22 shows the configuration of a typical leg, with its underside facing up to reveal the weld at the seam.

Originally, the seam was welded by manually clamping the piece in a fixture, to draw the edges closely together, and then fusing the seam with a hand-operated gas tungsten-arc torch. Although this method welded 39 legs per hour, it was too slow to satisfy increasing demands. Since the operation was simple, it was possible to develop a machine to solve the production problem without changing part design.

The operating cycle of the machine was initiated by inserting the workpiece into the clamping fixture. From this point on, the operator simply monitored the operation. The fixture automatically clamped the workpiece so that the sheared edges (burrs facing out) formed a tight square-groove butt joint. Next, the gas tungsten-arc torch started its traverse with a preflow of argon gas for shielding. A limit switch initiated the arc by closing the direct-current welding circuit, together with a superimposed high-frequency circuit used for arc starting only. Welding conditions are given in the table with Fig. 22. At the end of the 11-in. traverse, a second limit switch tripped the welding circuit. After a short argon postflow, the part was automatically ejected.

Since neither the mechanical strength of the joint nor the appearance of the weld

was critical, visual inspection was made for uniformly good appearance; rejection rate was less than 1%. Smooth-appearing welds with no need for cleanup were obtained more consistently than by manual welding.

With the change to automatic welding, not only did production rate increase, but it was soon found that one operator could easily manage two machines simultaneously. Operating two machines on this basis, production rate increased to 210 legs per hour. Although the two machines required an investment of $15,000, the entire cost was recovered in approximately 3 months.

Example 137. Use of Automatic Welding To Reduce Production Costs (Fig. 23)

Originally, tractor engine hoods (Fig. 23a) were deep drawn from a single sheet of cold rolled 16-gage (0.060 in.) fully killed low-carbon steel of drawing quality. The front section (containing the headlight openings) was identical for all models, but the rear section (covering the radiator and air filter) differed in length and location of openings. To reduce tool and die costs and to eliminate problems in drawing, it was decided to draw the front sections separately and weld them to rear sections as needed.

Since finished hoods were under no appreciable stress but were painted and exposed to view, the objective was to obtain, at a high production rate, a uniformly low-profile weld that could easily be roll-planished and polished flush with the surface. It appeared that this objective could be reached best by using automatic, single-pass gas tungsten-arc welding on a butt joint, without filler metal.

In designing the machine for automatic welding, the major problem was how to position the workpieces. Welding the 33-in.-long seam entirely in the flat position was most desirable, but this would require considerable workpiece manipulation, which appeared too costly. To position the parts for welding up one side, across the top, and down the other side introduced a number of undesired welding variables, including nonuniform weld profile. Positioning the parts so that the joint lay in the horizontal plane meant welding in the relatively difficult horizontal position; however, this position made welding conditions essentially the same throughout the weld length. Locators and clamping fixtures could be made rigid, and only the torch and its supporting arm would be required to move. This positioning was adopted because it entailed minimum tooling expense and low cost for the automatic machine.

As shown in Fig. 23(b), the two portions of the hood were held in close alignment by clamping them against two vertically

Fig. 22. Swivel-chair leg that was welded automatically at 5½ times the production rate obtained in manual welding (Example 136)

spaced fixtures, made of a copper alloy. Clamping force was exerted by a vertical and a horizontal air piston. The vertical clamp forced the joint edges closely together; the horizontal clamp held the work metal against the fixtures (see section A-A in Fig. 23b). The torch was mounted on a spring-loaded slide, which in turn was mounted on a supporting arm connected to a centrally located drive shaft. As the drive rotated in the direction of welding, the slide was displaced in the radial direction by means of a stationary cam having a curvature identical with the joint. Once the torch was set in correct operating position, welding was accomplished automatically in a single pass. Because the speed changed through corner radii, microswitches tripped to start and stop a second speed, overriding straight-line speed control. For easy arc starting, an ultraviolet-ray lamp was aimed to create an ionized path at the torch tip.

Postweld operations included inspection, roll-planishing and polishing of the welded joint (see Fig. 23c) prior to painting. After welding, the joint was subjected to 100% visual examination for penetration and weld continuity. The slight deformation in weld shape (due to welding in the horizontal position) and minor surface porosity were corrected largely by planishing the weld to within a few thousandths of an inch from the surface of the sheet metal. During the polishing operation, the weld profile was made flush with the sheet-metal surface, and was carefully examined for depressions or porosity that remained.

Automatic welding proved to be a successful substitution for the original method. Parts were produced with satisfactory appearance, at reasonable cost. Average floor-to-floor time for loading the machine, welding, and unloading was 2 min per piece. Other details of the welding operation are given in the table with Fig. 23.

Example 138. Simultaneous Welding of Four Box Corners at High Speed (Fig. 24)

Figure 24 shows a low-carbon steel enclosure for electrical controls, in the form of a rectangular open-top box, that was produced in sizes ranging from 2½ to 6 in. in depth, 5 to 36 in. in width and 8 to 36 in. in length. Thicknesses ranged from 0.030 in. to 0.078 in. These enclosures were produced by blanking, bending the four sides to form the box shape, and welding the four corner joints in the vertical position. Joint requirements called for a full-penetration seal weld having a smooth appearance suitable for painting. Aluminum-killed steel of drawing quality was selected to avoid weld porosity, since no filler metal was used.

To meet competitive prices on these products, a completely automatic setup, using high-speed welding, was constructed. The setup involved automatic sequencing of the production cycle, including initial fixturing of parts, synchronizing the simultaneous operation of four welding torches, and the final ejection of the welded product.

After forming, the enclosures were positioned and automatically clamped in a fixture consisting of twelve water-cooled copper chill bars, three bars being located at each of the four corners (see detail A in Fig. 24). Four water-cooled gas tungsten-arc welding torches, each having its own power supply, automatically advanced to welding position. At this point, a weld-sequence timer switched on the welding power. Each welding power supply was equipped with high frequency, for easy arc starting, and with upslope and downslope control. Upon completion of the welds, the enclosures were automatically ejected. Welds

were spot checked by visual inspection for voids and general appearance as to smoothness and roundness. Additional welding details are given in the table with Fig. 24.

Spot Welding

Adaptation of the gas tungsten-arc process to spot welding permits automatic arc spot welding of sheet-metal assemblies where access to only one side of the joint is possible. The capabilities of this method are especially useful for welding of corrugated structures for aerospace applications.

Gas tungsten-arc spot welding may be automated to the extent determined necessary to produce quantity and quality welds. The process is used for spot welding of automobile bodies, double-wall structures, aerospace fuel ducts, brackets to thin-wall skins, and foil-thin skins to thicker materials.

Gas tungsten-arc spot welding is capable not only of making spot welds on overlapped sheets (considered as the conventional procedure), but also of producing short welds that join two abutting edges (see Example 139 and Fig. 25); the latter are actually intermittent square-groove welds.

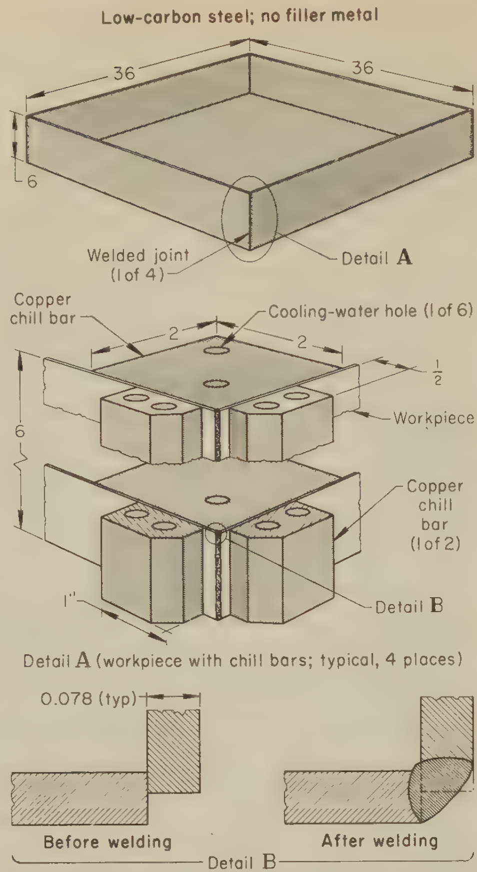
Equipment. An arc timer and a special torch (often called a gun) are the only additional pieces of equipment needed for spot welding. High-frequency stabilizing current is used to initiate the arc. Preflow and postflow of shielding gas are normally used.

The arc timer is usually built into power supplies designed for gas tungsten-arc welding, but external or auxiliary timers may be used. Arc time ranges from about ¼ sec to over 5 sec.

The welding torch is usually of pistol-grip design with a finger switch. Metal nozzles are used, because the nozzle is in contact with the work and is used to apply enough pressure to ensure close contact of the parts being spot welded together. Arc-spot torches are either air cooled or water cooled, depending on capacity and duty cycle.

Use of Filler-Metal Wire. Two major problems encountered in gas tungsten-arc spot welding are crater cracking and excessively concave weld surface. A modification of the process to overcome these problems is the addition of filler metal to the arc spot weld. Equipment has been developed to feed filler-metal wire into the arc area during the arcing period. The major requirement of the equipment is the sequencing of operations. A programed controller provides for control of gas flow, welding current, tapering (decay) of welding current, and wire feed. The nozzle of the torch is more complicated than the conventional type. Provisions are made for properly feeding the filler wire into the arc without fouling the electrode or sticking in the weld puddle. This process has not been widely adopted; it shows the most promise for spot welding aluminum in thicknesses greater than can normally be spot welded by resistance welding.

Example of Practice. The example that follows describes the use of gas tungsten-arc spot welding equipment and techniques for joining abutting edges by intermittent square-groove welds, in an application for which quality was critical.



Joint type	Corner
Weld type	Fillet
Process	Automatic gas tungsten-arc

Example 139. Rimmed vs Killed Steels for Spot Welding Collapsible Steering Columns (Fig. 25)

Steel quality proved critical in spot welding the longitudinal seams of collapsible steering columns made of 0.065-in.-thick, cold rolled 1006 or 1008 steel, perforated and roll-formed into tubes 2 in. in diameter by 30 in. long. As shown in Fig. 25, the perforated (collapsible) section of the steering column was joined with fourteen 0.08-in.-diam butt welds, and the two unperforated sections were joined with seven 0.25-in.-diam butt welds.

Performance specifications required that all welds remain intact when the column collapsed. In view of the collapsibility of the column, this requirement was not considered severe.

Because of the high production rate desired for this part, weld time had to be held to an absolute minimum — which was 15 cycles (¼ sec). With such a short weld time, any gas generated during welding was trapped in the weld, resulting in porosity. Since the welds were made by an arc discharge without added filler metal, cleanness of the base metal was an important consideration. Hot rolled steel was not considered, because of the presence of a thin layer of oxide.

Preliminary work on a rimmed cold rolled steel indicated that too much gas was generated. Therefore, an aluminum-killed cold rolled steel, known to be relatively gas-free, was selected for this application. Welds were made with no porosity. As production experience was gained, it was found that weld strength was more than adequate. To lower cost, a trial run was made using semikilled steel. Although some porosity appeared, the welds were strong enough to meet the performance specification. Substituting the semikilled for the fully killed steel resulted in a saving of 3¢ to 4¢ per piece.

An automated five-station setup was used for welding. The steering columns were clamped in a jawlike fixture that held the abutting seam edges in correct alignment and position for welding. The fixture-and-part assembly was then shuttled through the five stations, where selected welds were made by energizing prepositioned, gas-shielded tungsten electrodes. Welding was the same as conventional gas tungsten-arc spot welding, except that instead of being produced between lapped sheets, the spot welds were centered on the abutting seam edges; thus, they were not true spot welds, but were short intermittent tack-type groove welds. The need for five stations was determined by the proximity, size and distribution of the welds along the seam and, to some extent, by distortion effects.

After welding was completed, the columns were given a 100% visual inspection. The high production rate of 1200 pieces per hour (see table of welding conditions with Fig. 25) was not obtained without occasional problems. One problem was arc blow, which caused the weld to deviate from true center on the seam. Arc blow was minimized by machine design. In addition, because seam edges were given no special edge preparation, burrs on sheared edges sometimes interfered with weld deposition. This difficulty was overcome by tighter control over the shearing operation.

For details of a program established in one plant for control of thickness and properties of as-received base metal, and for determination of capabilities of welding machines, to improve the quality of spot welds made by several processes, including gas tungsten-arc welding, the reader is referred to Example 377 in the article on Resistance Spot Welding, in this volume.

Cost

For some applications, gas tungsten-arc welding may be the only technically acceptable welding process for the work metal, or for the conditions under which welding must be accomplished. Such restrictive considerations are more important than cost in the selection of the welding process.

On the basis of cost alone, the use of gas tungsten-arc welding is limited primarily by the cost of the inert gases used for shielding and by generally rather low production rates (compared with those obtained in other arc welding processes). The average cost of inert gases in cylinders is 7¢ to 10¢ per cubic foot at a flow rate of 10 to 15 cu ft per hour. On the other hand, this process in its simplest form requires only a manually operated torch and a gas regulator and flowmeter, in addition to the welding power supply. Accordingly, the initial capital outlay for this minimal equipment is relatively modest.

Gas tungsten-arc welding can be employed for production welding most economically in the joining of thin sections, particularly where square-groove

welds (no bevel) can be made and no filler metal is needed. Under such conditions, welding speeds of 150 in. per minute are easily achieved using relatively simple automatic equipment. In more specialized applications, gas tungsten-arc welding is used with more fully automated equipment incorporating automatic control and programing of arc conditions, speed of torch travel, and rate of filler-wire feed.

Manual gas tungsten-arc welding has a versatility and flexibility that, coupled with the low capital outlay involved, provides a most useful tool for job-shop maintenance and repair welding for which the work metal or other technical factors rule out the more commonly used and less costly processes. For example, gas tungsten-arc welding may be particularly desirable for rework or repair of production welds; for altering of parts machined incorrectly; for welding tubes to tube-sheet in heat exchangers; and for the root pass in pipe welding (see Example 128). In addition, this process is sometimes used for complete piping welds; for the repair of worn or broken dies; and for retrofit modifications of existing equipment or products.

The primary step in determining the cost of a gas tungsten-arc weld is to analyze the length of time required for making the weld, and the amount of filler wire required. This may be done by observing the actual job, by estimation from tables, or by estimation from past experience. Once these elements are determined, the cost of the weld can be figured if the purchase prices and rates of consumption are known. The methods for determining the cost of labor, gas, filler metal, electricity and electrodes are outlined in Table 10. A sample calculation of welding costs for a specific application is given in detail in Table 11.

When comparing the cost of gas tungsten-arc welding with the cost of other welding methods, it should be remembered that the cost and time for finishing the weld will be largely eliminated when gas tungsten-arc welding is used.

Table 10. Procedure for Determining Costs of Gas Tungsten-Arc Welding(a)

Labor Cost, \$ = (Time for job, minutes) × (1/60) × (Welder's hourly rate, \$)
Gas Cost, \$ = (Arc time, minutes) × (1/60) × (Gas flow rate per hour, cu ft) × (Cost per cubic foot of gas, \$)
Filler-Metal Cost, \$:
Automatic Welding = (Arc time, minutes) × (Feed rate per minute, in.) × (Wire weight per inch, lb) × (Wire cost per pound, \$)
Manual Welding = (Wire used, in.) × (Wire weight per inch, lb) × (Wire cost per pound, \$) (b)
Electric Power Cost, \$ = (Welding current, amp) × (Arc voltage) × (1/1000) × (Power cost per kwhr, \$) × (Arc time, minutes) × (1/60)
Electrode Cost = Approx 4% of gas cost

(a) No overhead or amortization of equipment is considered. See Table 11 for a sample calculation based on this procedure. (b) Or: total weight of wire used per job, in pounds, times cost of wire per pound.

Table 11. Cost Calculations for a Specific Weld, Using Procedure Shown in Table 10

Welding Conditions	
Work metal	Aluminum alloy, 1/16 in. thick
Type of weld	Butt
Process	Manual gas tungsten-arc
Current	70 amp
Voltage	10 v
Welding time	13 minutes
Arc time	10 minutes
Gas flow rate	20 cfh
Filler-metal wire	3/32-in.-diam ER4043
Weight of wire used	0.14 lb
Cost Items	
Labor	\$5.00 per hr
Electricity	\$0.03 per kwhr
Filler metal	\$1.40 per lb
Gas	\$0.10 per cu ft
Cost Calculations	
Labor (13/60 × \$5.00)	\$1.08
Gas (10/60 × 20 × \$0.10)	0.33
Filler metal (0.14 × \$1.40)	0.20
Electricity (70 × 10/1000 × \$0.03 × 10/60)	0.0035
Electrode (4% of \$0.33 gas cost)	0.0132
Total cost of weld(a)	\$1.63

(a) Total of items above; does not include overhead and equipment amortization, which may be the deciding factor in a cost comparison.

Safety

Gas tungsten-arc welding is no more hazardous than other welding processes if adequate precautions are observed with regard to eye protection, protective clothing, and ventilation.

Eye Protection. The filter-plate lenses used in helmets and face shields should be of the deepest shade that permits adequate visibility of the welding operation. (As a guide, AWS recommends shade No. 11 for gas tungsten-arc welding of nonferrous metals, and No. 12 for ferrous.) The use of medium-shade (No. 2) flash goggles is recommended in addition to the welding helmet for both the welder and other personnel present in the welding area.

Protective clothing is needed to shield the welder from the intense arc radiation. The tungsten arc is fully exposed, and the ultraviolet and infrared radiations may produce an arc burn that resembles sunburn except that it is more severe. Dark-colored clothing is preferred to light, because the rays more readily penetrate light-colored fabrics. Light colors are also more reflective, and may cause eye burns even when a helmet is worn. Cotton fabrics should be avoided. Clothing should be made flame resistant by immersing it in sodium tetraborate or sodium stannate and ammonium sulfate solutions. Cuffless trousers should be worn to prevent entrapment of hot slag or spatter. Gauntlet gloves should be worn to protect the hands and wrists from arc burns and possible weld spatter.

Ventilation. Adequate ventilation that does not disturb the gas shield can be obtained by placing a low-velocity suction duct several inches away from the welding operation. Fans or drafts of over 50 sfm may blow the protective gas envelope away from the weld zone, causing oxidation of the heated metal.

During welding operations, ozone and noxious fumes are generated, which may become toxic in large concentrations. The fumes from some chlorinated solvents (three examples are carbon tetrachloride, trichlorethylene, and tetrachlorethylene), when exposed to a tungsten arc, form a toxic gas, phosgene, even at a long distance (hundreds of feet away) unless walls or baffles keep these fumes from the welding area.

Care should be taken when working with toxic metals. Air-supplied face shields or respirators may be required in confined areas that are not adequately ventilated. Argon or helium may displace the air that the welder requires for breathing.

Adequate ventilation is mandatory for all gas tungsten-arc welding. Detailed information concerning ventilation is contained in the American National Standards Institute publication Z49.1, "Safety in Electric and Gas Welding and Cutting Operations"; also suggested for reading is the American Welding Society pamphlet A6.1-66, "Recommended Safe Practices for Gas-Shielded Arc Welding".

Plasma-Arc Welding

PLASMA-ARC WELDING is an arc welding process in which the heat is produced by a constricted arc between a nonconsumable tungsten electrode and a workpiece (transferred arc), or between a nonconsumable tungsten electrode and a constricting orifice (nontransferred arc).

When an arc is established through a gaseous column separating two electrodes, some of the gas becomes ionized. This ionized material, called plasma, consists of free electrons, positive ions, and electrically neutral atoms. The plasma, or current-conducting, section of the arc is kept hot by the resistance heating effect of the current passing through it. Thermal ionization, the term employed to describe ionization that takes place in a high-temperature atmosphere, results from collisions of molecules and electrons in the gas and from radiation.

Plasma-arc welding is closely related to gas tungsten-arc welding (see the preceding article in this volume). Plasma is present in all arcs. If a constriction containing an orifice (nozzle) is placed around the arc, the amount of ionization, or plasma, is greatly increased. This results in higher arc temperature, a more concentrated heat pattern, and higher arc voltage than can be obtained with a nonconstricted arc.

Much of the text of this article is from an unpublished paper prepared for an ASM conference by N. F. Bratkovich, Section Chief, Joining Processes, Material Engineering Dept., Indianapolis Operation, Detroit Diesel Allison Div., General Motors Corp.

The examples in this article were contributed by members of six of the Metals Handbook welding committees.

For plasma-arc welding, constriction of the arc is produced by the design of the welding torch. Figure 1 shows the heat patterns and arc temperatures for a nonconstricted arc, used in gas tungsten-arc welding, and a constricted arc, used in plasma-arc welding.

Applicability

Plasma-arc welding is adaptable to both manual and automatic operation, and can be used to produce either continuous or intermittent welds. Welds may be made with or without the addition of filler metal. Plasma-arc welding is most often an alternative to gas tungsten-arc welding. It is sometimes competitive with oxyacetylene welding and electron-beam welding and occasionally with resistance seam welding (see section on Plasma-Arc Welding vs Alternative Processes, page 145).

Metals Welded. Plasma-arc welding is adaptable to joining carbon and alloy steels, stainless steels, heat-resisting alloys, refractory metals, copper alloys, nickel alloys, and titanium alloys. Aluminum alloys have been successfully plasma-arc welded, but this process has not been used to any significant extent for welding these alloys.

Metals that have low melting temperatures and low boiling temperatures, such as lead and zinc, are not amenable to plasma-arc welding.

Welding Positions. Plasma-arc welding is generally considered to be an all-position process, depending somewhat on whether or not filler metal is used.

Work-Metal Thickness. Plasma-arc welding is well adapted to welding thin sections. Because of the stability and dimensional control provided by the constricted arc, foils as thin as 0.001 in. have been welded in production, with current as low as 1½ amp. However, welding of such thin metal requires extremely precise fixturing and the closest control possible. The minimum work-metal thickness is usually considered to be 0.003 in., although 0.002-in.-thick stainless steel, for use in convoluted bellows, has been successfully welded for several years.

The maximum work-metal thickness is usually determined by cost. When work-metal thickness exceeds ¼ in., other welding processes are usually faster and more economical. However, when quality requirements are high, plasma-arc welding is sometimes used for the root pass, and a faster, cheaper process, such as submerged-arc welding or gas metal-arc welding, is used for succeeding passes.

Advantages. The constricted arc used in plasma-arc welding offers several advantages over the nonconstricted arc used in gas tungsten-arc welding:

1. Concentration of energy is greater.
2. Arc stability is improved, particularly at low current levels.
3. Heat content is higher.
4. The plasma has higher velocity.
5. There is less sensitivity to variations in arc length.
6. Tungsten contamination is eliminated.
7. Less welder dexterity is required for manual welding.
8. Solid backing is not required for obtaining complete penetration, because the keyhole technique can be used (Fig. 3).

In comparison with gas tungsten-arc welding, plasma-arc welding per-

mits greater welding speed and closer control of the process, and can be used for welding thinner sections.

Disadvantages. The main disadvantages of plasma-arc welding, compared with gas tungsten-arc welding, are:

1. Higher cost of equipment (generally two to five times as much)
2. Short life of the orifice body
3. Need for greater welder knowledge, although not necessarily greater dexterity on the part of the welder
4. High rate of inert-gas consumption.

Fundamentals of the Process

In plasma-arc welding, a tungsten electrode is used, as in gas tungsten-arc welding. Two separate streams of gas are supplied to the welding torch. One stream surrounds the electrode within the orifice body and passes through the orifice, constricting the arc to form a jet of intensely hot and fast-moving plasma. This gas must be inert and is usually argon.

The other stream of gas, the shielding gas, passes between the orifice body and the outer shield cup. It prevents the molten weld metal and the arc from becoming contaminated by the surrounding atmosphere. An inert gas, such as argon, can also be used for shielding, but nonoxidizing gas mixtures, such as argon with 5% hydrogen, have often proved advantageous (see the section in this article on Orifice and Shielding Gases, page 141).

Distance from orifice to work is commonly maintained at about 3/16 in.; this distance is less critical than the distance from the end of the electrode to the work in gas tungsten-arc welding. A distance of 1/8 to 1/4 in. does not significantly affect welding results.

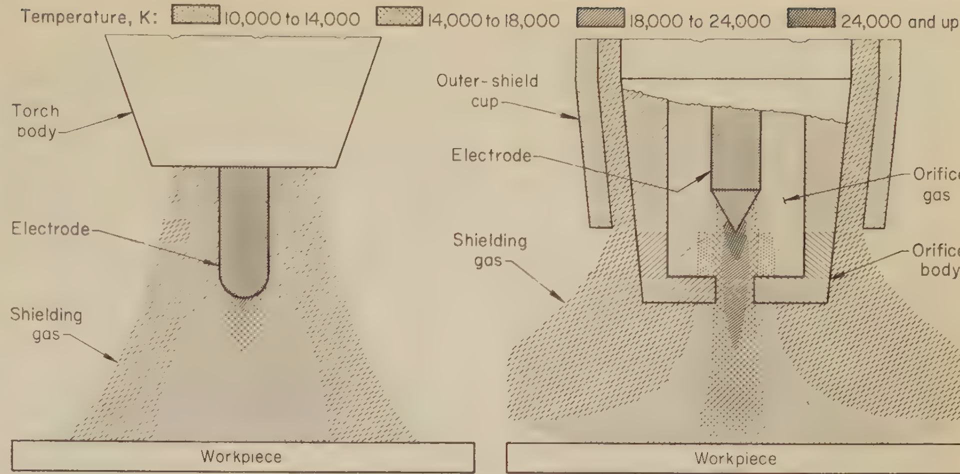
Arc Types. Two arc systems are used to generate plasma: a transferred arc and a nontransferred arc. In the transferred type, the arc is established between the electrode and the workpiece. A nontransferred arc is established between the electrode and the inside of the orifice body, and heat is delivered to the work by the hot plasma only.

For welding, the transferred arc is used almost exclusively, because the arc delivers more heat to the work. This system is shown in Fig. 2. Note that the negative lead from the power supply is connected to the electrode and the positive lead is connected to the workpiece. This electrical hookup is called straight polarity. The positive lead is also connected, through a resistor, to the orifice body. This permits establishment of a pilot arc at a low current level, as needed.

The nontransferred arc may be used in special welding applications when a lower energy concentration is desirable. Its main use is in joining or cutting of nonconductive work materials. For a nontransferred arc, there is no electrical connection to the work.

Heat-Energy Concentration. In concentration of heat energy, the constricted plasma arc falls between the unconstricted arc used for gas tungsten-arc welding and the electron beam in electron-beam welding. Heat-energy concentrations for the three processes, based on width of fusion zone in 1/4-in.-thick 410 stainless steel, are shown in Fig. 3. Normally, the plasma-arc and gas tungsten-arc processes yield similar welds if the melt-in (conventional fusion) mode of welding is used. However, with the plasma-arc process, a special technique called keyhole welding is possible, and it yields the deeper, narrower penetration shown in Fig. 3 (see the description of this technique under "Keyhole Welding", page 142).

Current. Plasma-arc welding can be done at considerably lower current than gas tungsten-arc welding, often at a current as low as 1 amp, and sometimes at 0.1 amp. High current is also used. The line of demarcation between high-current and low-current operation is arbitrary, although usually low-current welding is considered to be that done in the range of 0.1 to 100 amp, and high-current welding to be that done with current above 100 amp — usually 100 to 500 amp. Welding current seldom exceeds 500 amp and is usually less than 400 amp.



(a) Nonconstricted arc (gas tungsten-arc welding) (b) Constricted arc (plasma-arc welding)

Nonconstricted Arc		Constricted Arc (3/16-In.-Diam Orifice)	
Shielding gas	Argon, at 40 cfh	Shielding gas	Argon, at 40 cfh
Current	200 amp	Current	200 amp

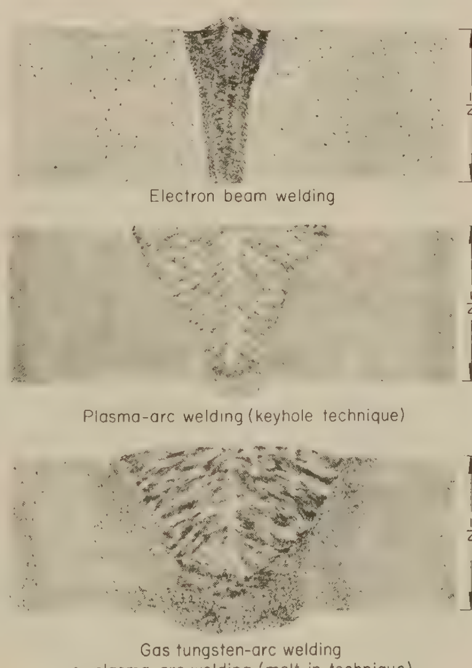

Fig. 3. Typical fusion-zone widths for electron beam welding, plasma-arc welding (keyhole technique), and gas tungsten-arc welding

Power Supply

Plasma-arc welding is done almost exclusively with straight-polarity direct current from a constant-current power supply (drooping voltage). Reverse polarity causes excessive deterioration of the electrode. The direct current can be rectified from alternating current or supplied by a motor-generator or an engine-driven generator. Power supplies for arc welding are described in the articles on Shielded Metal-Arc Welding, Gas Metal-Arc Welding, and Gas Tungsten-Arc Welding, in this volume.

Rectifiers having an open-circuit voltage of 65 to 80 v are most commonly used as the basic unit. Power supply units for gas tungsten-arc welding can be converted for plasma-arc welding. Also, power supplies that have appropriate adjustments are made especially for plasma-arc welding. The nature of the application usually dictates the adjustments required. For instance, power supplies with current slope control are required for welding circumferential

joints where a keyhole must be initiated and closed out gradually (see the section on Keyhole Welding in this article). Programing equipment that controls current slope and gas flow at desired intervals is available.

An essential piece of equipment for plasma-arc welding is a power supply for starting the arc.

Arc Initiation. Because the electrode tip is within the orifice body (Fig. 2 and 4), the arc cannot be started by touching it to the workpiece, as in gas tungsten-arc welding; other means must be employed for arc initiation.

For low-current welding (under 100 amp), a system such as that shown in Fig. 4 is most commonly used. In this system, a separate direct-current power supply (identified as "Pilot-arc power supply" in Fig. 4) is connected to the electrode and to the copper orifice body. By means of this supplementary power supply, a pilot arc is initiated between the electrode and the interior of the orifice body. To start the pilot arc, the electrode is advanced by means of an adjusting screw until it touches the bottom of the orifice body. The electrode is then withdrawn to a distance that is specified on the particular torch, in terms of number of turns of a vernier-type thumbscrew.

The pilot arc is maintained during short periods of downtime, during which time a small amount of argon is flowed through the orifice while the pilot arc is operating.

When the pilot arc has been established, the contactor to the lead attached to the workpiece (Fig. 4) is closed, and the hot ionized orifice gas forms a conductive path between the electrode and the workpiece when the orifice of the torch is held close to the work. The conductive path results in striking of an arc between the electrode and the workpiece.

This method of starting the arc for low-current welding provides a smooth start and eliminates the tracks and etch marks that can result from high-frequency starting. However, some systems use a high-frequency generator to initiate the pilot arc.

For high-current welding, the arc is usually started by a high-frequency current superimposed on the main welding current, as in gas tungsten-arc welding. The high-frequency current is obtained from a separate supply, as shown in Fig. 2.

Welding Torches

Torches for plasma-arc welding are more complex than those for gas tungsten-arc welding, because separate passages are required for the orifice gas and the shielding gas, and because the orifice body must be protected by a water-cooled jacket.

A torch for manual plasma-arc welding is shown in Fig. 5. It is provided with a handle for holding, a means for securing the tungsten electrode in position and conducting current to it, separate passages for the orifice and shielding gases, a water-cooled orifice body (copper), and an outer shield cup (usually of ceramic material). Torches for automatic plasma-arc welding are similar to manual torches.

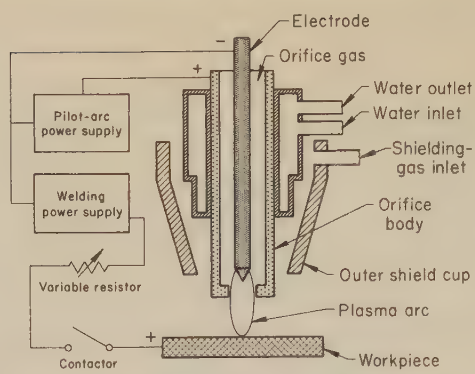

Fig. 4. Schematic diagram of a low-current plasma-arc welding system, using a transferred arc

Table 1. Typical Relationships of Orifice Diameter to Current and to Flow Rate of Orifice Gas

Orifice diameter, in.	Current, amp	Flow rate of orifice gas, cfh
0.030	1 to 25	½
0.052	20 to 55	1
0.086	40 to 100	1½

Table 2. AWS Classifications and Composition Limits for Tungsten Arc Welding Electrodes (AWS A5.12-69)

AWS classification	Tungsten, % min(a)	Thoria, %	Zirconia, %	Other, % max(b)
EWP	99.5	...	...	0.5
EWTh-1 ...	98.5	0.8-1.2	...	0.5
EWTh-2 ...	97.5	1.7-2.2	...	0.5
EWTh-3(c) .	98.95	0.35-0.55	...	0.5
EWZr	99.2	...	0.15-0.40	0.5

(a) By difference. (b) Total. (c) EWTh-3 is a tungsten electrode with an integral lateral segment throughout its length that contains 1.0 to 2.0% thoria; average thoria content of the electrode is as shown in this table.

Controls for gas and welding current are usually separate from the torch and are operated either by a foot control or automatically.

Orifice Diameter. Table 1 shows the relation of orifice diameter to current, and the increase in orifice-gas flow with increase in orifice diameter. An orifice diameter as small as 0.030 in. may be used with very low current.

Multiple-Port Orifice Bodies. Most plasma-arc torches have only one port (orifice) in the orifice body, as shown in Fig. 2, 4 and 5, but torches having multiple ports are available and have certain advantages.

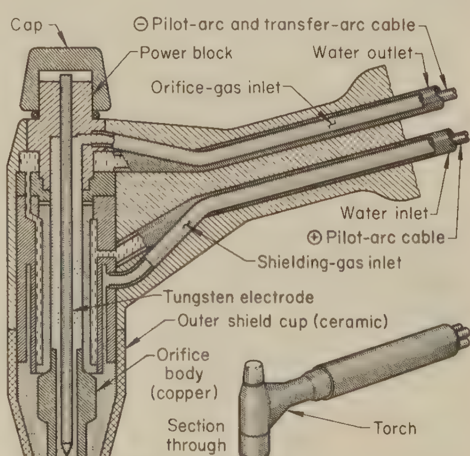

Fig. 5. Typical torch for manual plasma-arc welding

Various types of multiple-port orifice bodies, including those with holes arranged in rows, circles, and other geometric patterns, have been evaluated. The most successful design is one that has the central orifice bracketed by two smaller ports, with a common horizontal centerline for all three ports (Fig. 6). These two ports, each of which has about one-fourth the cross-sectional area of the main orifice, convey a portion of the orifice gas, and change the normally circular heat pattern from the plasma arc into an oval or elongated shape. When the multiple-port orifice body is aligned so that the common centerline of the ports is perpendicular to the weld joint, the arc is elongated in line with the joint. The elongated heat pattern permits greater welding speed and produces welds with narrower heat-affected zones. In one application, in welding a square-groove butt joint in ⅛-in.-thick stainless steel, maximum welding speed with a single-port orifice body was 12 in. per minute, but use of a multiple-port orifice body permitted an increase in speed to 18 in. per minute. With both the single-port and multiple-port orifice bodies, the weld was made with a current of 180 amp, orifice-gas flow of 15 cfh, and shielding-gas flow of 35 cfh.

Orifice-Body Life. The relatively short life of the orifice body in the plasma-arc torch has prevented a more widespread use of plasma-arc welding. Deterioration of the orifice body is due to arcing between the electrode and the area within the orifice body near the orifice and to the intense heat generated by the plasma arc. Orifice-body life is generally less with small torches (those that operate at less than 100 amp), because water cooling is less effective than with large torches.

Occasionally, orifice bodies have deteriorated to such an extent that they were no longer usable after only a few minutes of arc time. However, this is unusual. In one large aircraft plant, in girth welding of titanium, using a 250-amp current, orifice-body life is usually 24 hr of arc time.

To prolong the life of orifice bodies, several approaches have been tried. One is to design the bodies so that the critical area is an insert that can be quickly changed. This greatly reduces cost compared with replacing the entire orifice body. Also, because the distance between the end of the tungsten electrode and the nearest point on the inside of the orifice body is critical, controlling this distance to the optimum value helps to prolong the life of the orifice body. This optimum distance varies for different sizes and designs of torches. The setting that should be used is marked on each torch. Usually, this distance is controlled by an adjusting screw on the torch. On some torches, gages that are inserted through the orifice are used as a means of setting the electrode.

Electrodes

The nonconsumable electrodes used in plasma-arc welding are made of tungsten of commercial purity (99.5%

W) and of tungsten alloyed with thoria or zirconia. The five electrode compositions listed in Table 2 are used for both plasma-arc welding and gas tungsten-arc welding.

The tungsten-thoria electrode EWTh-1 is often preferred for plasma-arc welding, but all of the grades listed in Table 2 have been successfully used.

The EWP, or pure tungsten, electrodes have lower current-carrying capacity than the tungsten-thoria and tungsten-zirconia electrodes. They have good resistance to contamination. Compared with EWP electrodes, tungsten-thoria electrodes have higher electron emission and higher current-carrying capacity, and generally longer life. Tungsten-zirconia electrodes (EWZr in Table 2) are preferred where tungsten contamination of the weld must be kept at a minimum.

Standard diameters and lengths of tungsten electrodes are given in Table 3. Because the current used in plasma-arc welding seldom exceeds 500 amp, the 5⁄32-in.-diam electrode is the largest commonly used. Table 4 lists typical ranges of current used with the various diameters of electrodes.

Electrode Shape. The arcing end of an electrode used for plasma-arc welding is ground to an included angle of approximately 60°, and the tip is flattened slightly. The diameter of the flat area is not critical; it is generally about 1⁄32 in. maximum for 1⁄8 or 5⁄32-in.-diam electrodes and proportionately less for smaller-diameter electrodes.

Orifice and Shielding Gases

Usually, the same gas is used for the orifice gas and for shielding. This is done to avoid variation in the consistency of the arc effluent, which occurs if two different types of gas are used.

Argon is a suitable orifice and shielding gas for welding all metals, but it does not necessarily produce optimum results for all metals. Argon is used for welding carbon steel, high-strength steel, and reactive metals such as titanium alloys and zirconium alloys.

Addition of hydrogen to the argon orifice gas produces a hotter arc and more efficient heat transfer to the workpiece, and higher welding speeds are obtained for a given arc current. The amount of hydrogen that can be used is limited, because excessive hydrogen may cause porosity in welds. The ability to use a higher percentage of hydrogen without inducing porosity depends on the techniques used and on the thickness of the metal being welded. Hydrogen is extremely detrimental in welding reactive metals such as titanium and zirconium alloys, because it results in embrittlement.

Argon-hydrogen mixtures are commonly used as the orifice gas and shielding gas for welding stainless steel (see Table 7). Permissible percentages of hydrogen usually vary from 1 to 5% in welding section thicknesses up to approximately 0.375 in. (see Tables 6 and 7). In some applications, the gas mixture may contain as much as 15% hydrogen (note Example 146).

Addition of helium to argon also produces a hotter arc for a given arc current, but at least 50% helium is needed

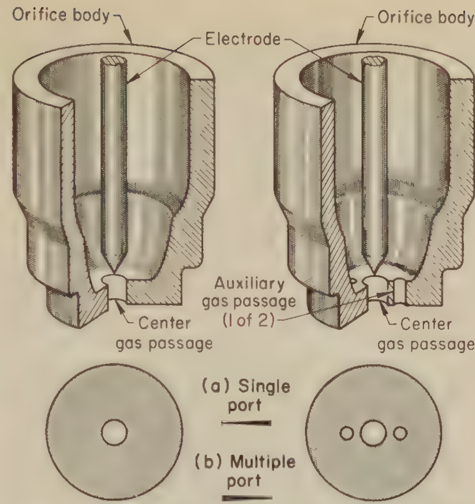

Fig. 6. Single and multiple-port orifice bodies

in a gas mixture before a significant change can be detected. Mixtures containing more than 75% helium behave about the same as pure helium, and have the same limitations. Mixtures containing 50 to 75% helium have been employed in making keyhole welds in titanium, where the use of this gas mixture permits higher travel speed than when pure argon is used and prevents concave root surface, which is sometimes obtained with pure argon.

The use of pure helium as an orifice gas increases the heat load on the torch and reduces its service life and current-carrying capacity. Because helium has a low mass, it is difficult to obtain a keyholing action at reasonable

Table 3. Standard Diameters and Lengths of Tungsten Arc Welding Electrodes (AWS A5.12-69)

Standard diameters, in.	Tolerance on diameter, in.	Standard lengths, all diameters(a), in.	Tolerance on length, in.
Diameters		**Lengths**	
0.010	±0.001	3, 6, 7	±1⁄16
0.020	±0.002	12, 18, 24	±1⁄8
0.040, 1⁄16, 3⁄32, 1⁄8, 5⁄32, 3⁄16, 1⁄4	±0.003		

(a) 0.010-in. electrodes are also available as coils.

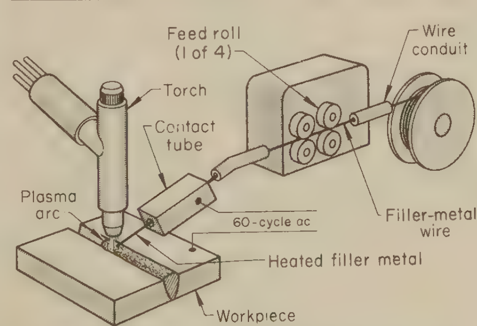

Fig. 7. A system for automatically feeding hot filler-metal wire to the weld puddle

flow rates. Therefore, pure helium is not used for making keyhole welds.

For further information on gases used in welding, and their storage and handling, see the articles on Gas Tungsten-Arc Welding and Gas Metal-Arc Welding in this volume.

Filler Metals

The use of filler metal in plasma-arc welding depends on whether or not additional metal is needed. Filler metal is available in wire form in virtually any composition needed. For all but special applications, filler metals are the same as those used for gas tungsten-arc welding (see section on Filler Metals on page 127 in the article on Gas Tungsten-Arc Welding in this volume).

For manual welding, the filler metal (generally in straight lengths that can be conveniently handled) is fed into the leading edge of the weld puddle. The height at which the filler metal is fed is not critical in plasma-arc welding, because the design of the torch ensures that there is no danger of its touching, and thereby contaminating, the electrode.

Automatic Welding. Most plasma-arc welding applications that use a current of more than 100 amp are automatic, at least to the extent of having the torch held mechanically. When filler metal is used in automatic welding, it is usually fed to the weld puddle by a constant-speed wire-feeding system (see the section on Wire-Feed Systems in the article on Gas Metal-Arc Welding in this volume). The rate of feed must be determined for each new application by experimentation.

Hot-Wire Systems. Welding speed can be increased by preheating the filler-metal wire before it enters the weld puddle. The usual method is to pass electrical current through the wire for a short distance before the wire enters the weld puddle. Figure 7 shows a hot-wire-feeding system commonly used for automatic welding.

Accessory Equipment

Accessory equipment required for plasma-arc welding, including jigs, fixtures, and the various types of positioners and handling devices, is generally the same as for other shielded-arc welding processes (see the sections dealing with these subjects in the articles on Shielded Metal-Arc Welding, Gas Tungsten-Arc Welding, and Gas Metal-Arc Welding in this volume).

Joint Preparation

Joint designs for workpieces up to about 0.060 in. thick are generally the same for plasma-arc welding as for gas tungsten-arc welding. Square-groove butt joints are commonly used for most workpieces in the above thickness range. Also, the conventional (not keyholing) method of welding is usually employed, and fusion is accomplished in the same manner as with gas tungsten-arc welding. Root opening and misalignment are less critical in plasma-arc welding, because of the "stiffness" of the plasma arc and its insensitivity to voltage changes.

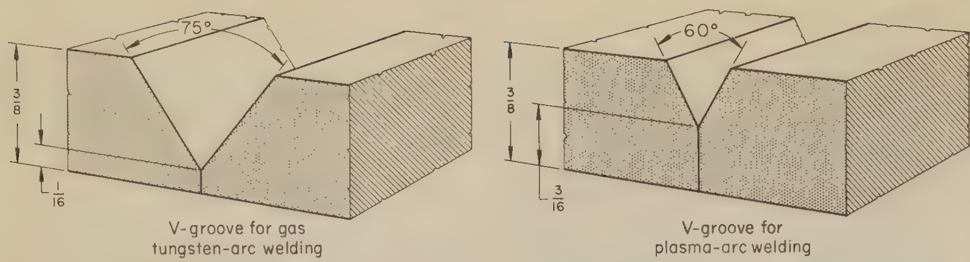

Fig. 8. Comparative typical joints for a V-groove weld to be made in ⅜-in. metal by gas tungsten-arc welding and by plasma-arc welding

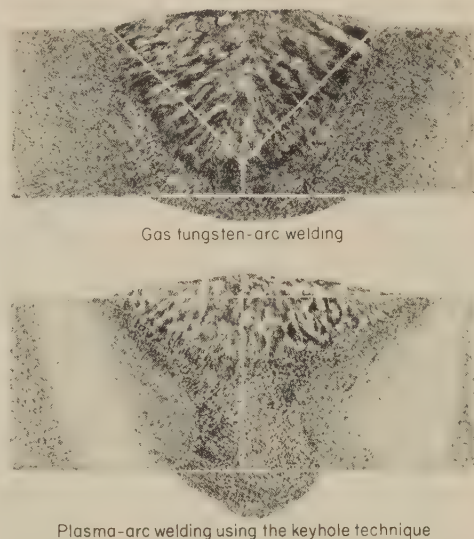
Edge-Flange Welds. For joining workpieces 0.002 to 0.010 in. thick, melting down of an edge-flange is commonly used. In effect, this technique at least doubles the thickness at the weld joint of the metal being welded. The pieces to be welded can be flanged on a roll flanger. A typical correlation between metal thickness and flange height is presented in Table 5.

Butt Joints in Thin Metal. Low-current plasma-arc welding has been successfully applied to stainless steels. Table 6 lists typical conditions for making low-current butt welds in thin stainless steel, either manually or with mechanized equipment.

Square-Groove Butt Joints. For joining workpieces in the thickness range of 0.060 to 0.250 in., the keyhole technique is usually employed (see the section on Keyhole Welding in this article). For some metals, such as titanium alloys, the keyhole technique can be used for thicknesses up to ½ in. without providing a V-groove (Table 7). The keyhole technique often permits welding of metals up to ¼ in. thick in one pass, with or without filler metal. However, for welding thicker metal (and sometimes for metal less than ¼ in. thick), a more uniform weld is obtained by using at least two passes, often the first without filler metal and the second with filler metal.

Machined-groove joints are usually required for the plasma-arc welding of workpieces ¼ to 1 in. thick, but because of the greater penetration of the plasma arc, compared with the gas tungsten arc, the groove depth can be much less. Consequently, the weld can be completed in fewer passes, and with less filler metal. Joint preparation required for plasma-arc welding and gas tungsten-arc welding of a V-groove is compared in Fig. 8.

Figure 9 compares plasma-arc welding and gas tungsten-arc welding for joining ¼-in.-thick type 410 stainless steel. For gas tungsten-arc welding, it was necessary to make a deep V-groove to leave a small root face (about 1/16 in. thick) that the arc could penetrate. The weld was then completed by making one root pass (without filler metal) and two filler-metal passes. For plasma-arc welding, using the keyhole technique, no joint preparation was required and the weld was completed with one root pass and one filler-metal pass. The arc time per 100 in. of weld in the table that accompanies Fig. 9 shows plasma-arc welding to be approximately four times as fast as gas tungsten-arc welding. An additional saving is obtained in reduced joint-preparation time.



Item	Gas tungsten-arc welding	Plasma-arc welding
Joint preparation	Scarf V-groove	None
Number of passes:		
Fusion	One	One
Filler metal	Two	One
Travel speed, ipm	4	10
Arc time per 100 in. of weld, minutes	75	20

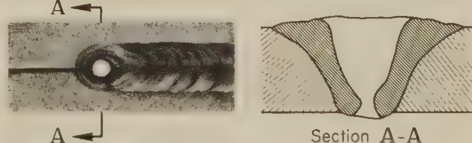

Fig. 10. Appearance of a keyhole weld in ¼-in.-thick stainless steel plate

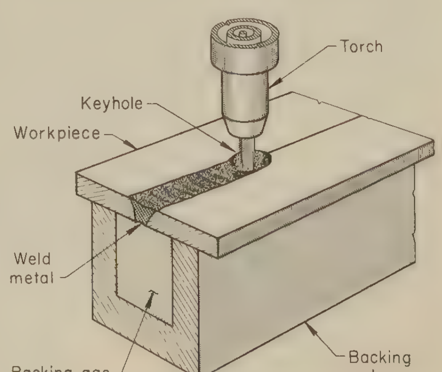

Fig. 11. Typical backing used with the keyhole technique

Keyhole Welding

Because of the intense heat and mechanical force of the plasma arc, the keyhole technique can be used with plasma-arc welding. A hole is produced at the leading edge of the weld puddle by the force of the plasma arc displacing the molten metal, allowing the arc to pass completely through the workpiece. As welding progresses, surface tension causes the molten metal to flow in behind the hole to form the weld bead. A keyhole weld produced in butt welding ¼-in.-thick stainless steel, as revealed photographically from above the weld and schematically at a cross section through the keyhole of the workpiece, is shown in Fig. 10.

The major advantages of the keyhole technique are the ability to penetrate rapidly through relatively thick root sections and to produce a uniform underbead without mechanical backing. Also, the ratio of the depth of penetration to the width of the weld is much higher, resulting in a narrower weld and heat-affected zone (see Fig. 3) Presence of the underbead is proof of complete joint penetration and simplifies weld inspection. Because of the precise control that is required, keyhole welding is usually done automatically. However, a successful keyhole weld can be produced manually by a skilled welder.

The keyhole technique can be applied to steel and stainless steel in the thickness range of 0.060 to 0.250 in. — total thickness of plate or thickness of root face for thicker plates with prepared joint edges. For metals that have lower density or greater surface tension in the molten state, such as titanium alloys, the keyhole technique can be employed for thicker sections, often up to 0.600 in.

Backing Requirements. The weld puddle of a plasma-arc keyhole weld is supported by the surface tension of the molten metal. It is not necessary, therefore, to employ close-fitting backing bars, which affect chill and ability to hold assembly tolerances. However, as in gas tungsten-arc welding, shielding gas is generally required on the back side of the weld to protect the molten underbead from atmospheric contamination. A backing as shown in Fig. 11 provides a duct for flow of the shielding gas at the weld root. This type of backing supports and aligns the workpiece, contains backing gas, and provides a vent space for the plasma jet. The groove is generally about ¾ in. wide and 1 in. deep.

Starting a Keyhole Weld. When welding metal less than ⅛ in. thick, longitudinal and circumferential keyhole welds can be started at full operating current, travel speed, and orifice-gas flow. The keyhole is developed with little or no disturbance in the weld puddle, and the weld surface and underbead are left smooth.

The operating currents and orifice-gas flows required to weld metal more than ⅛ in. thick generally produce a plasma arc that is likely to gouge or tunnel underneath the molten metal just prior to piercing through the joint. Because this gouging action may cause porosity and severe surface irregulari-

ties, starting tabs are used whenever possible to establish the keyhole off the workpiece. When welding heavy circumferential joints, a smooth transition from shallow penetration to a keyhole can be accomplished with a programed increase in welding current and orifice-gas flow. A typical slope-up control cycle for current and gas flow for starting a keyhole weld is shown on the left-hand side in Fig. 12. These functions are performed automatically by commercial welding controls.

Terminating a Keyhole Weld. If the welding current is turned off abruptly at the end of the weld, the keyhole will not close. This is no drawback if the weld can be stopped on an end tab, but if end tabs cannot be used, the keyhole can be closed by use of a slope-down control to reduce the welding current and orifice-gas flow gradually, as shown on the right side of Fig. 12. The net effect of a programed reduction in orifice-gas flow and welding current is to reduce the arc force and heat input and allow the molten metal to flow gradually into the keyhole and solidify.

In the event of a power failure or other malfunction that would cause welding to stop before the weld is completed, the keyhole would be left in the weldment. This hole can be filled in by repositioning the plasma-arc torch several inches behind the hole, recycling the control to make a new start and running over the original keyhole. The only indication that a repair has been made is a slight sink in the surface of the weld, which is filled in by the next pass.

Typical Operating Conditions for Various Metals

Table 7 gives typical operating conditions for plasma-arc welding of carbon and alloy steels, stainless steel, titanium, copper and brass. The same gas is recommended for orifice gas and shielding gas. Except for 0.375-in. stainless steel and 0.600-in. titanium, a square butt joint can be used, and except for 0.125 and 0.250-in. copper, the keyhole technique is employed for all root passes. After a root pass is deposited by plasma-arc welding, filler metal can be deposited by any suitable welding process.

Carbon and Alloy Steels. Typical operating conditions for plasma-arc welding of a low-carbon steel, a medium-carbon alloy steel, and a high-strength alloy steel, in different thicknesses, are given in Table 7. The high-strength steel (D-6ac) requires preheating (to 600 F) and postheating (at 750 F for 1 hr).

Stainless Steel. Typical conditions for plasma-arc welding of various thicknesses of stainless steel are shown in Tables 6 and 7. For all thicknesses, the electrode tip is ⅛ in. from the nearest point on the inner surface of the orifice body; orifice-to-work distance is 3⁄16 in.

The use of the keyhole technique on square butt joints in stainless steel is usually limited to metal less than 0.375 in. thick. However, 0.375-in. stainless steel can be fused by this technique if all welding conditions are closely controlled. Suitable conditions for a typical application include: travel speed, 8 in. per minute; current, 250 amp at 38 volts; orifice gas, 99.5% argon – 0.5% oxygen at 15 cfh; and shielding gas, 99.5% argon – 0.5% oxygen at 40 cfh. Even slight variations in these conditions can produce unsatisfactory welds, and so keyhole welding of square-groove butt joints in 0.375-in. stainless steel is not recommended. (Table 7 specifies a 60° included angle V-groove with a 3⁄16-in. root face for plasma-arc welding of 0.375-in. stainless steel.)

Titanium Alloys. One of the major applications of plasma-arc welding is

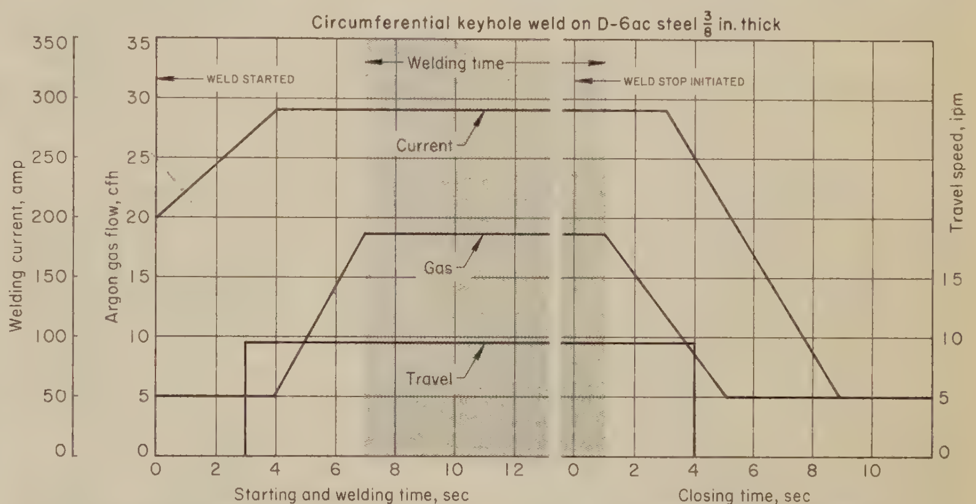

Fig. 12. Slope-control pattern for welding current and orifice-gas flow for starting and terminating a keyhole weld in ⅜-in. D-6ac steel. This is typical of slope-control patterns for welding other thicknesses of other metals.

(a) Orifice-to-work distance is 3⁄64 in. for carbon and alloy steels, and 3⁄16 in. for the other metals welded. A multiple-orifice torch is used. (b) Preheat to 600 F; postheat at 750 F for 1 hr. (c) Backing gas required. (d) 60° included angle; 3⁄16-in. root face. (e) 0.045-in.-diam filler-metal wire fed at 60 ipm. (f) Backing gas and trailing gas shield required. (g) 30° included angle; ⅜-in. root face. (h) Conventional fusion technique and graphite backup were used.

the joining of titanium alloys. Keyhole welds can be made through thicker square butt joints in titanium than in stainless steel and low-carbon steel, because titanium has a lower density. As with gas tungsten-arc welding, plasma-arc welding requires backing gas and a trailing gas shield to prevent atmospheric contamination of the weld bead and the adjacent base metal.

Copper and Brass. Keyhole welds are difficult to make in copper thicker than 0.093 in., because the high thermal conductivity of copper makes it necessary to use such high currents in welding thicker sections that a large weld-puddle area melts and droops down before a keyhole can be formed. Conditions for melt-in fusion welds are shown for metal thicknesses of 0.125 in. and greater in Table 7. Best results have been obtained in welding deoxidized copper; porosity is a relatively common occurrence when welding electrolytic tough pitch copper.

Manufacture of Stainless Steel Tubing

Continuously formed stainless steel pressure tubing conforming to ASTM A312 is made from strip rolled into tube form and butt welded, using the plasma-arc process, generally without filler metal. Installation of plasma-arc equipment in tube mills has resulted in substantially increased welding speed, compared with gas tungsten-arc welding. A comparison of average welding speeds for gas tungsten-arc welding and for plasma-arc welding on tubing of various wall thicknesses is shown in Table 8. Plasma-arc welding shows the greatest speed advantage on thicker-wall tubing. In addition, the rejection, or repair, rate when using plasma-arc welding is lower than when using gas tungsten-arc welding on thick-wall tubing, because of the uniform penetrating power of the plasma arc.

A schematic view of plasma-arc tube welding is shown in Fig. 13. Weld-bead shape and reinforcement are controlled by adjusting four variables: the welding current, the location of the arc relative to the centerline of the pressure rolls on the tube mill, the force exerted by the pressure rolls, and the backing-gas pressure inside the tube.

In beginning a production run, the arc is started and a keyhole is established approximately 1 in. ahead of the centerline of the pressure rolls. Excessive weld metal (reinforcement) at the top and bottom of the tube joint (Fig. 14a) indicates that the weld bead is too hot when it reaches the pressure point between the rolls and is, therefore, soft enough to be upset. This condition can be corrected by moving the torch farther ahead of the pressure rolls, allowing more time for the weld puddle to cool before it comes under forging pressure. If there is not enough reinforcement at the top of the joint (Fig. 14b), the torch should be moved closer to the pressure rolls. Pressure-roll force can also be increased or decreased to change the amount of weld reinforcement.

If excessive drop-through occurs (Fig. 14c), it can be corrected by increasing the backing-gas pressure. The backing gas is confined between plugs or diaphragms mounted on a pipe or lance inside the tube. Backing-gas pressure can be controlled by connecting a hose to the backing-gas chamber and exhausting the gas into a beaker or tube of water. Gas pressure is increased until bubbles appear in the water. Thereafter, pressure in the chamber will depend on how deeply the hose is immersed in the water.

Conditions for Plasma-Arc Welding

Joint type	Edge
Weld type	Corner flange
Filler metal	None
Orifice gas	Argon, at 0.6 cfh
Shielding gas	95% A – 5% H_2, at 25 cfh
Orifice diameter	0.030 in.
Power supply	1 to 10 amp dc (with continuous high-frequency pilot circuit)
Current	5 amp, dcsp
Welding speed	5 ipm

Fig. 15. Electronic package that was plasma-arc welded to fuse a thin corner joint (Example 140)

Plasma-arc tube welding, unlike gas tungsten-arc tube welding, does not require arc-voltage control or automatic adjustment of orifice-to-work distance. This may greatly reduce the cost differential for equipment between the plasma-arc and gas tungsten-arc processes. Constant travel speed for the tube and good joint fit-up are essential for good-quality welds.

When tube diameter is 1 in. or less, the speed obtainable using plasma-arc welding is about the same as for gas tungsten-arc welding. For making this size of tube, a V-groove is formed as the edges of the strip are brought together. Keyholing, with its accompanying speed advantage, becomes impractical, because for the maximum wall thickness that would prevail for a 1-in.-diam tube there is not enough metal at the joint to support the molten weld puddle.

Circumferential Pipe Welding

Plasma-arc welding has been used to make circumferential joints in stainless steel pipe and in pipe of some other materials, in the horizontal and vertical pipe positions. This type of weld would normally be made by multiple-pass gas tungsten-arc welding, using a backing ring and filler-metal on a prepared joint. The use of plasma-arc welding permits keyhole welding of square-groove butt joints in one pass in pipe of 0.090 to 0.250-in. wall thickness. On pipe with wall thickness from 0.250 to 0.375 in., a V-groove with a 60° included angle and a root face half the thickness of the wall is used. This type of prepared joint requires two passes — a root pass using the keyhole technique, and a second pass using filler-metal wire. Slope control for welding current and orifice-gas flow is employed, to start and terminate the keyhole weld (Fig. 12).

Welding of Vessels

Welding of circumferential joints in tanks or vessels is an extension of the technique used to weld circumferential pipe joints. The vessel must be positioned and rotated so that the joint is in the horizontal position.

Plasma-arc welding on a vessel, involving the joining of girth seams on a D-6ac steel missile case, is described in Example 142 in this article.

Cost

Whether or not plasma-arc welding will be more expensive than another welding process will be determined only by careful evaluation of the application and the welding processes.

Equipment. Plasma-arc welding equipment is two to five times more expensive than gas tungsten-arc welding equipment of the same capacity, but is far less costly than electron-beam welding equipment of the same capacity.

Maintenance cost is greater for plasma-arc welding than for other arc welding processes. Frequent replacement of orifices is the principal contributor to the high maintenance cost of plasma-arc welding equipment.

Productivity capability of plasma-arc welding is high, and its potentiality for high production must be evaluated before it can be determined whether or not the high cost of equipment would be justified. In applications where plasma-arc welding is up to four times as fast as alternative processes, equipment costs are rapidly amortized if production quantities are high.

Several examples in the next section of this article show time and cost savings resulting from the use of plasma-arc welding in preference to an alternative process. One of them (Example 147) involves the production of about five million parts per year.

Plasma-Arc Welding vs Alternative Processes

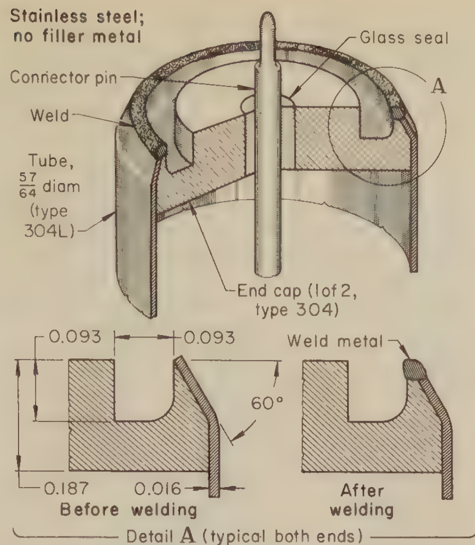
Plasma-arc welding is most often an alternative to gas tungsten-arc welding, of which it is a refinement. In other applications, plasma-arc welding competes with such widely different processes as electron-beam welding, oxyacetylene welding, or resistance seam welding. The examples that follow compare plasma-arc welding with these processes for specific applications.

Example 140. Plasma-Arc Welding vs Gas Tungsten-Arc Welding for Manual Fusion of Thin Joints (Fig. 15)

Enclosures for small electronic and electromagnetic devices were made of a thin stainless steel case into which was fitted a reverse-flanged cover containing glass-insulated connector pins. The enclosures were hermetically sealed by fusing the outer edge to form a corner weld (Fig. 15). The procedure was set up for manual welding by clamping the fitted stainless steel cases in the copper-faced jaws of a small, movable bench vise.

Originally, the weld was made by using a small gas tungsten-arc torch at low amperage. Manual seam tracking was difficult and tedious because the low amperage, needed to avoid overheating, required holding the arc length to within about 1/32 in. Small variations resulted either in stubbing the electrode tip or breaking the arc. As a result, arc restrikes, tip dressing and leaky welds were frequent. When amperage was increased to permit a longer arc, overheating often damaged the glass seals.

These problems were overcome to a large extent by changing over to a small plasma-arc unit designed for operation at approximately 1 to 10 amp. The lightweight torch (about 3 oz heavier than, and roughly the same size as, the gas tungsten-arc torch) had a 0.030-in.-diam orifice. This torch produced a shielded plasma column with an effective operating length of 1/8 to about 3/8 in., when used in the transferred-arc mode at 5 amp. The arc was initiated in the nontransferred mode — that is, as a pilot arc in a high-frequency circuit between the tungsten electrode and a copper anode within the torch body. When the torch nozzle was brought within operating distance, the dc welding circuit was closed by transfer of the arc to the grounded workpiece.



Conditions for Automatic Plasma-Arc Welding

Joint type	Edge
Weld type	Edge-flange
Number of passes	One
Welding position	Flat
Fixtures	Clamping jig; rotating positioner; fixed torch mount
Torch	10 amp, water cooled
Electrode	0.020-in.-diam EWTh-2
Filler metal	None
Orifice gas	Argon, at 0.68 cfh
Shielding gas	95% A – 5% H_2, at 20 cfh
Orifice-to-work distance	0.090 to 0.120 in.
Power supply	10-amp, 110-v (max) control unit
Current	5 amp, dcsp
Voltage	50 v
Welding speed	3 ipm
Preheat, postheat	None

Fig. 16. End cap in place on small electrical component, showing cap and joint design used for plasma-arc welding (Example 143)

After welding, the arc returned to the nontransferred mode.

Because of arc-length tolerance, manual welding was easier to control. Low heat input avoided damage to the glass seals, while the absence of frequent starts and stops resulted in better weld quality. Productivity increased, largely due to fewer rejects. The plasma-torch electrode required occasional dressing because of arc erosion, but dressing because of base-metal contamination was eliminated. Welding details are given in the table with Fig. 15.

Table 8. Average Speed for Fabricating Stainless Steel Tubing by Gas Tungsten-Arc Welding and by Plasma-Arc Welding

Wall thickness, in.	Welding speed, ipm: Gas tungsten-arc	Welding speed, ipm: Plasma-arc	Increase with plasma-arc welding, %
0.109	26	36	38
0.125	22	36	64
0.154	20	36	80
0.216	8	15	88
0.237	6	14	134

Example 141. Welding Speed — Plasma-Arc Welding vs Gas Tungsten-Arc Welding (Table 9)

Three metals used for aerospace components were welded by plasma-arc and gas tungsten-arc processes to compare times required for making welds. Samples welded were: 1/4-in.-thick type 410 stainless; 1/4-in.-thick maraging steel (18% Ni); and 0.095-in.-thick titanium alloy Ti-6Al-4V.

Welding conditions and results are given in Table 9. Plasma-arc welding took a fifth to a tenth as long to complete 100 in. of weld as gas tungsten-arc welding, partly because fewer passes were required and partly because travel speed was greater.

Example 142. Plasma-Arc Welding vs Gas Tungsten-Arc Welding for Making Missile Cases of D-6ac Alloy

Missile-case assemblies comprised five cylindrical sections 10 ft in diameter by about 10 ft long, and two hemispherical end domes. Each cylindrical section was fabricated from plate 3/8 in. thick by 9 ft wide by 32 ft long. The plate was formed into a cylinder and welded longitudinally. The 10-ft-diam hemispherical forgings were then welded to the ends of the cylinders.

Gas tungsten-arc welding, the process originally qualified for use in making the missile cases, required five passes with filler metal to complete a single circumferential butt joint, using a single-V groove with a 90° included angle, and a 0.060-in. root face. Maximum travel speed for any pass was about 5 in. per minute, and more than 14 hr of arc time was required to weld a single cylinder (one longitudinal weld and two circumferential welds). The welding operation was further complicated by the need for a 650 F preheat, joint tolerance and fit-up problems resulting from the size of the weldment, deterioration of ceramic-coated backing bars, and by the need for interpass cleaning.

Plasma-arc welding was used to fabricate a prototype cylinder. This technique employed a single-V groove with a 60° included angle and a 3/16-in. root face. A weld was completed in two passes, the root pass being made without filler metal, at a travel speed of 10 in. per minute, and the cover pass, with filler metal, at about 6 in. per minute. Because the underbead of the root pass was only about 5/32 in. wide, accurate following of the joint seam was essential. Total arc time to weld a single cylinder was about 4¼ hr, as compared with more than 14 hr for gas tungsten-arc welding. Filler-metal requirements were reduced, interpass cleaning time was a quarter that required for gas tungsten-arc welding, joint penetration was consistent, backing-bar problems were eliminated, and quality and mechanical properties of the welds met all specification requirements. However, plasma-arc welding was not used, because production of the missile cases was almost completed.

Example 143. Change to Plasma-Arc Welding From Gas Tungsten-Arc Welding for Attaching Tube End Caps (Fig. 16)

A delicate electrical component required hermetic seals between two end caps and a tube section (Fig. 16). Each end cap contained a connector pin insulated from the

cap by a glass seal and joined to an internal circuit by wrapped and brazed wires. Originally, the part was designed for a single-pass weld by gas tungsten-arc welding at each end. For this process, end caps did not have the heat-barrier groove and rolled-over edge shown in Fig. 16.

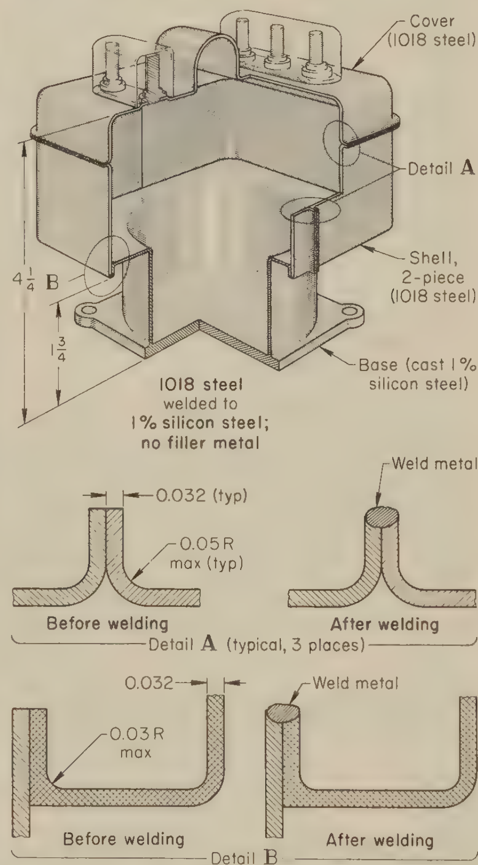
The part was fixtured for rotation about its vertical axis under a stationary electrode holder and the edge between the tube and cap was gas tungsten-arc welded. Several serious problems arose. Because a low-heat-input arc was essential in order to avoid overheating the glass seal, very precise electrode positioning was needed to maintain stability of the arc operating on low amperage. Also, to ensure proper electrical grounding of the two parts during welding, machining tolerances on the end cap and roundness tolerances on the tube were extremely close. When the welds made by this procedure were leak tested, about 80% were rejected; 30% could be salvaged by rewelding. Because rejection rate was too high, this welding procedure was abandoned.

Plasma-arc welding, using a new joint design, was tried. By using a very small plasma-arc torch, a much greater arc-length tolerance was obtained. End caps were beveled to permit the tube to be rolled over the edge, thus forming a tight mechanical joint more tolerant of dimensional variations. In addition, a groove was cut in the end caps to isolate the welded edges and to provide a longer heat path to the glass seal and a greater area for heat dissipation by radiation and convection. The groove also reduced restraint to shrinkage of the weld metal when the assembled relay housings were cooled.

The same clamping fixture, turntable and torch mount were used as with gas tungsten-arc welding. New equipment comprised a low-current plasma-arc welding unit, separate gas cylinders for orifice and shielding gases, and a plasma-arc torch.

The end caps were preplaced in the tube, the tube assembly was loaded in the fixture, the torch was positioned at an angle of 45° from vertical, and the weld was made. After one revolution of the work, the arc was continued for an overlap of about ⅛ in., after which the current was shut off by a foot control. The part was turned over, and the operation was repeated on the other end. Additional details for plasma-arc welding are given in the table that accompanies Fig. 16.

After assembly with other components, each unit was tested with air at 300 psi while immersed in water, and with a halide leak detector, using a mixture of 75 lb Freon and 300 lb air. Use of plasma-arc welding and the new joint design decreased rejections to 3%.



Joint type	Edge

(a) For touch-up and repair, a bare low-carbon steel rod was used.

Fig. 18. Relay housing that was plasma-arc welded, and the joints used (Example 145)

Example 144. Change From Gas Tungsten-Arc Welding to Automatic Plasma-Arc Welding To Join Terminals on a Computer Memory-Grid Array (Fig. 17)

A computer memory-grid array was constructed of 18 plastic frames. Terminals on the outer sides of the stacked frames were welded to join the several layers, as shown in Fig. 17. The terminals were 0.010-in.-thick strips of 0.004-in.-thick copper, coated on both sides with 0.003 in. of BCuP-5 brazing alloy. Originally, the joints were welded by the gas tungsten-arc process, using a small hand-held torch. Because 1122 welds had to be made on each of the four sides of the array, manual gas tungsten-arc welding was too slow. Furthermore, weld spatter caused short circuits and high-resistance leaks, which altered the functioning of the array.

A change was made to automatic low-current plasma-arc welding. Before welding, the frames were clamped together and a copper grounding plate was placed over the joints, as shown. The terminals extended through holes in the grounding plate and projected 0.020 in. beyond. In addition to being an electrical ground, the grounding plate served as a fixture for holding the joints, as a heat shield to protect the plastic frames, and as a heat sink to conduct heat away from the terminals after the weld was made. The assembled array was placed in a traversing mechanism that passed each row of joints under the plasma-arc torch and, at the end of each row, indexed to the next row. The machine shut down automatically when the last row of joints on a side had been welded.

At each end of the grounding plate was a type 302 stainless steel arc-starting plate, where the arc was struck. The arc-starting plates burned through and warped quickly and had to be replaced frequently.

Automatic plasma-arc welding reduced welding time for an array from 7 hr to 30 min. On the average, only two joints in each array had to be repair welded. (An array contained about 4500 joints.) Actual arc time for one side was 2½ min. Welding details are given in the table that accompanies Fig. 17.

Example 145. Selection of Plasma-Arc Welding for Assembling Relay Housings (Fig. 18)

Housings for power relays used in aircraft and missiles were plasma-arc welded after consideration of soldering, brazing, gas tungsten-arc welding, and electron-beam welding. Soldering and brazing were eliminated because welding was more convenient, less expensive, and produced better joints. Electron-beam welding was ruled out because of the high cost of equipment, the welder skill required, and the effect of the vacuum on various electrical components. Equipment was available for plasma-arc welding, and its operation required less welder skill than gas tungsten-arc welding.

Housings were required to be hermetically sealed. Each housing was made of four components — a cover, a two-piece shell, and a base, as shown in Fig. 18. The base was a 1% silicon steel casting; the other components were press formed 1018 steel. The formed parts were 0.032 in. thick, and the joint areas of the cast base were also 0.032 in. thick.

Joints (Fig. 18) were designed for ease of assembly and to permit deposition of small edge-seal welds. In addition, this type of joint simplified repair welding.

After joint edges were degreased and wire brushed, the components were first assembled in a special tack welding fixture, a reasonable allowance being made for some mismatch. Tack welds were placed on the sides, and at the four corners of the cover and the base. The workpiece was then removed from the tack welding fixture and

placed in a manually rotated welding fixture, with the vertical axis turned to the horizontal. The piece was held by power-arm-actuated holding clamps. Next, a two-piece band of 1-by-⅜-in. copper was fitted around the shell and fastened with a garter spring, to serve as a heat sink to protect glass seals on terminal studs and connector pins. The straight sides and then the cover were manually welded in a single pass, using the settings and conditions given in the table that accompanies Fig. 18. Mismatch was adjusted (where needed) by melting down the protruding edge. The unit was allowed to cool to room temperature, and then the shell was welded to the cast base.

The plasma-arc torch operated continuously — in the pilot-arc (nontransferred) mode when not welding and in the transferred-arc mode when welding. Filler metal was required only for touch-up or repair, and then a bare low-carbon steel rod was used. Because the power arm attached to the fixture permitted the workpiece to be turned as needed, all welding could be done in the flat position. During welding, the assembly was purged with helium at a rate of 3 to 5 cu ft per hour.

Completed welds were inspected visually for pinholes, which were ground out and repaired. The units were given a preliminary leak test by pressurizing them with helium at 15 psi and observing bubble emission when units were immersed in the testing solution. Leaking joints were repair welded. Finally, the units were tested by mass spectrometer to make sure that the leak rate was less than 1.4×10^{-5} cu cm per second per cubic inch of sealed volume. Less than 1% of the relays were rejected in this final inspection.

The presence of 1% silicon in the cast steel presented no problem in maintaining weld quality.

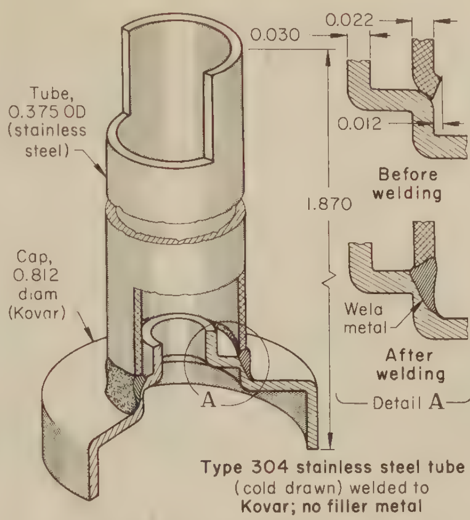
Example 146. Change From Oxyacetylene Welding to Plasma-Arc Welding for Joining Stainless Steel to Kovar (Fig. 19)

A circumferential weld was required to join a type 304 stainless steel tube to a Kovar electrode cap of a relay component, as shown in Fig. 19. [Kovar, an alloy with 29% Ni, 17% Co, 0.2% Mn, remainder iron, is used for making glass-to-metal seals because its coefficient of expansion is the same as that of certain types of glass.] The chief requirements of the welded joint were: (*a*) medium joint penetration, (*b*) smooth appearance, (*c*) carbon-free surface, (*d*) strength equal to that of the tube wall, and (*e*) resistance to penetration of mercury at 80 psi.

Originally, oxyacetylene welding (without filler metal) was used for making the weldment, the procedure employed being as follows: Prior to welding, both components were annealed in a hydrogen atmosphere. The tube and cap were clamped in a special jig to maintain alignment. The assembly was mounted, axis vertical, on a turntable, and welding was done in a single pass, using a hand-held torch. From 80 to 90 pieces were produced per hour, but welds were of poor quality, over 50% being rejected for carbon deposits and poor bonding and spreading of metal at the interface between the two components. [When the oxyacetylene welding process was used, the tube ends were not flared, as they were when plasma-arc welding was adopted (shown in the "Before welding" view in detail A, Fig. 19).]

Other joining processes, including brazing and gas tungsten-arc welding, were investigated. Brazing was unsatisfactory because it introduced metals into the joint that were attacked by mercury. Gas tungsten-arc welding was rejected because of the danger of contamination of the weld by the tungsten electrode.

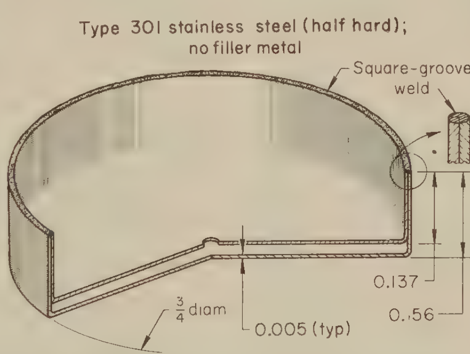
The problems were solved by changing to low-current plasma-arc welding. Details of the welding procedure are given in the table that accompanies Fig. 19. The prewelding treatment was the same as described above for oxyacetylene welding. No changes in fixturing were required, but joint design was slightly modified by flaring the tubes as shown in Fig. 19. With plasma-arc welding, production averaged 60 pieces per hour, but the rejection rate dropped to 0.05%, which more than compensated for the lower production rate.



Conditions for Plasma-Arc Welding

Joint type	Edge
Weld type	Corner-flange
Fixtures	Clamping jig; rotating positioner
Welding position	Horizontal (see figure)
Number of passes	One
Torch	10 amp, water cooled
Electrode	$\frac{3}{64}$-in.-diam EWTh-2
Filler metal	None
Orifice gas	Argon, at 0.6 cfh
Shielding gas	85% A – 15% H_2, at 18 cfh
Orifice-to-work distance	¼ in.
Power supply	0.1-to-10-amp, 60-to-80-v rectifier
Current	9 amp, dcsp
Voltage	70 v
Welding speed	6 rpm
Production rate	60 assemblies per hour

Fig. 19. Relay component that was plasma-arc welded, requiring fusion of type 304 stainless steel to Kovar. Joint design and weld are shown at right. (Example 146)



Conditions for Automatic Plasma-Arc Welding

Joint type	Edge
Weld type	Square-groove
Fixtures	Clamping jigs; rotating table; torch mount
Welding position	Flat
Torch	Machine held, water cooled
Electrode	0.020-in.-diam EWTh-2
Filler metal	None
Orifice gas	Argon, at 0.6 cfh
Shielding gas	97.5% A – 2.5% H_2, at 14 cfh
Orifice-to-work distance	0.050 in.
Power supply	10-amp, single-phase rectifier
Current	3.5 amp, dcsp
Welding speed	28 ipm
Annual production	5 million cups

Fig. 20. Double-wall cup that was sealed by plasma-arc welding to reduce rejection rate (Example 147)

Example 147. Change to Plasma-Arc Welding From Resistance Seam Welding To Decrease Rejections (Fig. 20)

Rejection rate for the small thin-wall double cup shown in Fig. 20 was about 4.5% when resistance seam welding was used to make the seal weld. The major requirement was that the press-fit-and-welded joint between the two 0.005-in.-wall cups be pressure-tight under a test applied at a later stage of assembly. Rejections were a significant cost factor because about five million parts were produced per year.

By changing to automatic low-current plasma-arc welding, welding time was increased threefold, but rejections were reduced to less than 1%.

Automation for plasma-arc welding was accomplished by installing two welding stations, each provided with clamping jigs for holding parts in position and rotating them under the torch. The torch was rigidly mounted on sliding ways so that it could be positioned accurately over the edge joint of an assembly at either station. A cup assembly was loaded on the fixture at one welding station, and rotation and the arc were initiated by a push button. While this assembly was being welded, another was being loaded on the second fixture. After the first cup had been welded, the torch was moved to the other welding station, and the second cup was welded.

Welding details are given in the table that accompanies Fig. 20. The completed welds were examined at a magnification of eight diameters. After further assembly, the finished unit was pressure tested with low-pressure, clean, dry air while immersed in water for 10 sec.

Welding Stainless Steel Foil

At very low currents, plasma-arc welding can be used for joining stainless steel foils (0.001 to 0.005 in. thick). For this work, a system such as that shown in Fig. 4 is used.

The following current settings (dcsp) and welding speeds have been satisfactory for welding three different thicknesses of stainless steel foil, using argon plus 1% hydrogen at 0.5 cfh through a 0.030-in.-diam orifice and at 20 cfh for shielding:

0.001-in. foil	0.3 amp, 5 ipm
0.003-in. foil	1.6 amp, 6 ipm
0.005-in. foil	2.4 amp, 5 ipm

Only edge-flange welds for butt joints are recommended for welding foil, and precise fixturing is a primary requirement. Figure 21 shows a typical fixturing arrangement for making the edge-flange weld. An essential part of any fixture used is a backing groove at least ¼ in. deep, because the underside of the joint must be shielded with gas during welding. The width of the backing groove is not critical; a range of $10t$ to $24t$ (t being the foil thickness) is satisfactory. Also, considerable tolerance is allowed on spacing between hold-down clamps; it can range from $15t$ to $30t$ (Fig. 21).

Hard Facing by Arc Welding

*By the ASM Committee on Hard Facing**

HARD FACING is the process of applying, by welding, a layer, edge or point of wear-resistant metal onto a metal part to increase its resistance to abrasion, erosion, galling, hammering or other form of wear. This article deals with the use of arc welding for this purpose. Hard facing by oxyacetylene welding is described in the article that begins on page 587 in this volume.

Hard facing may be applied to new parts to improve their resistance to wear during service, or to worn parts for the purpose of restoring them to serviceable condition. It is frequently used in applications where systematic lubrication against abrasion is not feasible or is inadequate to give the desired service life. In general, the wear-resistant coating is applied only to those critical surfaces of components where wear is maximum. Worn parts can be satisfactorily refaced or rebuilt many times before their replacement becomes mandatory.

The economic success of the process often depends on selective application of relatively expensive hard facing alloys to comparatively inexpensive base metals. Heavy or bulky parts that are difficult and costly to move can often be repaired or rebuilt in the field or in the plant where they are installed, by welding with portable equipment.

Hard Facing Alloys

Most hard facing alloys are marketed as proprietary materials. They are classified here in five major groups (1 to 5), primarily according to total alloy content (elements other than iron), with subdivisions based on the major alloying elements (see Table 1). Table 2 gives typical compositions of specific alloys in each subgroup. Usually both the wear resistance and cost increase as the group number increases. Table 2 in this article is a revised and expanded version of Table 2 in the article on Selection of Hard Facing Alloys, page 821 of Volume 1 of this Handbook. Choice of the form and type of alloy depends on the application and the welding process to be used.

Forms. Alloys for hard facing are usually available as bare cast or tubular rod, covered solid or tubular electrodes, or solid wire, and powder. The availability of a particular alloy in a given form depends on the ability of the alloy to be cast, shaped into wire or tubing, or produced in powder form. Alloys that do not lend themselves to economical production by any of these methods are usually inserted in granular form into a low-carbon steel tube during the process of roll forming the tube from strip. The continuous tube can be cut to rod lengths for "stick" electrodes or it can be coiled for use as electrode wire in semiautomatic or automatic welding.

Many alloys are available in more than one form. The bare cast and bare tubular rod forms are used in gas tungsten-arc welding, covered electrodes in shielded metal-arc welding, solid wire in gas metal-arc or submerged-arc welding, tubular (alloy-cored) wire in open-arc welding, and powder in plasma-arc welding.

Alloy Composition. The alloys in group 1A (see Table 2) are low-alloy steels that, with few exceptions, contain chromium as the principal alloying element. The total alloy content (including carbon) is between 2 and 6%. These are often used as buildup materials for support of harder, more highly alloyed hard facing alloys.

The alloys in groups 1B1 and 1B2 are similar to those in group 1A except that they contain a higher total alloy content (6 to 12%), and in group 1B2, carbon content is 2% or more. Many tool steels are included in this group. Group 1B2 includes several alloy cast irons.

Alloys of group 1 have the greatest shock resistance of all hard facing alloys except the austenitic manganese steels (groups 2C and 2D), and have better wear resistance than low-carbon or medium-carbon steel, which is the base metal to which they are usually applied. These alloys are less expensive than the other hard facing alloys, and are extensively used where machinability is necessary and only moderate improvement over the wear properties of the base metal is required.

The alloys in groups 2A1 and 2A2 are chromium-containing alloys with total alloy content of 12 to 25%. Many of these alloys have an appreciable content of molybdenum. The alloys with carbon content of 1.75% or more are shown in group 2A2; they are medium-alloy cast irons.

Molybdenum is the principal alloying element in nearly all group 2B alloys, most of which also contain appreciable amounts of chromium. These and the group 2C steels have total alloy content between 12 and 25%.

Group 2C alloys are austenitic manganese steels. Although manganese content predominates, the alloys contain appreciable amounts of nickel or molybdenum as an austenite stabilizer.

The hard facing alloys of groups 2A1, 2A2 and 2B are more wear resistant, less shock resistant, and more expensive than those in group 1. Groups 2C and 2D are highly shock resistant, but have limited wear resistance unless subjected to work hardening. Group 2D alloys have total alloy content of 30 to 37%, and carbon content ranging from less than 0.10% to more than 1.0%.

Group 3 alloys have total alloy content from 25 to 50%. They are high-chromium alloys, many of which contain nickel or molybdenum, or both. Carbon content ranges from about 1.75% to more than 5%. Group 3B alloys contain appreciable amounts of molybdenum and chromium, and group 3C, of cobalt and chromium. Groups 3A, 3B and 3C alloys are characterized by massive hypereutectic alloy carbides that impart wear resistance and some degree of resistance to corrosion and heat. They are more expensive than the alloys in groups 1 and 2.

Cobalt-base and nickel-base alloys with total content of nonferrous metals from 50 to 99% are classified in group 4. The cobalt-base alloys (group 4A) are generally rated as the most versatile of the hard facing materials. They resist heat, abrasion, corrosion, impact, galling, oxidation, thermal shock, erosion, and metal-to-metal wear. Some of these alloys retain useful hardness up to 1500 F and resist oxidation temperatures up to 2000 F. The nickel-base alloys (group 4B) are most effective for service involving both corrosion and wear. They are superior to the other hard facing alloys where wear is caused by metal-to-metal contact, as in bearings. They retain useful hardness up to about 1200 F and resist oxidation at temperatures up to 1600 F.

Group 5 alloys (not listed in Table 2) consist of hard granules of tungsten carbide distributed in a metal matrix. Various matrix metals are employed, including iron, carbon steel, nickel-base alloy, cobalt-base alloy, and bronze. The tungsten carbide materials provide maximum abrasion resistance under service conditions involving low or moderate impact.

Alloy Selection. For guidance in the selection of hard facing materials for specific applications, see the article on Selection of Hard Facing Alloys, on pages 820 to 833, in Volume 1 of this Handbook.

Selection of Welding Process

For a given hard facing application, the selection of the most suitable welding process and the welding technique to be used may be as important as the selection of the alloy. Along with service requirements, the physical characteristics of the workpiece, the metallurgical properties of the base metal, the form and composition of the hard facing alloy, the property and quality requirements of the weld deposit, the skill of the welder, and the cost of the operation must be considered in selecting an arc welding process. Discussion of these factors and their influence follows. Discussion of the individual processes appears on pages 156 to 160.

Workpiece Factors. The size, shape and weight of the workpiece always influence welding process selection. Very large, heavy parts that require hard facing or buildup coatings, and that are difficult or impossible to transport, usually require selection of an arc welding process for which the equipment can be readily moved to the site of the workpiece. In such applications, welding is most likely to be manual or semiautomatic, particularly when hard facing of relatively inaccessible areas is involved. In contrast, parts that can be conveyed readily to the welding equipment and that are to be processed in large quantities can be hard faced most effectively and economically by machine or automatic methods. Shielded metal-arc and open-arc welding, for which portable equipment is readily available, lend themselves to field applications, whereas submerged-arc, gas tungsten-arc, gas metal-arc, and plasma-arc welding are better suited to in-plant applications.

Properties of Base Metal. The chemical composition, melting temperature range, and expansion and contraction characteristics are the principal attributes of the base metal that influence selection of a welding process. The susceptibility of the base metal to thermal cracking, oxidation, or contamination at elevated temperatures also may need to be considered. Thus, when rapid heating could cause thermal cracking of the base metal, adequate preheat and a welding process that provides a moderate heating rate, preferably without sacrifice in efficiency, should be selected. In addition, the cooling rate from the welding temperature may have to be controlled, and residual stresses may have to be reduced by postweld stress relieving.

Form and Composition of Hard Facing Alloy. The physical and metallurgical properties of the hard facing alloy determine the forms in which it is available. Some of the harder, more brittle alloys cannot be produced in the form of drawn wire, and therefore they are produced as mixtures of powder and are inserted in a carbon steel tubular wire if they are to be used in gas metal-arc welding, open-arc welding, or submerged-arc welding, which require a continuous electrode wire. A variety of forms, such as wire, bare cast rod, or bare tubular rod, can be used as filler metal in gas tungsten-arc welding. Compositions of hard facing alloys are given in Table 2.

Table 1. Classification of Hard Facing Materials by Alloy Groups

Group	Total alloy content, %	Principal alloying elements
Low-Alloy Ferrous Materials		
1A	2 to 6	Cr, Mo, Mn
1B	6 to 12	Cr, Mo, Mn
High-Alloy Ferrous Materials		
2A	12 to 25	Cr, Mo
2B	12 to 25	Mo, Cr
2C	12 to 25	Mn, Ni
2D	30 to 37	Mn, Cr, Ni
3A	25 to 50	Cr, Ni, Mo
3B	25 to 50	Cr, Mo
3C	25 to 50	Co, Cr
Nickel-Base and Cobalt-Base Alloys		
4A	50 to 100	Co, Cr, W
4B	50 to 100	Ni, Cr, B
4C	50 to 100	Cr, Ni, Co
Tungsten Carbide		
5	75 to 96	WC in metal matrix

Properties and Quality Requirements of the Deposit. The properties and quality of hard facing deposits depend primarily on the hard facing alloy. Other influential factors are the base-metal composition, the welding process and method employed, the number of layers deposited, and other welding characteristics. The extent of base-metal "dilution" of the hard faced surface during welding will vary with the process and the number of layers. Dilution is the interalloying of the hard facing alloy and the base metal, and is usually expressed as the percentage of base metal in the hard facing deposit. A dilution of 10% means that the deposit contains 10% base metal and 90% hard facing alloy. As dilution increases, the hardness, wear resistance, and other desirable properties of the alloy deposit are reduced. Sometimes, in order to control composition, a buffer layer of weld metal is deposited between the base metal and the hard facing alloy. In addition to minimizing dilution, a buffer layer is often used to counteract the adverse effects of differences in coefficient of expansion-contraction between the hard facing alloy and the base metal.

One criterion for selection of a welding process should be the ability of the process to limit dilution while achieving a high deposition rate, and thus to avoid the necessity for a deposit thickness greater than that required for service. Typical dilution percentages, deposition rates, and minimum deposit thicknesses for different welding processes and various forms, compositions and modes of application of hard facing alloys are given in Table 3.

As shown in Table 3, dilution may vary from 1 to 60%, and the minimum practical deposit thickness of a single layer of hard facing alloy ranges from $\frac{1}{32}$ to $\frac{3}{16}$ in., depending on the welding process and the mode of application of the hard facing alloy. On parts where several layers have to be applied, deposits may be built up to an inch or more in thickness. For these parts, care must be taken in selecting the hard facing alloy, because very highly alloyed deposits are likely to spall if applied in thicknesses of more than $\frac{1}{4}$ in. When deposits less than $\frac{1}{32}$ in. thick are required, an alternative process, such as metal spraying, is usually more efficient than any welding process.

Welder Skill. It is essential to relate the quality requirements of the deposit to both the welding process and welder skill. For example, although manual gas tungsten-arc welding can be used to obtain high-quality deposits on relatively small areas, and in grooves and recesses, and although thin layers can be deposited with dilution as low as 10%, relatively high welder skill and close control of the welding operation are necessary. In contrast, automatic submerged-arc welding requires a minimum of welder skill and results in high deposition rates, but penetration is deep, dilution is greater, and consequently it may be necessary to make use of a buffer layer or to deposit two or more layers of the hard facing alloy to obtain the full properties of the alloy.

In general, earthmoving and mining equipment can be hard faced adequately in the field by relatively unskilled welders. Selection of process is usually based on maximum deposition rate, and high dilution rates will seldom significantly affect the suitability of the coating for service. Hard facing of valves, on the other hand, requires highly skilled welders and precise control of the welding operation, and is frequently automated. Excessive dilution or contamination of the deposit can result in failure of the part during service.

Cost. Depending on their form and composition, hard facing alloys cost from about 50¢ to more than $11 per pound. Equipment and operating costs for appropriate welding processes also vary considerably. These differences are discussed in the sections dealing with specific processes and in some of the production examples.

Relating Selection Factors. At least three selection factors must be coordinated — namely, the base metal, the composition and form of the hard facing alloy, and the welding process.

Many components used in mining and quarrying machinery are large and rugged, and by following a few simple rules for hard facing, satisfactory service can be obtained. Dimensional limits are relatively broad and metallurgical quality is seldom critical. Consequently, acceptable hard facing of these components is likely to involve only the minimum number of selection factors, as in the following examples.

Examples 148 to 151. Selection of Alloy and Welding Process for Hard Facing Components of Mining and Quarrying Equipment

Example 148 — Rock-Crusher Rolls. These rolls, usually made of austenitic manganese steel, were hard faced to reduce the rate of over-all wear and to ensure an even wear pattern across the working face. Typically, a roll was surfaced with both buildup and hard facing layers.

Alloy selection for the buildup layer depended primarily on the base metal. A group 2C alloy (austenitic manganese steel) was suitable for austenitic manganese steel

rolls, and a group 1A alloy, for low-alloy steel rolls. Following buildup, a group 3 alloy was deposited, using transverse beads, two layers thick, on the area subjected to the most severe wear — the center two-thirds of the roll face. The outer portions of the roll face were surfaced with a group 2A alloy.

Hard facing was done by shielded metal-arc welding or semiautomatic open-arc welding. A typical austenitic manganese steel roll with a diameter of 36 in. and a face width of 18 in. required about 200 to 250 lb of deposited metal for buildup and hard facing.

Example 149 — Pug-Mill Knives. These knives, usually made of hardenable carbon steel, were selectively hard faced with a group 5 alloy (tungsten carbide) to resist severe abrasive wear and to maintain a sharp cutting edge. The leading face and edge of a knife were the critical locations for wear. The hard facing alloy was commonly applied by manual shielded metal-arc or oxyacetylene welding. Other knives made of cast iron were preheated to 1200 F, this temperature was held during welding, and knives were cooled slowly.

Example 150 — Traction Wheels. Wheels for mine cars, skips, cranes and other mobile equipment were hard faced to improve their wear resistance. A typical flanged wheel made of carbon steel (0.30 to 0.40% C) was hard faced with a group 1B alloy. The part was given a soaking preheat of 300 to 400 F before welding. The coating was applied by shielded metal-arc welding or by automatic submerged-arc welding, depending on the number of wheels to be processed. After hard facing, the wheels were cooled slowly to avoid cracking the overlay and to improve machinability, and they were then turned to finish dimensions.

Example 151 — Screen-Deck Sections. Cast austenitic manganese steel screen-deck sections, used in heavy-duty rock-screening equipment, were hard faced with a group 3A alloy to extend their service life. A continuous, two-pass layer was deposited, using semiautomatic open-arc welding. Hard facing normally resulted in a 75% improvement in the life of the screens.

Arc Welding Processes Used for Hard Facing

The arc welding processes capable of providing the fusion bond required in hard facing applications (listed in descending order of their use) are shielded metal-arc, submerged-arc, open-arc, gas metal-arc, gas tungsten-arc, and plasma-arc welding. Oxyacetylene welding is described in the article on Hard Facing by Oxyacetylene Welding, page 587, in this volume.

Oil-Refinery Applications. Several arc welding processes are used in hard facing components of catalytic-cracking equipment. Surfaces exposed to the action of the moving catalyst, which sometimes impinges at high velocity and at temperatures that may reach 1200 F, are subjected to severe erosion and abrasion. Hard facing of such surfaces eliminates the need to design

Table 3. Characteristics of Welding Processes Used in Hard Facing

Welding process	Mode of application	Form of hard facing alloy	Weld-metal dilution, %	Deposition, lb per hr	Minimum thickness, in.(a)	Applicable hard facing alloys
Oxyacetylene	Manual	Bare cast rod; tubular rod	1 to 10	1 to 6	1/32	All(b)
	Manual	Powder	1 to 10	1 to 15	1/32	All(b)
	Automatic	Extra-long bare cast rod; tubular wire	1 to 10	1 to 6	1/32	All(b)
Shielded metal-arc	Manual	Flux-covered cast rod; flux-covered tubular rod	15 to 25	1 to 6	1/8	All(b)
Open-arc	Semiautomatic	Alloy-cored tubular wire	15 to 25	5 to 25	1/8	Iron-base
	Automatic	Alloy-cored tubular wire	15 to 25	5 to 25	1/8	Iron-base
Gas tungsten-arc	Manual	Bare cast rod; tubular rod	10 to 20	1 to 8	3/32	All(b)
	Automatic	Various forms(c)	10 to 20	1 to 8	3/32	All(b)
Submerged-arc	Semiautomatic	Bare tubular wire	20 to 60	10 to 20	1/8	Iron-base
	Automatic, single wire	Bare tubular wire	30 to 60	10 to 25	1/8	Iron-base
	Automatic, multiwire	Bare tubular wire	15 to 25	25 to 60	3/16	Iron-base
	Automatic, series arc	Bare tubular wire	10 to 25	25 to 35	3/16	Iron-base
Plasma-arc	Automatic	Powder(d)	5 to 30	1 to 15	1/32	All(b)

(a) Recommended minimum thickness of deposit. (b) Iron-base, nickel-base, and cobalt-base alloys; tungsten carbide composites. (c) Bare tubular wire; extra-long (8-ft) bare cast rod; tungsten carbide powder with cast rod or bare tubular wire. (d) With or without tungsten carbide granules.

heavy components with large thickness allowances to compensate for erosion in service.

For hard facing high-temperature refinery equipment, iron-base alloys containing 25 to 35% Cr, 3 to 5% C, and varying amounts of manganese, nickel or molybdenum (Group 3A), and cobalt-base alloys containing 25 to 35% Cr, 0.5 to 3% C, 3 to 14% W, and 1 to 3% Mo and Ni (Group 4A), have been found to be most successful. In general, for components subjected to temperatures up to 1000 F, the high-chromium iron-base alloys are used, and the cobalt-base alloys are preferred for components that are subjected to higher service temperatures, above 1000 F.

In the fluid-catalyst type of catalytic-cracking unit, the components that are normally hard faced include slide valves in lines carrying hot catalyst and in flue-gas lines, catalyst cyclone separators, deflector baffles in vessels and orifice chambers, and the catalyst-carrying lines.

A typical slide valve is usually made of a 5% Cr, 0.5% Mo steel. Because the temperature of the catalyst-containing stream often exceeds 1000 F, a cobalt-base hard facing alloy containing about 1% C is generally used. For more severe conditions, a cobalt-base alloy containing up to 3% C is sometimes used. Use of these alloys entails some sacrifice in ease of deposition and some increase in sensitivity to cracking of the deposit. To minimize sensitivity to cracking and required thickness of the overlay material, repair of eroded areas and buildup are accomplished with type 310 or 312 stainless steel prior to depositing a final and relatively thin layer of a hard facing alloy. A stainless steel coating is also applied to other surfaces that are directly exposed to high temperature but not to the action of the flowing catalyst.

Minimum thickness of the hard facing overlay on slide valves is about ⅛ in. Deposition is by shielded metal-arc welding, and when close dimensional tolerances are specified, the deposit is finish machined or ground. By hard facing, the operating life of slide valves is extended three to ten times, depending on the severity of service.

The surfaces of a catalyst cyclone separator are selectively coated with hard facing deposits of carbon steel, 5% Cr steel, and stainless steels 410 and 304, the selection of which depends on the conditions of wear in the separator. Depending on operating temperature, alloys of group 3A or 4A are deposited manually in areas subjected to high catalyst velocities and where it is not possible to apply abrasion-resistant refractory linings. Shielded metal-arc welding is done in the flat position whenever possible, using the shingle-overlap method to minimize dilution. Deposit thickness ranges from ⅛ to ¼ in.; after deposition, the surface is ground to a thickness no greater than 1⁄16 in. The hard facing deposits are stress relieved as required. As a result of hard facing, the service life of separator components is increased two to five times.

Among the various components of fluid catalytic-cracking units, the catalyst lift pipes account for the largest volume of hard facing alloy. These pipes range from 2 to 6 ft in diameter and are generally made of carbon steel, although the hotter portions of the pipe may be made of 5% Cr, 0.5% Mo steel. Some pipes contain slight bends, and the hot catalyst, moving at a velocity of 15 ft per second, causes extensive erosion in these regions unless they are protected by hard facing. Alloys of either group 3A or 4A are used for this purpose, depending on whether the operating temperature is below or above 1000 F.

Because large areas are surfaced, semiautomatic welding processes are preferred. Open-arc welding is most widely used; submerged-arc welding is also suitable. Welding is done in the flat position, using the weave-bead technique to provide a minimum buildup thickness of ⅛ in.

When depositing a high-carbon high-chromium iron-base alloy, the welding conditions are controlled so as to produce a pattern of fine hairline cracks perpendicular to the direction of the weld and of catalyst flow. The hairline-crack pattern and the brittle nature of the deposit prevent progression of cracks into the base metal, which might cause structural failure — such failures are likely to occur when a few widely scattered cracks are produced in the coating. To minimize distortion in piping, the coating is deposited by "quartering" — that is, with each bead covering 90° of the pipe circumference after the first bead has been deposited, the pipe is turned 180°, and then alternately through 90° and 180° until the overlay is completed.

Before joining sections of hard faced pipe by welding, the edges of the pipe are beveled by machining or grinding away the hard facing deposit, so as to prevent the pipe weld from being contaminated by the facing alloy. After the

weld joint is completed, hard facing is applied to it manually. The pipe is then stress relieved at 1000 F or higher, depending on the base metal.

The components of the moving-bed type of catalytic-cracking unit that are usually hard faced include lift pipes, downcomers, lift bells, wear plates, shrouds, and plug valves. These operate at 900 to 1200 F. Air-distributor cones, which operate at temperatures up to 1500 F, are also protected by hard facing alloys. Most of these components are well suited to hard facing by automatic open-arc welding. The hard facing alloys used are the same as those used for the fluid-catalyst units.

Hard Facing by Shielded Metal-Arc Welding

The equipment used for hard facing by shielded metal-arc welding is similar to that used for welding joints by shielded metal-arc welding, which is described in the article that begins on page 1 of this volume. Speed of travel, position of the electrode relative to the puddle, arc voltage, and amperage are modified to minimize penetration and the consequent dilution of the deposit. Depending on the surface area to be faced, the bead-deposit pattern may be of the stringer or weave type, with or without staggering of beads, as dictated by service requirements. Selection of the bead pattern and sequence depends also on the accessibility of the surface to be hard faced and the distortion limits of the workpiece. The width of weave should usually be no greater than 2½ times the diameter of the electrode.

Shielded metal-arc welding is used for manual surfacing of small or complex parts, and for maintenance and field repair, where welding must be done in all positions. The principal disadvantages of the process are the low deposition rates obtained and the resultant high labor costs per pound of alloy deposited.

Shielded metal-arc welding is used for hard facing the slide valves and cyclone separators of catalytic-cracking units, as noted in the previous section.

Coke-pusher shoes, which are used in the coke ovens of steel mills, are also hard faced by shielded metal-arc welding. In service, the shoes are supported by a ram and are used to push highly abrasive, hot coke out of the ovens into hopper cars for transfer to a quenching tower. In emptying an oven, the ram travels about 40 ft, making many such trips during each shift. The sole of the shoe is subjected to severe heat and abrasion as it rides over the pulverized hot coke and the brick oven floor. Hard facing of such shoes by shielded metal-arc welding is described in the following example.

Example 152. Hard Facing Coke-Pusher Shoes by Shielded Metal-Arc Welding (Fig. 1)

The base of a coke-pusher shoe sole made of low-carbon steel plate (about 10½ in. wide and 48 in. long) was hard faced manually, using covered electrodes of one of the higher-carbon alloys of groups 3A or 3B. The shoe was positioned to permit flat-position welding, and an overlay about ¼ in. thick was applied to the working surface

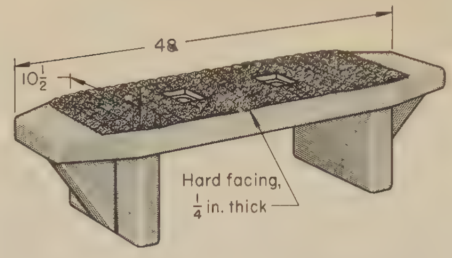

Fig. 1. Coke-pusher shoe with sole hard faced by shielded metal-arc welding (Example 152)

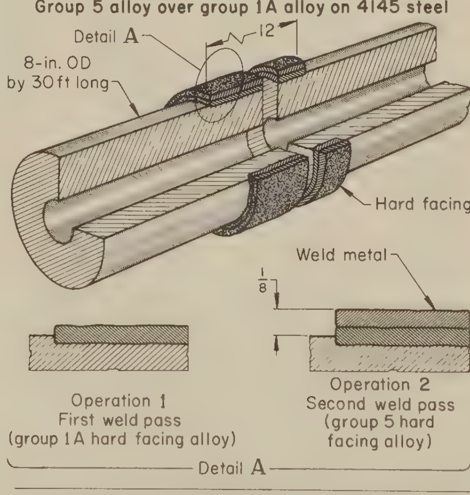
of the sole, as shown in Fig. 1. By properly slanting the shoe, the beads were stacked, so as to obtain a deposit consisting of a single thick layer with 4-in.-long beads running parallel to the direction of wear. Neither preheating nor postheating was employed. Transverse bead checking (cracking) was typical, but not detrimental. About 50 lb of hard facing alloy was required for a single shoe. The service life of pusher shoes hard faced with a group 3A or 3B alloy was 18 months, compared with a 3-month service life for shoes coated with less wear-resistant alloys.

Hard Facing by Submerged-Arc Welding

In general, the advantages of the submerged-arc process for hard facing are the same as for joint welding applications (see the article on Submerged-Arc Welding, page 46 in this volume). Weld-metal quality is consistently high, and the high current densities normally employed permit high deposition rates. Also, the high speed and deep penetration that are characteristic of the process make it



Conditions for Submerged-Arc Welding and Open-Arc Welding

Power supply	600-amp rectifier
Hard facing alloys	Group 1A; group 5(a)
Flux	Neutral, with group 1A alloy; none, with group 5 alloy
Current	400 to 450 amp
Voltage	35 v
Preheat and postheat	700 F
Travel speed	24 ipm
Surface finish	Rough, as welded
Depth of deposited metal	⅛ in. (total)

(a) First layer with group 1A alloy; second layer with group 5 alloy.

Fig. 2. Drill collar showing hard facing deposits made in two passes, using submerged-arc and open-arc welding (Example 153)

adaptable to some applications involving both buildup and facing. Other advantages include excellent appearance, improved working conditions, and more uniform quality resulting from the flux-covered arc, elimination of weld spatter, and the ease of removal of fused flux (slag) from the hard facing deposit after it cools.

Likewise, the major disadvantages of submerged-arc welding for hard facing are essentially the same as for joint welding applications. It is generally limited to hard facing of simple round or flat parts, and is not usually adaptable to field work. Also, because of the deep-penetration characteristic of submerged-arc welding, there is a high percentage of base-metal dilution (see Table 3) and a large buildup of heat in the workpiece. To obtain an undiluted surface deposit, two or three layers of hard facing alloy are sometimes needed. Also, submerged-arc welding is not readily applicable for hard facing components made of austenitic manganese steel, because the excessive heat buildup may prove detrimental and cause the alloy to become brittle.

Applications involving the use of submerged-arc welding for hard facing are discussed in the three examples that follow.

Example 153. Hard Facing of Oil-Field Drill Collars by Submerged-Arc and Open-Arc Welding (Fig. 2)

Steel drill collars, 30 ft long and 8 in. in outside diameter, and made of 4145 steel, were hard faced by submerged-arc and open-arc welding. Two layers of alloy were deposited around the collar, as shown in Fig. 2.

Before hard facing, collar surfaces were cleaned with a solvent to remove cutting fluids and rust preventives. The collar was then placed on a stand equipped with rollers and a power-driven three-jaw chuck that was capable of slowly rotating the collar during the hard facing operation. Using portable high-pressure gas burners, the collar was preheated to 700 F for a distance of 12 in. on either side of the area to be hard faced. The hard facing was done in two passes, the first by submerged-arc welding and the second by open-arc welding, using the conditions given in the table accompanying Fig. 2.

In the first pass, 9½ lb of a group 1A alloy was deposited, using a neutral flux; in the second pass, 4¾ lb of a group 5 alloy was deposited without any flux. The combined thickness of the deposits was about ⅛ in. The electrode was positioned ⅝ in. off-center, and a spiral motion of the welding head was used to obtain a stringer bead.

The unit cost of hard facing a drill collar of the above dimensions was about $54, and the cost of the welding unit was between $2000 and $2500.

Many carbon and low-alloy steel components used in such earthmoving equipment as crawler tractors, power shovels, and cranes, are rebuilt and hard faced with alloys of groups 1A and 1B.

In service, crawler tractors are ultimately rendered inoperative by deterioration of the undercarriage track system, caused by impact and excessive metal-to-metal wear. Track-system parts are not lubricated because lubricant and road sand form an abrasive slurry that accelerates wear. Track parts are operated dry until wear causes them to become loose and out-of-timing. Components are then rebuilt

by welding and hard faced, as in the following example.

Example 154. Hard Facing of Tractor Rollers and Idlers by Submerged-Arc Welding (Fig. 3)

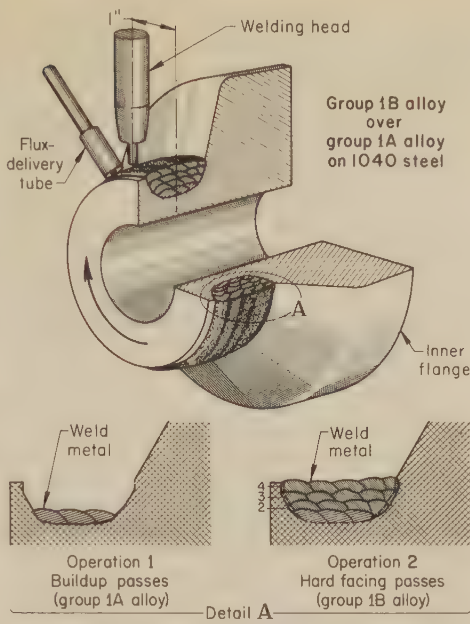
Using automatic submerged-arc welding, tractor rollers and idlers, ranging in size from 7 to 35 in. in outside diameter and from 4 to 11 in. in width, were welded with buildup and hard facing layers at travel speeds up to 70 in. per minute. A typical roller is shown in Fig. 3, and applicable processing data are given in the accompanying table.

Before hard facing, the rims and flanges were cleaned with a wire brush to remove rust and earth, and the inside of the tread area was uniformly ground. Working surfaces showing evidence of tears, thinning, or cracks were repaired by shielded metal-arc welding.

No preheating was used. Components that were worn concave were built up with a type 1A alloy, using a uniform stepover, or overlap, pattern for the beads, as shown in Fig. 3, operation 1. When the surfaces were evenly restored, three complete hard facing layers were deposited, using a group 1B alloy and the bead pattern shown in Fig. 3, operation 2. With each complete revolution, a stepover or overlap equivalent to a third to a half of the bead width was employed. The electrode was positioned off-center, in the direction opposite to that of rotation, at a distance of 3/4 to 1 in. for rollers and 1 1/4 to 1 1/2 in. for idlers. The axis of the roller was kept inclined to the horizontal at an angle of 45° to 60°, and that of the idler at 20°. Roller flanges were backed up by a copper plate, which helped to support the flux and to extract heat from the flange.

Current input for the rollers and idlers ranged from 275 to 450 amp and voltage ranged from 28 to 32 volts. Reverse-polarity direct current was used The depth of each layer was between 1/8 and 3/16 in. The number of layers used depended on the amount of wear that had taken place. Travel speed was from 25 to 45 in. per minute for rollers and from 35 to 70 in. per minute for idlers.

To minimize bore shrinkage, the mass of the parts, other than weld surfaces, was kept relatively cool by carefully restricting current (heat) input and by allowing the parts to cool after each layer. In general, the hard facing sequence for a set of rollers consisted of welding one layer on each roller in turn, starting at the outer flange and finishing at the inner flange.



Conditions for Automatic Submerged-Arc Welding

Part	Tractor roller, 5 to 11 in. in width and 7 to 11 in. in outside diameter(a)
Power supply	600-amp transformer-rectifier

Current	275 to 450 amp, dcrp
Voltage	28 to 32 v
Travel speed	25 to 45 ipm(c)
Depth of deposited metal	1/8 to 3/16 in.(d)

(a) Tractor idlers (4 to 11 in. wide and 21 to 35 in. in outside diameter) were hard faced in the same way. (b) Group 1A alloy for buildup pass and group 1B alloy for hard facing passes. (c) Travel speed for idlers was 35 to 70 ipm. (d) Each layer had the thickness indicated.

Fig. 3. Tractor roller hard faced using automatic submerged-arc welding, showing details of buildup and hard facing passes (Example 154)

Blades for shearing hot metal are often made of carbon steel (0.50 to 0.80% C) and are used in steel mills to crop, and shear to length, hot slabs, bars and billets. The blade edges are hard faced to retain their sharpness and shape, and to withstand high impact loads without spalling and to resist thermal shock. Blade sizes vary over a wide range, depending on the sizes of stock to be sheared. Examples 164, 165 and 166 describe the hard facing of alloy tool steel shear blades with other tool steels, by various welding processes. The example that follows deals with hard facing a shear blade made of a medium-carbon steel with a group 2A, 2B or 4A alloy by submerged-arc welding.

Example 155. Blades for Hot Shearing (Fig. 4)

A shear blade, 48 by 12 by 8 in. with hard faced cutting edges, is shown in Fig. 4. Before hard facing, the cutting edges of the blade were machined to form suitable stepped recesses, as shown in Fig. 4. Blades were then preheated to 400 to 500 F. Using submerged-arc welding and a 1/8-in.-diam electrode wire, weld metal was deposited on each cutting edge in multiple layers, providing sufficient allowance for final machining or grinding to square corners. Immediately after hard facing, the blades were covered with an asbestos blanket to ensure a slow rate of cooling.

Depending on the service requirements, several types of hard facing alloys were employed, including modified stainless steels, alloys of groups 2A and 2B, and cobalt-base alloys of group 4A. Smaller blades and those requiring cobalt-base alloys (which are not available in wire form) were faced by shielded metal-arc or oxyacetylene welding. Automatic submerged-arc welding was preferred for larger blades because of its high deposition rate and more uniform weld deposit.

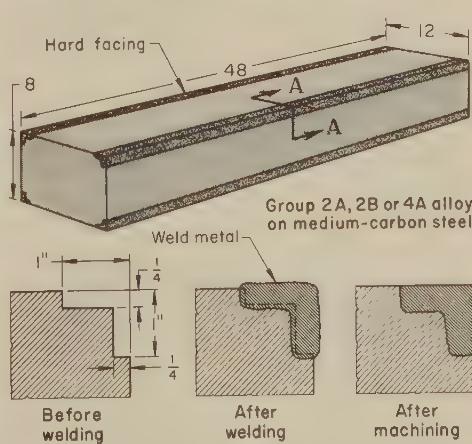

Fig. 4. Typical hot shear blade with hard faced cutting edges, and sectional views of cutting edges before and after welding, and after machining (Example 155)

Surfacing with corrosion-resistant alloys by submerged-arc welding is described in Examples 62, 63 and 64 in the article on Submerged-Arc Welding, which begins on page 46.

Hard Facing by Open-Arc Welding

Open-arc welding is a semiautomatic consumable-electrode process that does not employ either a flux or a shielding gas. It is used to a considerable extent for hard facing (see Examples 148, 151 and 153). The electrode wire, which is fed continuously, is tubular, with alloying elements in the core as powder or granules. These wires contain deoxidizers, but no flux.

A principal advantage of open-arc welding is the low cost of the equipment. Neither flux-handling equipment nor gas-regulating apparatus is required. Thus, it is the simplest semiautomatic welding process, requiring only one accessory — a device to feed the continuous electrode wire. The electrode holder is similar to the electrode holder used for flux-cored arc welding by the self-shielding method.

Open-arc welding produces more weld spatter than the other arc welding processes, but this spatter is rarely objectionable in hard facing applications.

Hard Facing by Gas Metal-Arc Welding

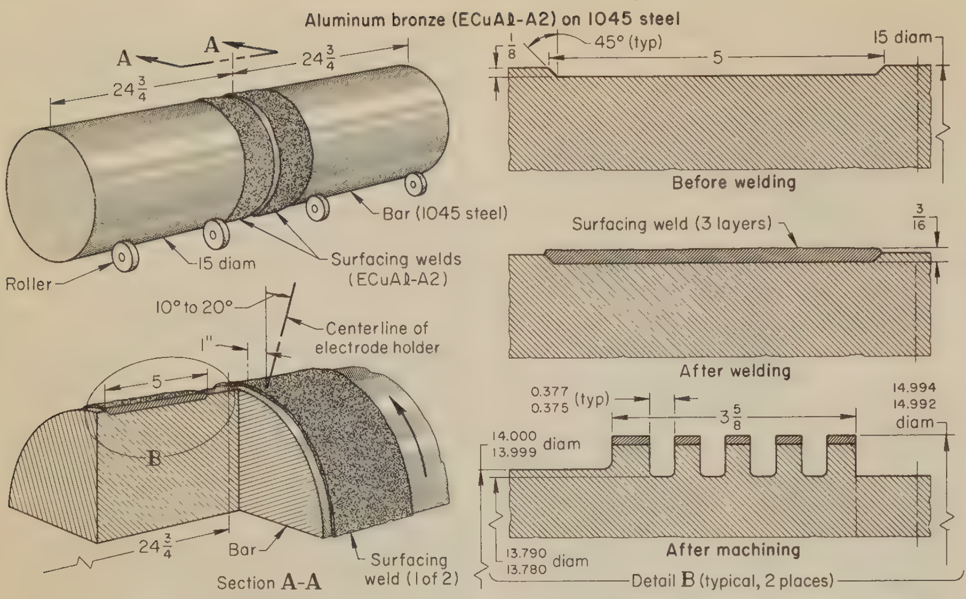
In hard facing by gas metal-arc welding, the arc and weld areas are protected by a flow of shielding gas — carbon dioxide, argon or helium, either singly or in combination, or with a small amount of oxygen. A detailed description of the process is provided in the article on Gas Metal-Arc Welding, which begins on page 78 in this volume.

The use of shielding gases adds to the cost of hard facing, but the higher cost can be justified when the shielding gases prevent weld-metal oxidation and alloy loss and provide required weld quality. Wire electrodes must be used with this process, however, and since some of the hard alloys are not available in wire form, this limits the use of gas metal-arc welding for hard facing.

The application of this process to surfacing steel with bronze and other corrosion-resistant metals is described in Examples 91 to 94 in the article on Gas Metal-Arc Welding, in this volume. The example that follows describes surfacing of a medium-carbon steel piston with a wear-resistant aluminum bronze (see also Example 159).

Example 156. Choice of Gas Metal-Arc Welding Over Alternative Processes for Quality and Speed in Surfacing a Piston With Aluminum Bronze (Fig. 5)

Lands between the piston-ring grooves in heavy-duty hydraulic pistons were surfaced with aluminum bronze to make a bearing surface for sliding contact with the



Conditions for Surfacing by Gas Metal-Arc Welding

Power supply	500-amp rectifier(a)	Number of layers	Three
Electrode wire	1/16-in.-diam ECuAl-A2	Weight of filler metal deposited per piece(b)	20 lb
Current	260 to 280 amp, dcrp	Deposition rate	0.0833 lb per min(c)
Voltage	24 to 27 v	Welding time per piece(b)	4 hr(c)
Shielding gas	Argon, at 45 cfh	Preheat	400 to 450 F for 3 hr
Work-rotation speed	14 to 16 surface in. per min	Postheat	400 to 450 F; cover, cool slowly

(a) Three-phase, constant-voltage type. (b) Two pistons. (c) In surfacing by shielded metal-arc welding, time per piece (two pistons) had been 12 hr (deposition, 0.027 lb per min); by gas tungsten-arc welding, 14 hr (0.0238 lb per min).

Fig. 5. Surfacing of two heavy-duty pistons head-to-head in a single length of bar, to obtain wear-resistant lands after machining. For this application, gas metal-arc welding was considerably faster than two processes previously used. (Example 156)

cylinder walls. As shown in Fig. 5, the pistons were made in pairs from a 15-in.-diam solid bar of 1045 steel, and were positioned head-to-head in the bar with an allowance of 2 in. between them for machining. Before the pistons were cut apart, a 5-in. span at the head of each cylinder was undercut ⅛ in. to accommodate the surfacing weld; then the pair of pistons was surfaced as a single unit before being cut apart and finish machined (see detail B in Fig. 5).

At first, shielded metal-arc welding with covered aluminum bronze electrodes was tried, but it produced an extremely porous surface weld containing many inclusions and voids, which necessitated a great deal of repair welding. The time required for making the surfacing welds on one pair of pistons was 12 hr.

When the method was changed to semiautomatic gas tungsten-arc welding, surface condition was good, and repair welding was considerably reduced. However, more welding time was needed (14 hr per pair of pistons) than with the shielded metal-arc process, and cost was excessive.

To reduce cost and production time, automatic gas metal-arc welding was tried. With this method, surfacing time was reduced to 4 hr per pair of pistons, and the quality of the deposit was acceptable.

For gas metal-arc surfacing, the piston blank was placed on rollers that turned it at a surface speed of 14 to 16 in. per minute. Equipment was provided to cause the electrode (positioned as shown in section A-A in Fig. 5) to step over approximately 5/32 to 3/16 in. with every revolution of the blank. This stepover produced an overlap slightly more than 50% of the width of the weld bead.

Details of the procedure using gas metal-arc welding are summarized in the table appearing with Fig. 5.

Hard Facing by Gas Tungsten-Arc Welding

Gas tungsten-arc welding (described in detail in the article that begins on page 113) offers several advantages in hard facing. Either the torch can be used manually or the process can be automated by attaching the torch to an oscillating mechanism and using a device to feed the hard facing filler metal into the arc region. By controlling the wire feed, width of oscillation, and travel speed, a closely controlled deposit can be obtained. The arc action is smooth, quiet and free of weld spatter, and produces high-quality hard facing deposits. The weld puddle can be controlled to permit out-of-position overlay applications. Hard facing alloys can be used in either rod or wire form.

There are some disadvantages to gas tungsten-arc welding for hard facing. A dilution of at least 10% is almost unavoidable. The argon or helium gas shield, which is relatively expensive, must be protected from air drafts to ensure its effectiveness. Deposition is so slow that the use of gas tungsten-arc welding for hard facing is limited to minor repairs and small parts.

The following example compares manual and automatic methods for hard facing by gas tungsten-arc welding.

Example 157. Manual vs Automatic Gas Tungsten-Arc Welding for Hard Facing of Valve Gates (Fig. 6)

Valve gates made of 4140 steel forgings, with typical dimensions and characteristic patterns of hard facing deposits developed by manual and automatic gas tungsten-arc welding, are shown in Fig 6. Both methods employed a 500-amp rectifier as power supply and a 3/16-in.-diam group 4A cobalt-base alloy rod (1.09% C, 26.25% Cr, 7.01% Fe, 4.22% W) for the overlay. A 300-amp torch was used with the manual method, and a 500-amp torch with the automatic method. Preparation of the workpiece (cleaning and machining the surfaces to be hard faced) was identical for both methods; no preheat was used in either method. The major differences between the methods were in the tooling and the weld patterns of the deposits. The manual method, without special tooling, deposited a coating to cover the entire front surface of the plate (see Fig. 6, Manual method). By using a variable-speed rotating table, an oscillating mechanism for the torch, and a cold-wire feeding mechanism for the alloy rod, the automatic method provided selective deposition on the surfaces, as shown in Fig. 6, Automatic welding. Thickness of deposit was about ⅛ in. After hard facing, the valve gates were stress relieved at 1150 F.

The following comparative data for the two methods were obtained:

Item	Manual	Automatic
Hard facing time:		
Pressure end, min	33.4	5.72
Fluid end, min	29.4	5.72
Total arc time, min	62.8	11.44
Deposition rate, lb per hour	1.84	2.75
Area hard faced, sq in.	23.4	18.4
Hard facing alloy consumed, lb	1.93	0.525

The automatic technique was faster and more economical, requiring less hard facing alloy than the manual method. It also resulted in fewer weld defects.

Prevention of Surface Cracks. Some of the most effective abrasion-resistant alloy coatings are susceptible to cracking, which can be aggravated by thermal gradients developed during welding and by marked differences in the thermal expansion-contraction characteristics of the base metal and the overlay. The most common measure employed to avert surface cracking is preheating the work. Another effective method is the application of a less crack-susceptible buttering layer, as described in the following example.

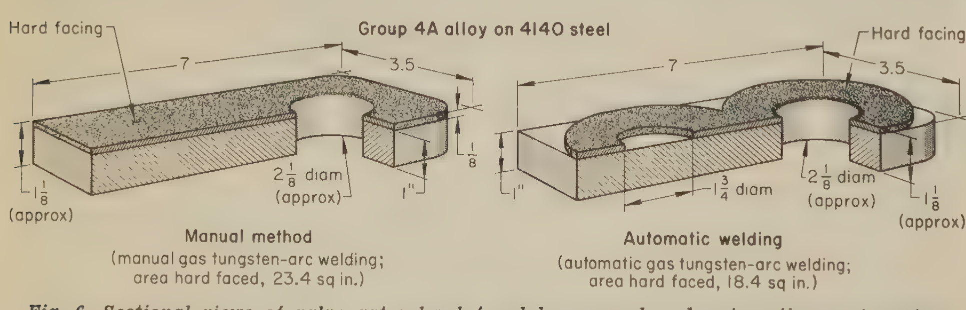


Fig. 6. Sectional views of valve gates hard faced by manual and automatic gas tungsten-arc welding. Because of selective deposition when using the automatic method, a smaller quantity of hard facing alloy was consumed. (Example 157)

Example 158. Use of a Buttering Pass To Prevent Cracking of a Brittle Overlay on Tool Fixtures (Fig. 7)

Tool fixtures used to finish bore connecting-rod assemblies were produced from blanks 5⅝ in. in outside diameter and 1 in. thick, of 3120 steel. After preliminary machining of the blank, a cobalt-base hard facing alloy of group 4A (nominal composition: 2.5% C, 30% Cr, 12% W) was deposited to obtain two raised-face areas, as shown in Fig. 7. The surfacing was done by manual gas tungsten-arc welding, using argon gas to shield the weld area; good deposition control was needed to ensure that the overlay was limited to the specified areas. After hard facing, the tool fixture was heat treated to Rockwell C 45 to 50; the two raised areas were subsequently surface ground to size.

Selection of the group 4A hard facing alloy was based on hardness (Rockwell C 54) and resistance to metal-to-metal wear (especially to galling), but because of brittleness of the deposited layer, about 85% of the welds cracked, resulting in frequent rejections and the need for weld repairs. Investigation revealed that cracking could be overcome by depositing an initial layer of a softer and tougher group 4A cobalt-base alloy (1.10% C, 28% Cr, 4% W). This alloy had a hardness of Rockwell C 44, a tensile strength of 105,000 psi, and good resistance to impact and thermal shock. As a result of this modification, rejections for cracking of the final hard facing deposit were reduced to 1% of the total number of welds made.

The procedure for making the initial pass consisted first in machining a 1⁄16-in.-deep recess at the inner circular edge of the tool fixture (Fig. 7, Before welding). This recess was then filled with the more ductile group 4A filler metal. The final pass was made with the harder group 4A filler metal, covering the areas shown in Fig. 7, After welding. The completed two-layer deposit was machined and ground to the dimensions shown in Fig. 7, After machining. The welding conditions for both passes are given in the table accompanying Fig. 7.

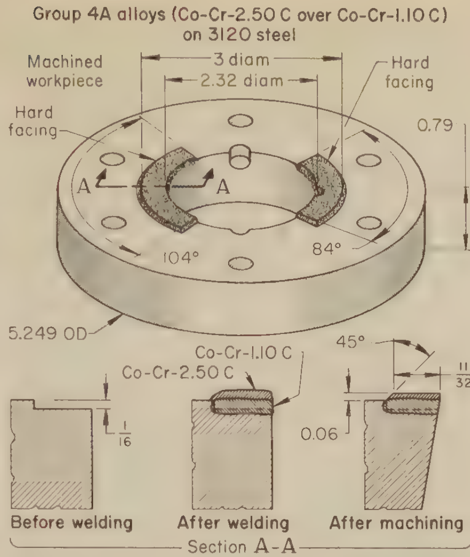
Effect of Overlay Composition on Wear Resistance. Because of the large variation in service conditions, predicting the performance of a given alloy is difficult, especially if experience under similar conditions is not available. A seemingly small change in the alloy used for hard facing, or the method, or both, may have a large effect on results. One such application is described in the example that follows.

Example 159. Change of Surfacing Alloy and Method of Welding To Prolong the Life of Pot Plungers (Fig. 8)

Pot plungers (pistons) like the one shown in Fig. 8 were used in hydraulic presses, for injection molding of rubber compounds in and around metal parts. The low-carbon steel plungers operated in heat treated 4140 steel pots with a clearance of 0.001 in.

Originally, the bearing surfaces of the plungers were overlaid with a low-fuming brass (such as RCuZn-E) to prevent galling and seizing of the plunger in the pot. Oxyacetylene welding was used for surfacing with this alloy. Because of the abrasiveness of the rubber compounds, the maximum service life of the plungers was 30 days, which was not acceptable.

Service life was extended to 24 to 36 months by changing the facing alloy to a hard, wear-resistant aluminum bronze (RCuAl-D), deposited by gas tungsten-arc welding. Oxyacetylene welding was not suitable for use with aluminum bronze, because the aluminum oxides that formed in the oxyacetylene flame rendered the use of conventional fluxes difficult and interfered with smooth metal deposition. Gas tungsten-arc welding required no flux and the argon shielding provided adequate protection against contamination.

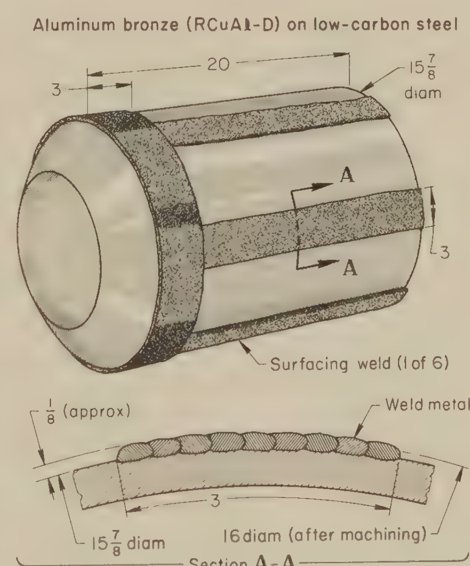


Conditions for Manual Gas Tungsten-Arc Welding

Power supply	300-amp transformer-rectifier, with high-frequency, foot-operated control
Electrode	1⁄16-in.-diam EWTh-2
Hard facing alloy	⅛-in.-diam group 4A(a)
Torch	200 amp, water cooled; with gas lens
Shielding gas	Argon, at 24 to 26 cfh
Welding position	Flat
Welding fixtures	None
Current	110 to 120 amp, dcsp
Arc starting	High frequency

(a) Alloy with 1.10% C for buttering pass; alloy with 2.5% C for surface pass.

Fig. 7. Tool fixture for finish boring of connecting rods, showing two areas built up by hard facing, using gas tungsten-arc welding (Example 158)



Conditions for Hard Facing by Gas Tungsten-Arc Welding

Welding position	Flat
Power supply	500-amp transformer-rectifier
Current	250 to 400 amp, dcsp
Voltage	Not regulated
Torch	500 amp, water cooled; ½-in.-diam cup
Electrode	5⁄32-in.-diam EWTh-2, taper ground
Filler metal	3⁄16-in.-diam RCuAl-D
Shielding gas	Argon, at 15 to 20 cfh
Welding speed	8 ipm

Fig. 8. Pot plunger surfaced in specific areas with aluminum bronze by gas tungsten-arc welding (Example 159)

Before surfacing, the outside of the steel plunger was sand blasted and cleaned with a wire brush. Preheating was not required. Weld beads, about ⅜ in. wide and ⅛ in. deep, were deposited longitudinally in a parallel, overlapping sequence, around the bearing-surface area, to form a band 3 in. wide. A second series of beads of the same size was deposited (in the same direction) to form six uniformly spaced bands, 3 in. wide, running lengthwise along the surface of the plunger. Welding was done in the flat position, and because of the rapid dissipation of heat by the mass of the plunger body, the surfacing operation was continuous. The aluminum bronze rods were 3⁄16 in. in diameter and 36 in. long. Electrodes were pointed, thoriated tungsten rods, and were 5⁄32 in. in diameter.

After surfacing was completed, the overlay was machined to a thickness of 1⁄16 in. A machining tolerance of 0.0005 in. was provided on the finished diameter, because specifications required the clearance between the plunger and pot to be 0.001 in. After machining, two longitudinal grooves ⅛ in. wide and 1⁄16 in. deep were cut in the overlay at the bearing surface to relieve air pressure and backflow of the rubber compound during plunging. Additional welding details are presented in the table that is included with Fig. 8.

Hard Facing by Plasma-Arc Welding

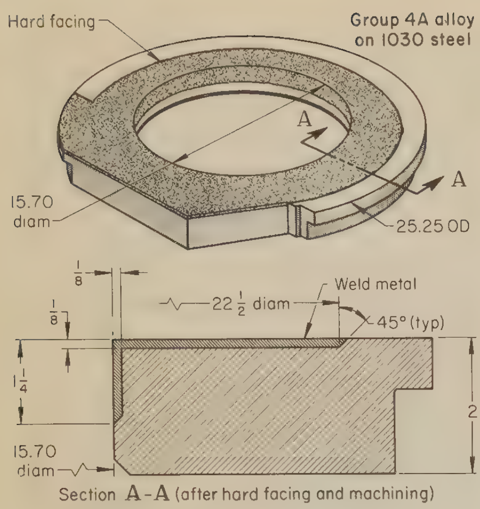
In hard facing by plasma-arc welding, the filler metal, in powder form, along with the plasma jet, is forced through a constricting orifice and accelerated to sonic velocity with intense heat (30,000 F) to form a bond with the base metal. A conventional direct-current power supply, connected in straight polarity, is used to maintain the arc and control the amount of heat input to the work. Plasma-arc welding as a joining process is discussed in detail in the article that begins on page 138 in this volume.

Plasma-arc welding enables high-density coatings of virtually any material or compound to be applied, provided that the material can be supplied in the appropriate particle-size range (−200 to +325 mesh), preferably in spheroidal form, and that it will conduct electricity, and will not undergo sublimation.

Among the advantages of plasma-arc hard facing is the ability of the process to limit penetration into the base metal to as little as 0.005 in., and to control base-metal dilution between 5 and 30%. Single-pass deposits between 0.010 and ¼ in. in thickness and ⅛ to 1¼ in. in width can be closely controlled. Greater widths can be developed. Speeds of more than 20 in. per minute are obtainable with 95% deposition efficiency. A wide selection of alloy powders is available for hard facing, and deposits are generally flatter and smoother than those produced by other arc welding processes, features that can reduce material and finishing costs.

Disadvantages of plasma-arc welding for hard facing are the high cost of equipment, the skill and knowledge required of the welding operator, and the need to bring the workpiece to the machine.

The successful use of plasma-arc welding in hard facing a component used in a rubber-compounding machine is described in the following example.



Conditions for Hard Facing by Plasma-Arc Welding

Power supply	600-amp rectifier
Hard facing alloy	Group 4A(a)
Argon flow	To arc, 8 cfh; with powder, 10 cfh; for shielding, 45 cfh
Preheat and postheat	None
Surface finish	Ground
Travel speed	3 ipm
Depth of deposited metal	3/16 in. (two 3/32-in. layers)
Width of deposited metal	3/4 in.

(a) Cobalt-base alloy with 2.5% C, 30% Cr, 12% W. Other high-carbon group 4A alloys were also satisfactory.

Fig. 9. Banbury-mixer rotor end plate that was hard faced more economically by plasma-arc welding than by shielded metal-arc welding (Example 160)

Example 160. Plasma-Arc Facing of Rotor End Plates for Banbury Mixers (Fig. 9)

Rotor end plates of Banbury mixers, used for compounding rubber, are subjected to severe abrasive wear during service. To improve their resistance to abrasion, rotor end plates (Fig. 9) made of 1030 steel were traditionally either chromium plated, carburized, or hard faced. For hard facing, shielded metal-arc welding was used until it was established that plasma-arc welding was more economical and about three times as fast.

The circular parts to be hard faced were set on a welding positioner equipped with a speed reducer capable of producing speeds down to one revolution in 30 min. The parts were positioned so that the welding head could progress linearly across the surface to be coated. The plasma-arc welding machine was equipped with power feed and a head-traversing mechanism; power was supplied from a 600-amp rectifier. With the torch 5/8 in. from the workpiece, a weaving pass was employed to produce a deposit 3/4 in. wide. The welding head had a period of oscillation of 3 sec, and an amplitude of 1 in. Linear deposition rate was 3 in. per minute. Argon gas was used to maintain the arc, feed the alloy powder, as well as to shield the arc.

A group 4A cobalt-base alloy powder (2.5% C, 30% Cr, 12% W) was fed at a rate of 33 grams per minute. Two layers, each with a deposit thickness of 3/32 in., were made. No preheating or postheating was required. After completion of the second layer, the deposits were ground to finished size. Additional details for hard facing by plasma-arc welding are given in the table accompanying Fig. 9.

Compared with shielded metal-arc welding, plasma-arc welding resulted in a large reduction in processing time and a saving in metal because there were no unused electrode ends. The use of a process that did not involve the need for a flux was also advantageous.

In the following example, plasma-arc hard facing competed successfully with hard facing by gas welding.

Example 161. Oxyacetylene vs Plasma-Arc Welding for Hard Facing of Valve Seats (Fig. 10)

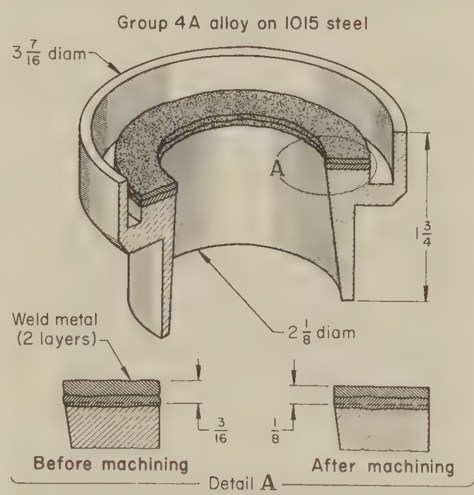
For purposes of comparison, oxyacetylene and plasma-arc welding were used for the hard facing of valve seats made of 1015 steel tubing and used in high-pressure steam-flow boiler-cleaning equipment. A sectional view of a typical valve seat, with dimensions, is shown in Fig. 10.

For oxyacetylene welding, the workpiece was first preheated to between 800 and 1350 F, and then a group 4A cobalt-base alloy (1.10% C, 28.0% Cr, 4.0% W) was deposited, using a 1/8-in. filler rod. Three layers were required to develop a deposit 1/4 in. thick. Total welding time per piece was 20 min. The operation was entirely manual and required the minimum of equipment. Other processing details are given in the table accompanying Fig. 10.

Plasma-arc hard facing, which was installed to replace the oxyacetylene process, was completely automatic and required only two layers. Elapsed time was 2 min, 24 sec to deposit a coating 3/16 in. thick. Major equipment was: a sequence programer, a 75-amp ac oscillator for the nontransferred arc, a 500-amp rectifier for the transferred arc, slope and timing controls, automatic power feed, guidance fixtures and positioners, gas shielding fixtures, and a plasma-arc torch.

The sequence of operations began with the cleaning of the part to remove rust, grease, and other soils that might cause porosity. The part was then placed in a holding and rotating fixture, and the plasma torch was set in position. No preheating was required. The entire hard facing sequence was controlled by the sequence programer. Welding was done in the flat position, using an arc length of 3/8 in. and a transferred-arc power setting of 79 amp. A cobalt-base alloy of group 4A (1.60% C, 28% Cr, 3% Ni, 4% W) in powder form was used for hard facing. Two layers, each 3/32 in. thick, were deposited (see Fig. 10); the interpass temperature was 500 F. Postheating was not required. After removal from the fixture, the hard faced surfaces were ground to finished dimensions, as shown in Fig. 10. Surface finish was 32 micro-in. Dye-penetrant inspection was employed to detect cracks and other surface defects.

The plasma-arc welding method reduced welding time by 87%, material cost by 10%, and weld repair work by 95%, compared with oxyacetylene welding.



Item	Oxyacetylene welding(a)	Plasma-arc welding(b)
Hard facing alloy	4A(c)	4A(d)
Preheat	800 to 1350 F	None
Postheat	None(e)	None
Number of layers	Three	Two
Weld time	20 min	2 min, 24 sec
Surface finish	Ground	Ground
Depth of deposit	1/4 in.	3/16 in.

(a) Fuel-gas flow: acetylene, 4 to 6 psi; oxygen, 7 to 9 psi. (b) Power supply: for nontransferred arc, 75-amp ac oscillator; for transferred arc, 500-amp dc rectifier. Argon flow: to arc, 9 to 11 cfh; with powder, 14 to 15 cfh; for shielding, 43 to 47 cfh. (c) Cobalt-base alloy with 1.10% C, 28% Cr, 4% W. (d) Cobalt-base alloy with 1.60% C, 28% Cr, 3% Ni, 4% W. (e) The hard faced stainless steel valve seats were cooled slowly in asbestos.

Fig. 10. Valve seat with hard facing layer deposited by plasma-arc welding (Example 161)

Comparison of Welding Processes

In rotary oil-well drilling, there is considerable abrasive wear on the shoulder areas of the joint used to connect sections of drill pipe, as the pipe rotates and moves up and down in the hole. The replacement costs for the tool joint justify the expense of hard facing, particularly when abrasive rock formations are being drilled. In directional drilling, especially in offshore operations, drilling is done through a casing. When a hard facing layer consists of fine particles of tungsten carbide embedded in a matrix of low-carbon steel, the deposits on the joints are less abrasive to the casing and yet retain high wear resistance.

A comparison was made of four welding processes used in hard facing of drill joints with this carbide-steel composite: manual oxyacetylene, automatic gas metal-arc, gas tungsten-arc, and plasma-arc welding. The working details of each process, and the relevant advantages of the three arc welding processes over oxyacetylene welding for this application, are discussed in the example that follows.

Example 162. Comparison of Four Welding Processes for Hard Facing of Tool Joints (Fig. 11; Table 4)

The design of a typical tool joint for rotary oil-well drilling is shown in Fig. 11. Joints varied in size as follows (see Fig. 11 for location of dimensions).

Size, in.	2 7/8	3 1/2	4 1/2	5
Weight, lb	34	41	74	122
Length, in.	14	16	17	17
Dimension D_1, in.	3	3 5/8	4 5/8	5 1/4
Dimension d, in.	1 7/8	2 7/16	3 1/4	3 3/4
Dimension D_2, in.	4 1/2	4 3/4	6	6 1/4

Tool joints were made of 4137H steel, oil quenched and tempered to 311 to 341 Bhn. The deposition of a wear-resistant coating of tungsten carbide particles in a matrix of low-carbon steel onto the tool joint by each of the four welding processes is discussed below.

Oxyacetylene Welding. The tool joint was first positioned on a turning mechanism actuated by a foot pedal, with the axis of the joint horizontal, the threaded end toward the welder. The part was cleaned and preheated to 400 to 600 F, using an indicating crayon to check the temperature.

By shielded metal-arc welding, stringer beads intended to serve as guide ribs for hard facing were deposited circumferentially along the area to be hard faced. The ribs were about 1/16 in. high and were spaced about 7/8 in. apart. They were interrupted every 120° by a gap of about 1/2 in.; the interruptions in successive ribs were staggered. Where previous hard facing was still visible, new ribs were deposited directly on the old ones.

After depositing the guide ribs, flux and weld spatter were removed from the surface. Hard facing alloy was deposited man-

ually, starting in the groove nearest the threaded end. Deposition continued in the direction of the tapered elevator shoulder, ending in a blend at the shoulder. The backhand technique was used, and a slight excess of acetylene. The depth of tungsten carbide deposited was approximately 1⁄16 in. Every effort was made to obtain a good bond with minimum puddling. The base-metal temperature, measured at a distance of 4 in. from the tool-joint shoulder, was not permitted to exceed 700 F. After hard facing, the joint was cooled in still air.

Gas Metal-Arc Welding. The tool joint was grooved as shown in detail A of Fig. 11, and preheated to 600 to 800 F. It was positioned so that the 18° tapered shoulder was horizontal, and the positions of the electrode holder and carbide feed were approximately as shown in Fig. 11, angle *a* and distances *m* and *w* being determined by trial and error. First, hard facing was applied to the tapered elevator shoulder, tungsten carbide being fed into the molten hard facing puddle immediately behind the arc. The part was then repositioned so that its centerline was horizontal. The filler metal and tungsten carbide were deposited, smoothly overlapping the initial deposit at the shoulder. The welding head was then indexed automatically so that each successive bead overlapped the preceding bead by about 1⁄8 in. After hard facing, the tool joint was cooled in air.

Gas Tungsten-Arc Welding. The procedure for gas tungsten-arc hard facing, including the location of the torch and carbide feed nozzle, was similar to that used for gas metal-arc welding except that the outside of the tool joint was not grooved for hard facing and the tungsten carbide was introduced differently. The surface of the base metal was brought to fusion temperature by the heat of the arc, and the tungsten carbide particles were fed onto the molten surface. As the weld metal solidified, a coating of carbide particles dispersed in a matrix of the base metal was obtained.

Plasma-Arc Welding. The plasma-arc process was an automatic operation similar to the gas metal-arc process, except that a plasma-arc torch was employed and iron powder was substituted for the 1⁄16-in.-diam consumable electrode wire.

Comparison. Details of welding conditions and cost data for the four processes are given in Table 4. A comparison of the three arc welding methods with oxyacetylene welding led to the following conclusions:

1 The arc welding processes could be readily automated, and hence were three to five times faster than oxyacetylene welding.
2 Equipment cost for automatic arc welding was much higher than for oxyacetylene welding. Initial investment in equipment for plasma-arc welding was about twice that for gas tungsten-arc or gas metal-arc welding and ten times that for oxyacetylene welding.
3 Labor cost (indicated by hard facing time in Table 4) was much higher for manual oxyacetylene welding than for automatic arc welding

Hard Facing of Austenitic Manganese Steel

Austenitic manganese steel (Hadfield's steel) is a tough, wear-resistant, nonmagnetic alloy usually containing 1.0 to 1.4% C and 10 to 14% Mn; it is available in cast and wrought forms. The high manganese content has an austenite-stabilizing effect; the usual hardening transformation is suppressed, and the austenite is completely retained when the steel is cooled rapidly from a high temperature to room temperature. The as-quenched steel is in a metastable condition, and, on moderate reheating, instead of the usual softening and increase in ductility, manganese steel becomes embrittled by partial transformation of the metastable austenite. Consequently, the welding and hard facing of manganese steel require techniques that will result in a minimum heat buildup.

Before hard facing, the surface of the manganese steel base metal should be clean, sound, and in the non-work-hardened condition. Grinding or air carbon-arc cutting can be used to remove work-hardened metal. Cracks and

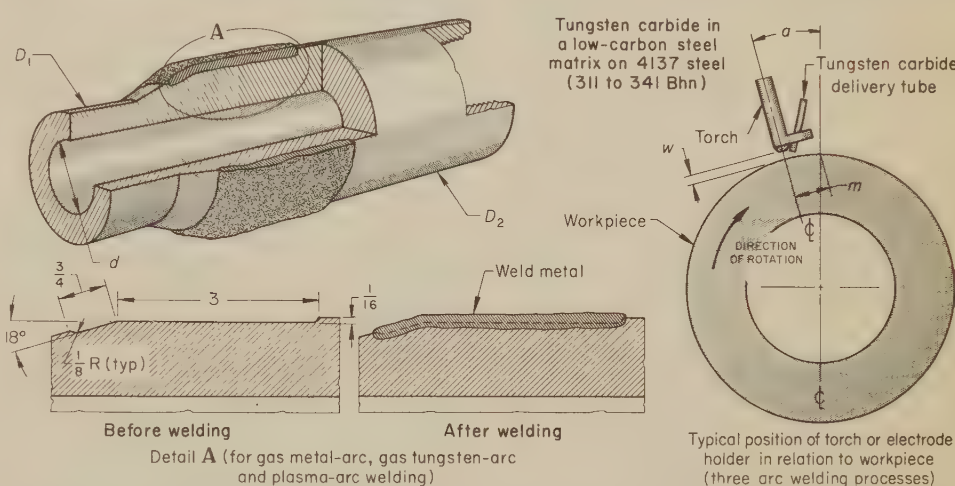


Fig. 11. Tool joint for oil-well drilling, showing the area that was hard faced, and sections through the weld groove before and after welding. Positions of torch or electrode holder and carbide feed tube are shown at the right. Values of a, m and w were determined by trial and error. See Table 4 for a comparison of data for four welding processes. (Example 162)

(a) Shielded metal-arc welding was used to deposit strings of beads that served as guide ribs for hard facing. Power for shielded metal-arc welding was supplied by a 200-amp unit; electrodes were 3⁄32 to 1⁄8-in.-diam E6010 or E6012. (b) 40% binder; remainder filler. (c) Includes argon for powder, shielding gas and orifice flow. (d) Iron powder flow, 100 grams/min. (e) Gas burner, furnace, or induction coil. (f) Induction coil.

other defects should be repaired by welding, using electrodes of austenitic manganese steel or related austenitic alloys. Except in extremely cold weather, manganese steel should not be preheated, and never above 200 F. The welding current and time must be adjusted to avoid overheating. Heat buildup can be minimized by skip welding — welding alternately on several parts — or by using an auxiliary cooling arrangement for the part.

Only arc welding is recommended for hard facing manganese steel components. Oxyacetylene welding is likely to be harmful, because of the relatively long period of heating involved. Arc length should be kept short and current input relatively low, so as to ensure arc stability and complete fusion bonding, while minimizing heat accumulation in the part.

Most covered electrodes for welding austenitic manganese steel can be used with the common power supplies (motor-generators, rectifiers and transformers). Most continuous wire electrodes for semiautomatic or automatic welding are used with direct current only. Small-diameter manual welding electrodes commonly have deposition rates of less than 2 lb per hour. At higher welding currents, and with the use of large-diameter heavily coated electrodes, deposition rates of 8 to 10 lb per hour can be obtained. Continuous-wire electrodes can deposit at rates as high as 15 lb per hour, and even higher.

When hard facing with high-chromium irons and other brittle wear-resistant alloys, checking of weld beads is normal and usually beneficial. These checks (small cracks across the bead) are superficial and do not penetrate into the tougher manganese steel base metal. On large parts, a regular check pattern helps to prevent stress buildup, which otherwise might cause failure of the part during service. Brittle facing materials are not applied in thicknesses of more than two or three layers.

To illustrate the hard facing of austenitic manganese steel, several applications involving mining-equipment components are described in the following paragraphs.

Dragline buckets are subjected to severe abrasive wear over most of their surface area during service. In handling hot slag, wear is accelerated by the abrasive action of the slag at elevated temperatures. To combat wear, buckets are commonly hard faced with semi-austenitic and austenitic high-chromium irons, notably the higher-carbon irons of groups 2A, 2B and 3A. Before hard facing, austenitic manganese steels of group 2C, or variations of these steels, are used to build up worn surfaces. In some areas of the buckets, the less-expensive group 1A alloys can be used for buildup.

A typical dragline bucket, after hard facing, is shown in Fig. 12. Note that the areas subjected to the most severe wear are protected by wear plates, which are welded to the bucket and then hard faced. These "heel" areas and the inside surfaces of the bucket are normally coated with a higher-alloy material, to provide maximum wear resistance. Other surfaces are

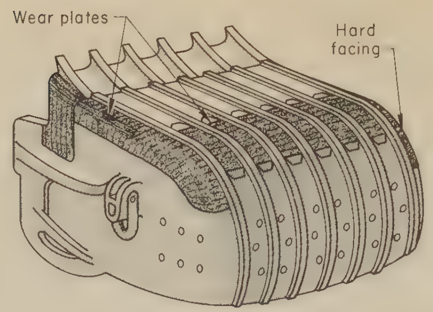

Fig. 12. Dragline bucket, showing hard facing on teeth, lips, wear plates, and other areas subject to wear

faced with a semiaustenitic material, which provides good abrasion resistance at moderate cost. Dragline buckets are frequently hard faced in the field, using shielded metal-arc welding or open-arc welding.

Before hard facing, badly worn bucket lips are built up with manganese steel to provide strength and support for the overlay. The lips and teeth are then hard faced only on the top with a solid layer of semiaustenitic alloy or a high-chromium alloy, depending on the severity of the wear encountered. Teeth and lips are self-sharpening when they are hard faced on the top only. When both top and bottom are hard faced, the teeth and lips become blunt. Most other external and internal surfaces are protected by stringer beads, spaced about ½ in. apart or arranged in suitable patterns.

Common stringer-bead patterns include line, crosshatch, herringbone, and waffle designs. The pattern most effective for a given application is determined by trial. During operation of the dragline bucket, pockets of abrasive material that collect between the facing beads add to the wear resistance of the part. Accordingly, where the operation entails working with loose abrasive material, parallel stringer beads are usually, but not always, laid perpendicular to the flow of material. For example, when rock is being worked, common practice is to use line stringers of hard facing placed parallel to the flow of the rock. Line stringers act as rails and assist the rock flow. Beads that are perpendicular to rock flow cause bumping. For sand, however, perpendicular beads are better. When both sand and rock are being worked, a diagonal crosshatch bead pattern is used. A judicious choice of stringer-bead pattern will help to conserve hard facing material and to minimize welding time; it will also minimize heat

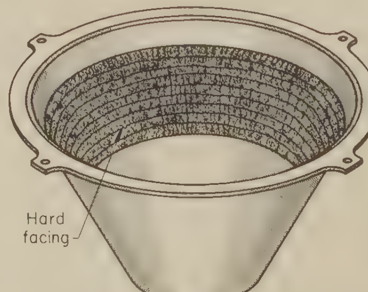

Fig. 13. Gyratory crusher liner with hard facing in the interior

input and help to hold down the overall weight of the part.

By the use of wear strips and hard facing, the service life of manganese steel dragline buckets can be increased considerably beyond that of bare (unfaced) buckets.

Crusher Liners. The hard facing of a manganese steel gyratory crusher liner, such as that shown in Fig. 13, is done with high-alloy materials having compositions similar to high-carbon alloys in groups 2A and 3A. Steels similar to the lower-carbon grades in groups 2A and 2B are also used, although they are less resistant to wear. In general, for a given application, the most abrasion-resistant material capable of withstanding the impact involved is selected for the overlay. Austenitic manganese steel electrodes of group 2C, or related austenitic alloys, are used for buildup.

Either shielded metal-arc welding or open-arc welding with continuous wire is suitable for buildup and for hard facing. Submerged-arc welding has been used, but it is likely to heat the base metal excessively. If equipment is available, automatic welding with a continuous-wire electrode is preferred. When manual welding is employed, the liner can be placed on a turning jig or on its side on the floor so that welding can be done in the flat position.

Before a worn crusher liner is welded, the surface is cleaned and inspected for structural defects. Minor defects are repaired by shielded metal-arc welding. If major defects are encountered and the liner is badly worn, it should be discarded. If buildup before facing is done manually, the use of round bars of manganese steel as inserts may greatly expedite the operation.

In a typical hard facing application employing automatic open-arc welding, the liner is mounted on a rotating positioner, the holding fixture permitting expansion and contraction of the part during welding. The welding head is mounted on a jib that is capable of reaching the inside surfaces. Hard facing begins at the smaller end of the liner, using a semiaustenitic or austenitic high-chromium alloy. The welding head is positioned at the bottom center of the part, with a slight lead, to provide the desired bead contour. Beads are about ⅛ in. high, and are overlapped to provide a surface having slight ridges.

The rotational speed of the positioner is varied to adjust for diameter changes of the liner, so as to keep the surface speed at the weld area constant as welding progresses in a spiral fashion, from the smaller to the larger end. An alternative practice is to space the first few full-turn beads a few inches apart, and then go back and fill in the intervening spaces. Welding is stopped for a short time if the base-metal temperature approaches 500 F, to allow the part to cool slightly and to keep the expansion relatively uniform. Prolonged heating above approximately 200 F is detrimental, not only to metal structure but also in its effect on work-metal shrinkage, distortion, stress buildup, and deposit check pattern. A check pattern, if not self-induced, is obtained by wiping the hot deposit with a wet

cloth or by lightly spraying it with water. Water cooling also keeps heat buildup low enough that welding can continue almost without interruption.

Hard facing alloys, particularly the more wear-resistant grades, are normally applied in two layers, or, at the most, in three layers. About 75 to 100 lb of electrode wire is required to hard face a liner 3 ft in diameter. Successful application and the development of an appropriate overlay pattern require careful study of the particular crusher. Placing an extra layer of hard facing, or using a more wear-resistant alloy at the sizing area or a tougher alloy for the upper section, are typical decisions that result from a study of the particular application.

Power-Shovel Bucket Teeth. Semiaustenitic or austenitic high-chromium irons, similar to some of the higher-carbon group 2 and 3 alloys, are excellent for most conditions of severe wear on bucket teeth. Where impact is severe and abrasion moderate, the martensitic steels of group 1B or the austenitic steels of group 2C, or modifications thereof, can be used. Tungsten carbide surfacing materials are suitable if the application involves digging loose abrasive material. In general, selection of the most wear-resistant alloy capable of withstanding the impact involved during service is favored.

A program for bucket-tooth maintenance usually requires the use of repointer bars and hard facing. The repointer bar, which consists of a short length of V-section bar, is welded to the worn tooth and thereby restores it to shape. Hard facing prolongs its service life. Figure 14(a) shows a tooth rebuilt with a rolled repointer bar. A length of bar about ¼ in. wider than the width of the tooth is prepared. First, the worn tooth is shaped by means of a gas torch or cutting arc to form a good joint with the bar. Using a manganese steel electrode of group 2C, or other recommended austenitic steel electrode, the bar is tack welded to the tooth with an offset of about ¼ in. from the tooth centerline, leaving a root opening about the size of the electrode being used. Welding is started on the side opposite the offset. As welding proceeds, the centerline of the repointer bar is drawn into line with the tooth centerline; the work is then turned over and welding is started on the opposite side. Welding continues, alternating from side to side, until the joint is fully welded, after which beads are deposited on the sides of the tooth to tie the ends of all weld beads together. Usually at least four teeth are rebuilt at one time, welding on each in turn, to minimize heat buildup.

Cast-to-shape repointers, designed to fit over the ends of worn teeth, are also extensively used. A type that is fillet welded to the worn tooth is shown in Fig. 14(b). Another type, shown in Fig. 14(c), incorporates grooves that are selectively filled with hard facing alloy to maintain the desired tooth shape as it wears. The grooves on the corners and sides of a tooth are filled with hard facing alloy to ensure a straight, sharp edge in service. This design permits deposition of a relatively brittle hard facing alloy on a tough base metal.

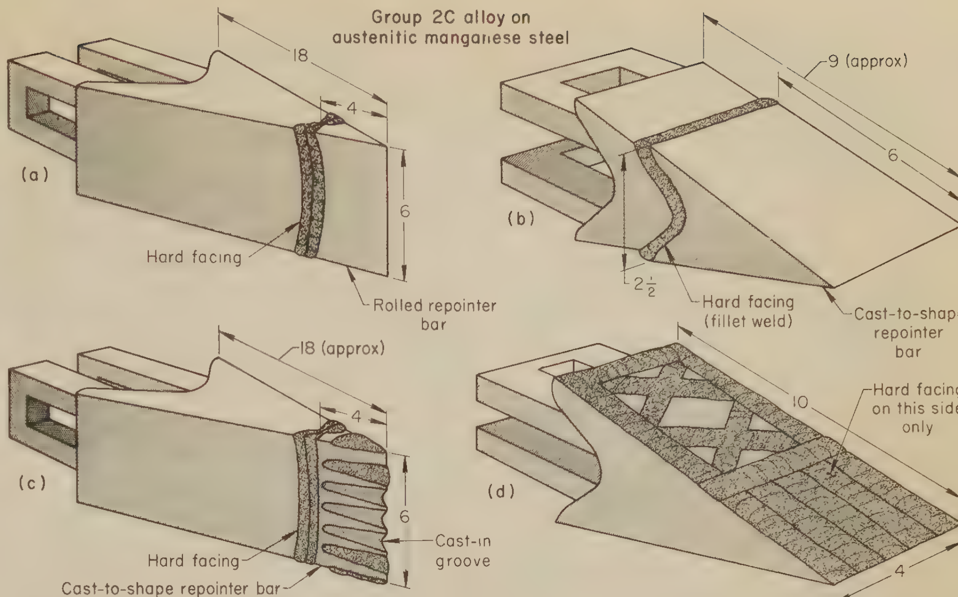

Fig. 14. Manganese steel bucket teeth rebuilt with (a) *rolled repointer bar,* (b) *cast-to-shape repointer bar, and* (c) *grooved cast-to-shape repointer bar.* (d) *Hard faced tooth, new or rebuilt, showing a typical bead pattern on top only to promote self-sharpening (see text).*

Hard facing bead patterns on shovel teeth vary with the type of service anticipated. A pattern commonly used is shown in Fig. 14(d). The tip of the tooth is hard faced with a single continuous hard facing layer on the top only. The crosshatch pattern of stringer beads behind the hard faced tip in Fig. 14(d) is often used to minimize "wash". For service that involves digging of ore or heavy rock, the surfacing beads are laid lengthwise on the tooth — continuously at the tip and in spaced stringers farther back on the tooth. If service involves contact with sand or other fine-particle abrasive material, the beads are laid across the tooth face, parallel to the tip line. Regardless of the bead pattern employed, if it is used only on the top the teeth will be self-sharpening (see the discussion in the preceding section on dragline buckets).

Shielded metal-arc welding is widely used for rebuilding and surfacing bucket teeth. Semiautomatic open-arc welding is also used when the volume of work is great enough to warrant its use.

Pulverizing Hammers. Maintenance of crusher hammers usually requires the use of electrodes of two types — one to rebuild the hammer to within about ³⁄₁₆ in. of the desired dimensions and the other for hard facing, to prolong service life. Austenitic manganese steel crusher hammers are usually rebuilt with group 2C or 2D alloys. If considerable buildup is required, round or square manganese steel segments can be welded on, as shown in Fig. 15(a), to reduce the amount of welding required to restore the hammer to shape. The hard facing alloys most often used are the high-carbon high-chromium alloys of groups 2A and 3A. Hard facing thickness is generally held to two layers. If impact on the hammer is severe, a martensitic steel, similar to some of the lower-carbon grades in group 1B, can be used for the hard facing layers, or an austenitic manganese steel may be used to finish the hammer completely to size.

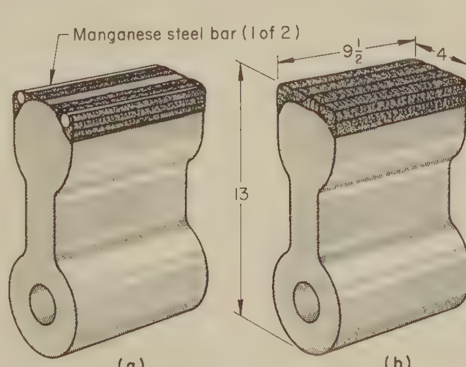

Fig. 15. Rebuilding a crusher hammer by welding and use of manganese steel bars (a), *and hard facing over the buildup* (b)

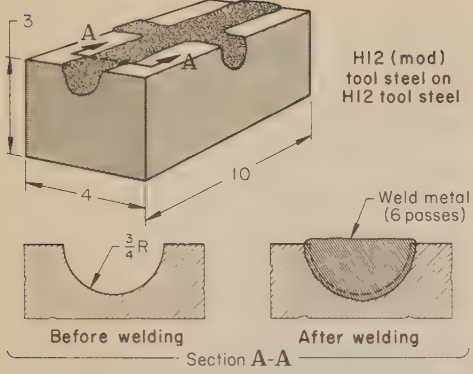
Hard facing applications on hammers have proved to be economical. In one installation, a new hammer used for crushing limestone lasted about 23 hr; hard facing with a high-chromium alloy increased the service life to more than 60 hr. In other applications, hard facing is known to have extended the service life of old hammers to four to seven times that attainable with new hammers. On the average, about 3 to 5 lb of electrode is required to rebuild and surface an 80-lb hammer. Maintaining a square edge usually limits welding speed. Several hammers are usually rebuilt at one time, skip welding from one hammer to another, so as to minimize heat buildup in the base metal of any hammer. A series of six hammers is often arranged in line, in positions that permit most of the welding to be done in the flat position. In some installations, hammers are rebuilt in place, within the crusher, to eliminate the time lost in dismantling and reassembly. With an efficient setup, rebuilding cost is as little as 25% of the cost of a new hammer. By following proper welding and heat-control procedures, hammers can be rebuilt many times before they are scrapped.



Conditions for Hard Facing by Shielded Metal-Arc Welding

Power supply	300-amp transformer-rectifier
Hard facing alloy	H12 (mod) tool steel(a)
Electrode holder	300 amp, hand held
Electrode diameter	⅛ in.
Welding position	Usually flat
Number of passes	Six; complete filling of groove
Current	110 amp, dcrp
Voltage	22 to 24 v
Preheat and interpass temperature	950 F
Stress-relief treatment	Peening after each pass
Postweld heat treatment	3 hr at 950 F, slow cool

(a) Covered electrodes with the following composition: 0.35 C, 0.30 to 0.40 Mn, 4.75 to 5.25 Cr, 3.00 to 3.50 W, 2.50 to 3.00 Mo, 0.30 to 0.40 V

Fig. 16. Hot upset forging die that was repair hard faced by shielded metal-arc welding (Example 163)

Hard Facing and Weld Repair of Metalworking Tools

Metalworking tools made of tool steel are hard faced and repaired with tool steel, not necessarily of the same composition as the tool. Thus, the compatibility of the base metal and the hard facing alloy, the ability of the facing alloy to perform in service at least as well as the base metal, and the welding characteristics of the two steels are major considerations that influence selection. Because most tool steel hard facing applications are limited to the repair or salvage of damaged or severely worn parts, the economy of hard facing and of repair welding is almost always based on the availability or cost of replacing the original tool.

Welding Processes Used. Shielded metal-arc, gas tungsten-arc, and gas metal-arc welding are widely used in hard facing and weld repair of tools. Manual and semiautomatic methods predominate over automatic methods, because tools are most often repaired individually, rather than in large quantities. Submerged-arc welding is used infrequently, because of its deep arc-penetration characteristic, which is usually detrimental in welding tool steel of high hardenability.

Typical Applications. The examples that follow describe the use of three arc welding processes for hard facing and weld repair of metal-cutting and metal-forming tools. The first example of the series shows how a change in electrode-wire composition had a beneficial effect on the life of repaired dies used in hot upset forging; the other two examples describe the hard facing of shear blades with tool steel.

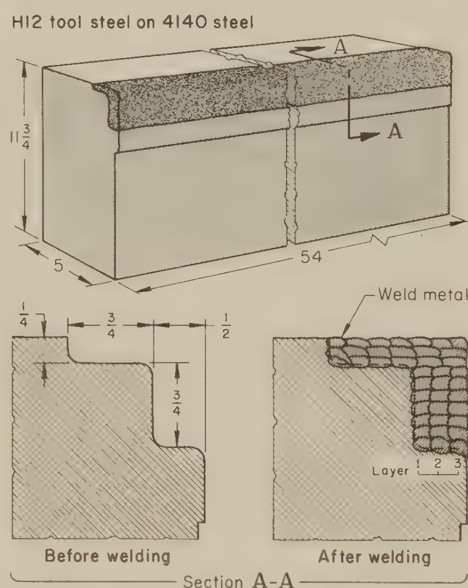
Example 163. Effect of Composition of Hard Facing Alloy on Life of Upset Forging Dies (Fig. 16)

In producing a universal-joint part, the life of a new set of hot upset forging dies made of H12 tool steel was 8000 pieces. When the dies were repaired, using H12 electrode wire of conventional composition and gas metal-arc welding, the dies were usable for an additional 8000 pieces. By changing to a covered H12 electrode with additional alloy content in the coating (total of 3.25% W and 2.75% Mo), the life of repaired dies was increased to between 18,000 and 20,000 pieces. Use of the covered electrode required a change from gas metal-arc to shielded metal-arc welding. The forging die is shown in Fig. 16, and the chemical composition of the covered H12 electrode is given in the accompanying table.

Preparation for welding was similar for both processes. It began with grinding the die impressions to a depth of ⅛ to ¼ in. below the cracks that had resulted from heat checking, to form grooves with a radius of about ¾ in., as shown in Fig. 16. The dies were then preheated in a furnace to 950 F, which was also the interpass temperature during welding. Welding was done in the flat position using reverse-polarity direct current. Six passes were required to fill the grooves. After each pass, the weld bead was stress relieved by peening. After welding was completed, the die block was held at 950 F for 3 hr and cooled slowly. Hardness was Rockwell C 54 to 57. The dies were then machined to size, using the electrical-discharge method.

Additional welding data are given in the table accompanying Fig. 16.

Shear blades used for shearing heavy steel bars at elevated temperatures require a combination of high-temperature impact resistance at the shearing surfaces and high yield strength with good impact and fatigue properties in the body of the blade, in order to perform most efficiently. To achieve this combination of properties at moderate cost, it is often feasible to hard face the edges of a carbon steel or a low-alloy steel blade with a hot work tool steel, provided the welding characteristics of the two steels are compatible. Example 155 describes the hard facing of a carbon steel shear blade by submerged-arc welding. Hard facing of low-alloy steel shear blades by gas metal-arc welding is described in the following example.



Conditions for Gas Metal-Arc Welding

Power supply	600-amp constant-potential rectifier
Hard facing alloy	H12 tool steel
Electrode diameter	0.045 in.
Electrode holder	600 amp, water cooled
Shielding gas	Argon – 1 to 2% oxygen, at 30 cfh
Welding position	Flat
Number of passes	40
Number of layers	Three
Current	250 to 400 amp, dcrp
Voltage	28 to 32 v
Stickout	½ in.
Welding speed	20 to 40 ipm
Preheat	650 F
Postweld heat treatment	3 to 4 hr at 1000 to 1025 F

Fig. 17. Shear blade hard faced using gas metal-arc welding (Example 164)

Example 164. Hard Facing of 4140 Steel Shear Blades With H12 Tool Steel (Fig. 17)

Shear blades made of 4140 steel, for hot shearing heavy steel bars, were hard faced by gas metal-arc welding. Shear-blade dimensions and details of the weld grooves before welding and the layer sequence in welding are shown in Fig. 17.

An electrode capable of depositing a facing equivalent to H12 tool steel was selected, the chemical composition of the electrode being adjusted to compensate for the possible loss of carbon and other alloying elements during welding. Compositions of the electrode metal, the deposited weld metal, and a typical H12 tool steel were as follows:

	C	Cr	W	Mo	V
Electrode metal	0.37	4.95	1.32	1.37	0.46
Weld metal	0.35	4.48	1.30	1.30	0.45
H12 tool steel	0.35	5.00	1.50	1.50	0.40

To begin the operation, the shear-blade blank was thoroughly cleaned and degreased; it was then machined to typical dimensions, as shown in Fig. 17. Before welding, the part was preheated to 650 F. Using a slightly overlapping technique, stringer beads were deposited. Further welding details are provided in the table accompanying Fig. 17. Care was taken to obtain flat beads with low penetration, in order to avoid excessive dilution of the weld metal. To further minimize dilution, the weld metal was deposited in three layers. The blade and the groove faces at the edge were positioned so as to permit flat welding; the first layer was completed on all faces before the second layer was started. Forty passes were required to complete the weld (see Fig. 17). After hard facing, the blades were held at 1000 to 1025 F for 3 to 4 hr, after which the shearing edges were ground to size. This procedure produced cutting edges ranging in hardness from Rockwell C 54 to 56. Blades hard faced in this manner were less expensive and lasted longer in service than unsurfaced tool steel blades.

High-carbon high-alloy tool steels, such as D2 (1.5% C, 12% Cr, 1% Mo), are usually difficult to hard face or repair. Nevertheless, procedures have been developed for welding these tool steels successfully. A procedure for repairing D2 tool steel shear blades, involving two different welding processes, is described in the following example.

Example 165. Repair Welding D2 Tool Steel Shear Blades (Fig. 18)

A welding procedure developed for salvaging tool steel dies, knives, and milling cutters proved successful for repair welding of the D2 shear blade shown in Fig. 18.

Before welding, the worn-out, chipped and cracked areas of the blade, as shown in Fig. 18(a), were ground to obtain a clean, smooth metal surface (Fig. 18b). The blade was then heated in a furnace to 800 F. In the absence of a furnace, slow, even heating with an oxyacetylene torch, using a

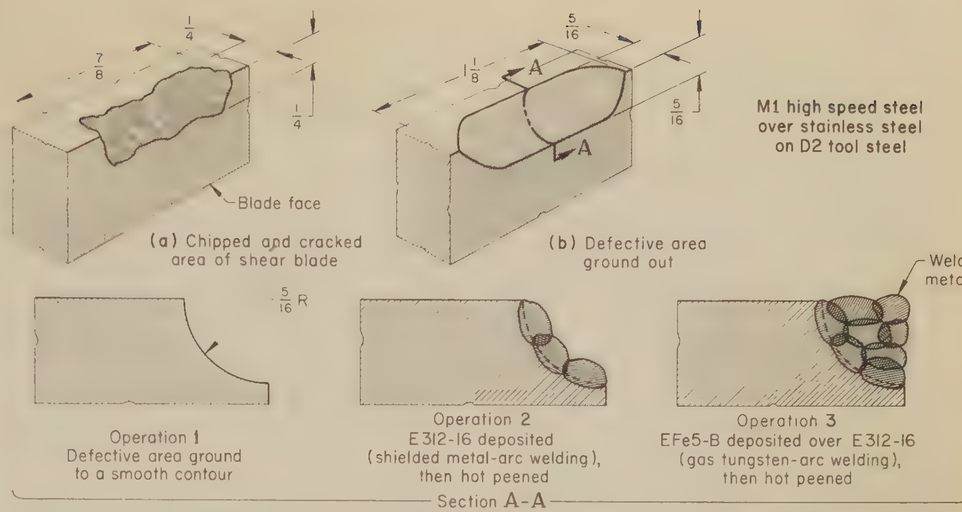
large tip and neutral flame, was satisfactory, the temperature being measured by temperature-indicating crayons.

For repair welding of tool steel blades, choice of a one-step or a two-step procedure depended on the depth of weld metal to be deposited. In this application, the depth of hard facing required did not exceed 3⁄16 in. after finish grinding, and excessive buildup of hard facing alloy would have increased cost, required excessive grinding, and increased the probability of weld cracking. Because the shear blade, after grinding, required a weld approximately 5⁄16 in. deep, an initial buttering pass with a softer, more ductile alloy was necessary. This underlayer was deposited by shielded metal-arc welding, using a flux-covered E312-16 stainless steel electrode, 3⁄32 in. in diameter. Stringer beads about 1 in. long were deposited (Fig. 18, Operation 2). After every 1-in. length of the deposit, the bead was thoroughly ball-peened. Welding and peening were done alternately until about 1⁄8 in. depth remained to be welded. Interpass temperature was maintained within ±100 F of the preheat temperature. Additional data are given in the table accompanying Fig. 18.

With the blade still maintained at interpass temperature, the hard facing was deposited by manual gas tungsten-arc welding, using an EFe5-B (M1 high speed steel) filler metal rod, 1⁄16 in. in diameter, and argon as shielding gas. As before, stringer beads 1 in. long were deposited and immediately peened; it was important to stop peening as soon as the bead cooled to a black heat. It was necessary to deposit a very shallow puddle in order to minimize dilution of the weld metal and consequent decrease in hardenability. To accomplish this, the welder used the technique of playing the arc chiefly on the filler metal.

After depositing sufficient metal, with provision for finish grinding the blade edge to size, the part was allowed to cool to room temperature in still air. Hardness of the deposit after grinding was Rockwell C 58. Additional welding details are given in the table with Fig. 18. Postheat treatment consisted of holding the hard faced blade at 800 F for 1 hr and cooling in air.

A new blade would have cost $35, whereas cost of repairing a blade by the above procedure was about $6 — $1 for material (gas and hard facing alloy) and $5 for labor. In addition, a blade could be salvaged in about 3 to 4 hr elapsed time, whereas a replacement might take weeks.



Welding condition	Underlayer	Hard facing layers
Welding process	Shielded metal-arc	Manual gas tungsten-arc
Power supply	300-amp transformer-rectifier with high frequency; time delay for gas and water; foot-operated control	
Electrode	3⁄32-in.-diam E312-16(a)	3⁄32-in.-diam EWTh-2

Fig. 18. Portion of shear blade showing: (a) *chipped and cracked area;* (b) *defective area prepared for repair welding; and sectional views of three successive stages of repair welding* (Example 165)

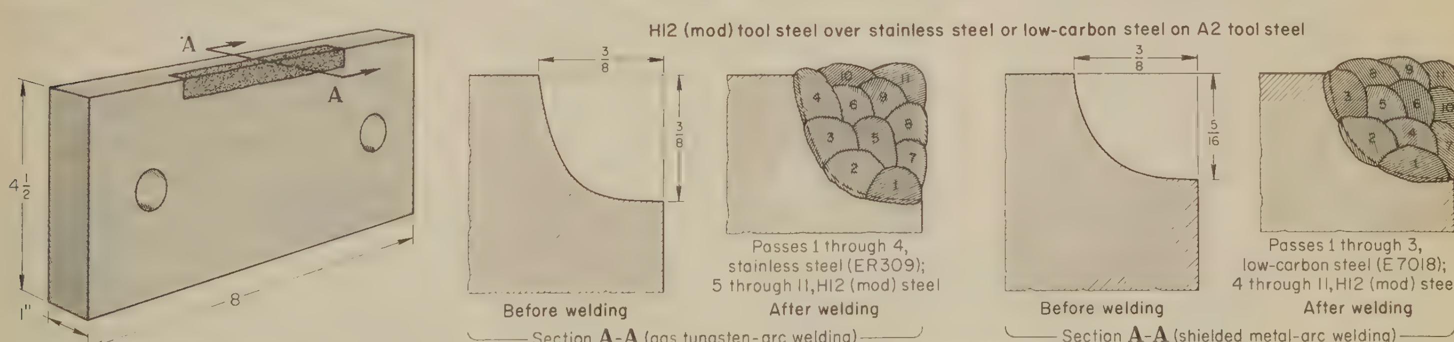
Shear blades made of A2 tool steel also are hard faced and repair welded, using either gas tungsten-arc or shielded metal-arc welding. Procedures for these welding processes, in applying an H11 tool steel repair overlay to an A2 tool steel shear blade, are described in the example that follows.

Example 166. Use of Gas Tungsten-Arc and Shielded Metal-Arc Welding To Make a Surfacing Repair Weld on A2 Tool Steel Shear Blades (Fig. 19)

The welding procedure used to repair damaged cutting edges on A2 tool steel shear blades required close control of conditions affecting heating and cooling of the base metal. A typical blade, for shearing 0.95% C steel sections, is shown in Fig. 19.

Among the problems commonly encountered in welding an air-hardening tool steel such as A2 are the presence of retained austenite in the deposit, and weld cracking. Retained austenite results from rapidly cooling the steel after prolonged heating in the austenitic region, and is characterized by a decrease in hardness after cooling. Cracking is usually caused by abnormal or uneven cooling. To avoid these problems, the following eight precautionary measures were strictly observed while preparing to weld and during the welding operation:

1 In grinding the cracked or broken areas of the damaged blades, precautions were taken against overheating and discoloration of the workpiece surfaces.



Welding condition	Gas tungsten-arc welding	Shielded metal-arc welding
Power supply	300-amp rectifier or 300-amp motor-generator	300-amp motor-generator or rectifier

(a) Composition: 0.75 to 1.00 C, 0.40 to 0.60 Mn, 5.50 to 5.75 Cr, 1.00 to 1.10 W, 1.75 to 2.00 Mo, 0.90 to 1.00 V

Fig. 19. Shear blade with edge hard faced with modified H12 tool steel, using gas tungsten-arc or shielded metal-arc welding (Example 166)

2 All welding was done indoors, in a draft-free environment.
3 Workpieces were preheated to 800 F in a furnace or by gas torch. Heating was even and uniform. The temperature of the workpiece was checked repeatedly with temperature-indicating crayons.
4 The ground connection was clamped securely, to ensure the absence of hardened arc spots on the workpiece and variations in welding current.
5 Weld bead deposits did not exceed 3 in. in length, which enabled them to retain the heat required to obtain good results from peening.
6 Immediately following deposition of each 3 in. of bead, the red-hot bead was lightly peened with a ball-peen hammer to prevent stress concentration and cracking; the deposit was then wire brushed.
7 The interpass temperature was checked after every third deposit and was kept in the range of 750 to 950 F.
8 Each bead was deposited as a straight stringer bead, without weaving or oscillation of the torch during welding.

Gas tungsten-arc welding was started by first depositing one complete layer of weld-metal beads, using 1/16-in.-diam ER309 stainless steel filler metal (25% Ni, 12% Cr). This buttering layer provided a ductile buffer between the hardened base metal and the subsequent passes of hardenable weld metal. (Either ER308 or ER316-ELC filler metal could be substituted for ER309.) The remaining passes were made with a rod of proprietary composition (see the table accompanying Fig. 19) equivalent to a modified H12 tool steel.

Machine settings and other welding conditions are given in the table with Fig. 19. Small, straight stringer beads made with low heat input and in the sequence shown in Fig. 19 were essential for the success of the operation.

After hard facing was completed, the workpiece was placed in a furnace previously heated to 200 F. Furnace temperature was then increased to 900 F, so that both the workpiece and the furnace were heated at the same rate. Parts were held at 900 F for 1 hr and were then removed and allowed to cool in a draft-free area. They were not covered at any time.

Hardness readings taken after repaired edges were ground to size and shape ranged from Rockwell C 57 to 60. This compared favorably with the base-metal hardness of Rockwell C 56 to 58.

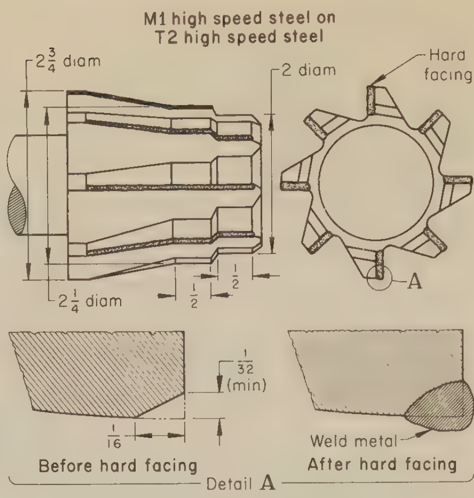
Shielded metal-arc welding was also successfully used for repair welding the damaged cutting edges of A2 tool steel shear blades, using the same procedural sequence as for gas tungsten-arc welding, except for the filler metals used and the details of operation. The eight precautionary measures listed above were strictly adhered to.

The initial layer (beads 1 to 3), as shown in Fig. 19 (right), was deposited using a 1/8-in.-diam E7018 low-hydrogen iron-powder electrode. The low hydrogen minimized the possibility of underbead cracking, and the iron powder favored use of high welding speed, which gave relatively low penetration. These beads formed a buffer layer of relatively ductile steel between the base metal and the subsequent layers of hard facing metal. Beads 4 through 11 were deposited with a 1/8-in.-diam modified H12 tool steel electrode (see the table with Fig. 19 for the composition).

Although the number of beads per layer could vary, depending on the size of the groove to be filled, the sequence pattern shown in Fig. 19 (right) was essential to the success of the operation.

Machine settings and other conditions for both types of weld deposit are given in the table with Fig. 19. The postheating procedure was the same as that employed after gas tungsten-arc welding.

High speed steels, which are extensively used for metal-cutting tools, are difficult to weld because of their high carbon and alloy contents. Weld repair of these tools is sometimes economically attractive, as in the following example,



Manual Gas Tungsten-Arc Welding

Power supply	300-amp transformer-rectifier; time delay for gas and water; foot-operated control
Electrode	3/32-in.-diam EWTh-2
Torch	375 amp, water cooled; with gas lens
Hard facing alloy	1/16-in.-diam RFe5-B(a)
Shielding gas	Argon, at 15 cfh
Welding position	Flat
Preheat and interpass temperature	900 F
Postweld heat treatment	1 to 2 hr at 1000 F(b)
Current	100 to 150 amp, dcsp
Voltage	Not controlled
Arc starting	High frequency

(a) Same composition as M1 high speed steel; heat treatable, if annealed, using M1 heat treating specifications. (b) Furnace cool or, if heated with a torch, bury in lime for cooling.

Fig. 20. Stepped reamer that was salvaged by hard facing, using manual gas tungsten-arc welding (Example 167)

which describes the repair welding procedure used in one application for salvaging high speed steel reamers.

Example 167. Repairing Worn Cutting Edges on High Speed Steel Reamers (Fig. 20)

The cutting edges of high speed steel reamers used for finishing holes in malleable iron castings were rapidly worn down by the action of sand inclusions and hard spots in the castings. The worn cutting edges could have been salvaged by cutting a portion from the front end of the reamer and regrinding all surfaces to size, but this operation would have been time-consuming and expensive. Instead, when wear exceeded tolerance limits, reamers were salvaged by hard facing the flutes, using manual gas tungsten-arc welding. The small, confined heat source obtained in the process permitted accurate placement of beads without the need for prior annealing of the reamer.

The front end of a high speed steel reamer with hard faced cutting edges is shown in Fig. 20. Preparation for welding consisted in grinding each cutting edge to a depth of not less than 1/32 in. below the original cutting surface (see sectional detail in Fig. 20). The ground edges were inspected to make certain that no cracks or partially separated chips remained. Oil and grease were removed with detergent, and oxide discoloration was removed with an emery cloth. The tool was preheated slowly to 900 F in a gas furnace provided with a neutral atmosphere. When a furnace was not available, an oxyacetylene torch was used for preheating; a neutral flame from a large tip was played over the tool surfaces to distribute the heat evenly; temperature was measured with a 900 F indicating crayon.

After preheating, a stringer bead was deposited along the full length of the prepared edge of each flute, starting at an end, using filler metals of 1/16-in. diameter and of composition comparable to that of M1 high speed steel. A power supply of 300-amp capacity was used to furnish straight-polarity direct current (electrode negative). Time delay for preflow and postflow argon and water circulation, and continuous high-frequency current for arc starting and stabilization were provided.

Current between 100 and 150 amp was used for welding and was controlled by a pedal. For details of machine settings and other welding conditions, see the table accompanying Fig. 20.

The welding technique used was important. The welder had to maintain a short arc with the heat directed mainly on the filler-metal rod, so as to create a shallow weld puddle. Dilution with base metal had to be held to a minimum to avoid decreasing the hardenability of the deposit. By uninterrupted operation, it was possible to use the heat input of welding to maintain interpass temperature at the preheat level. After welding, the tool was cooled to room temperature in a draft-free area.

As a postweld treatment, the tool was heated slowly to 1000 F and held at that temperature for 1 to 2 hr. When a furnace was not available, the tool was heated to 1000 F with a torch and buried in lime for at least 6 hr. After cooling, the tool was reground and returned to service.

The salvaging operation was repeated successfully several times on the same tool. Actual savings on reamers of different types varied with the cost of replacement. The stepped reamer of T2 steel, described here, was repaired at a cost of approximately $15, which was about one-fifth of its replacement cost. In general, savings of 50% or more could be realized.

531-543	Hard facing by oxyacetylene welding

Stud Welding

*By the ASM Committee on Flash, Friction and Stud Welding**

STUD WELDING is an arc welding process in which the contact surfaces of a stud, or similar fastener, and a workpiece are heated and melted by an arc drawn between them, and then are brought together ("plunged") rapidly under pressure to form a weld. Arc initiation, arc time, and plunging are controlled automatically.

The two basic methods of stud welding are known as arc stud welding and capacitor-discharge stud welding. Both methods involve direct current and arcing. For arc stud welding, a motor-generator, a transformer-rectifier, or a storage battery is the power supply. The power supply for capacitor-discharge stud welding is a low-voltage electrostatic storage system, and the arc is produced by a rapid discharge of stored electrical energy. A welding-current controller and a welding tool, or gun (stud gun), complete the necessary welding equipment for both methods of stud welding. In the arc method, a ceramic ferrule is generally used to retain the molten weld metal.

In both methods, the stud, or fastener, serves as the electrode; the gun is the electrode holder. Flux is generally used for arc stud welding of ferrous alloys; it provides cleaning action and a protective atmosphere. When used, flux is on or within the end of the stud. The arc time for capacitor-discharge welding is so short that flux is not needed. A shielding gas is usually introduced around the stud in welding nonferrous metals by both methods.

Generally, in arc stud welding, straight polarity (stud negative and workpiece positive) is used for ferrous alloys and reverse polarity for nonferrous alloys. Straight polarity is used in capacitor-discharge stud welding.

The procedure used to initiate the arc and to control the welding cycle and current varies with the method.

Stud welding is similar to percussion welding (see page 177).

Process Capabilities and Limitations

Stud welding is a rapid process. Welding time, which depends on the method and on the diameter of the stud, varies from 1 to 12 milliseconds for the capacitor-discharge method and from 0.10 sec to slightly more than 1 sec for arc stud welding. Melt-through and distortion are at a minimum in both methods. Maximum strength of the fastener is developed when the diameter of the weld base of the stud is not more than three times the thickness of the base metal.

Studs can be welded in places that are not readily accessible when other welding methods are used, and the welded area need not be in view of the operator. (In Example 171, a stud was inserted through the cover sheet and core of a honeycomb panel and was capacitor-discharge welded to the inner surface of the lower sheet.)

The shank of a stud or other weld fastener can be of any size, shape or type that can be gripped in the stud holder. Length can vary from 5⁄32 in. for a special capacitor-discharge application to several feet.

Usually, the weld base (the end of the stud or other weld fastener that is to be welded) is round for both processes. However, square and rectangular-base studs can be welded by the arc method. Studs 1⁄16 to 1¼ in. in diameter and rectangular welding pins ⅛ by ⅜ in. to ¼ by 1¼ in. have been welded. Small sheet-metal cups have been welded to workpieces using the capacitor-discharge method.

Suitable stud and base metals are the same as those welded by other arc welding processes. The metals most frequently stud welded are low-carbon steel, low-alloy high-strength steel, austenitic stainless steel, aluminum alloys, and some copper alloys. Alloy steels, magnesium alloys, titanium alloys, zirconium alloys, and zinc alloy die castings also have been stud welded.

Welding of various base metals and typical combinations of base metal and stud metal are described in the section on Metals Welded, on page 174.

Stud welded fasteners can replace fasteners normally secured by riveting, drilling and tapping, manual arc welding, resistance welding, or brazing. The studs are attached to only one side of the workpiece.

Applications. Stud welding is most often used to end-weld a stud or other fastener to a plane surface. The arc method can be used also to weld fasteners to curved surfaces such as pipe or to inside and outside corners of structural members.

Some typical applications of stud welding are: attaching wood floors to steel decks or framework; securing special linings in tanks, boxcars and other containers; studding boiler tubes; assembling electric panels; securing inspection covers of various kinds; securing trim moldings and emblems to automobiles; securing air, water, hydraulic, and electrical lines to buildings, vehicles and large appliances; welding shear connectors and concrete anchors to structures; and securing handles and feet to small appliances.

The process lends itself to automatic feeding of studs to the gun for welding at a rate of 45 per minute or more. Accuracy of location depends on product design and the process equipment.

Limitations are as follows:

1. Studs must be of a size and shape that permit chucking, and the cross-sectional area of the weld base of the stud must be within the range of the welding equipment.
2. Studs for arc stud welding usually must permit the use of a ceramic ferrule, or arc shield, around the weld base. Also, the weld base often must accommodate flux.
3. Studs for capacitor-discharge stud welding sometimes require a carefully designed, close-tolerance projection on the weld base, the function of which is to make initial contact with the workpiece to initiate the arc.
4. Areas to be welded must be clean and free from paint, scale, rust, grease, oil, dirt, zinc plating, or cadmium plating. Aluminum surfaces require oxide removal if badly oxidized.
5. Only one end of the stud can be welded to the workpiece.
6. Studs are secured to only one side of the workpiece. If a stud is required on both sides, a second stud must be welded to the opposite side.

Stud Welding Guns

The gun holds the stud in position while the welding current is applied; it can be hand held or bench mounted.

A gun for capacitor-discharge stud welding is shown in Fig. 1. Guns for arc stud welding are similar, except that provision is made for a ferrule holder or, when welding aluminum studs, a gas-adapter foot assembly.

Process Selection

Table 1 compares the applicability of arc and capacitor-discharge stud welding for various base metals, base-metal thicknesses, stud metals, and weld-base shapes and sizes. A comparison of the capabilities of arc and capacitor-dis-

C — Limited applicability
D — Not recommended; welding methods not developed at this time.

(a) Data apply primarily to round weld bases, but in arc stud welding, they apply to square and rectangular-shape bases.

charge stud welding when attaching aluminum alloy studs to Teflon-coated and natural-finish aluminum alloys is given in Table 2.

The following considerations are pertinent to process selection:

1 **Base Metal.** Low-carbon steel and austenitic stainless steel are weldable by both the arc and the capacitor-discharge methods. Some non-heat-treatable aluminum alloys can be welded by the arc method, but most such alloys and alloys 6061 and 6063 are welded by the capacitor-discharge method. Copper, brass and galvanized steel sheet usually are welded by the capacitor-discharge method only.

2 **Base-Metal Thickness.** If the base metal is less than 0.036 in. thick, the capacitor-discharge method should be used. (Tables 1 and 2 show minimum base-metal thickness for various stud diameters, for arc and capacitor-discharge welding.)

3 **Weld-Base Shape.** The weld base for capacitor-discharge stud welding is nearly always round. Square or rectangular pins, collared studs or split pins are all arc stud welded.

4 **Weld-Base Diameter.** For diameters greater than 3/8 in., arc stud welding must be used. The diameter range for capacitor-discharge stud welding is 1/16 to 3/8 in.

Arc stud welding results in a much larger heat-affected zone than the capacitor-discharge method. Also, capacitor-discharge welding results in a very small fillet; arc stud welding, in a relatively large fillet.

The weld-fillet size in arc stud welding is controlled by the ceramic ferrule, which serves as a dam to contain the molten metal. Dimensions of the weld fillet usually must be considered in the design of parts through which the studs pass. In Example 173, holes in the mating part were increased from 9/16 to 5/8 in. in diameter, to clear the fillet.

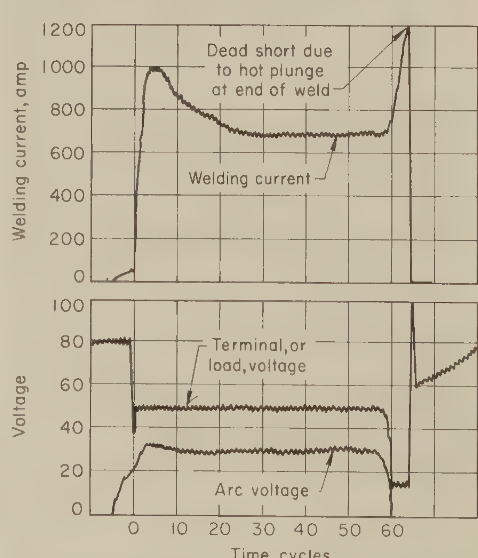

Fig. 2. Oscillograph traces of current and voltage during arc stud welding for 65 cycles (based on 60 cycles per second)

Arc Stud Welding

Arc stud welding is used to best advantage when the base metal is thick enough to enable the weld to be made without burn-through and the full strength of the welded stud to be developed. For low-carbon steel, the weld-base diameter of the stud should be no more than three times the base-metal thickness.

Rust-coated and scale-coated surfaces can be welded if the weld area is cleaned with a wire brush, or if the scale is broken with a centerpunch so that the arc can be established at the centerpunch mark. The weld area on oiled, painted and plated surfaces should be cleaned to ensure sound welds. Excessive oxide must be removed from the weld areas on aluminum workpieces.

Power Supply. A transformer-rectifier, a motor-generator, or a storage battery can be used to supply the direct-current power needed for arc stud welding. Some of the power-supply units made for other arc welding processes are satisfactory, but equipment designed specifically for arc stud welding is recommended, for greater efficiency and the most appropriate voltage and amperage characteristics.

The power needed for welding the larger-diameter studs frequently is obtained by connecting two or more power-supply units in parallel.

Characteristics of power supply for arc stud welding include:

1 **A high open-circuit terminal voltage** (the voltage at the welding terminals when welding is not taking place) of 60 to 100 volts. Control components, such as the timer, relay and contactor, are designed to operate in this voltage range. A high open-circuit voltage energizes the control components efficiently; if the open-circuit voltage is below 55 volts, operation of the control unit may become erratic.

2 **Drooping volt-ampere characteristic** is preferred, because it provides a relatively high open-circuit voltage that is above the arc voltage, and because it helps to establish and maintain the arc. Also, it provides a more stable arc. The momentary increase in current caused by the stud shorting out the welding arc when the stud is plunged into the base metal at the end of the weld cycle is relatively small.

The constant-voltage curve is flat. Also, most constant-voltage machines have a low open-circuit voltage, generally about 40 volts. Because the volt-ampere curve is flat, current for a dead-short condition is, theoretically, unlimited. This means that whenever drops of metal short out the arc, current is very high, causing the arc to blast and be unstable for stud welding. Thus, constant-voltage machines are not usually employed for stud welding, because low open-circuit voltage results in erratic operation or in nonoperation of the control units, and the flat volt-ampere curve causes an unstable arc. Constant-voltage machines can be used, however, if a special control unit that operates on 115-volt alternating current is employed, but arc characteristics are not ideal.

3 **Rapid Current Rise.** The welding current should rise to its peak value in

less than two cycles, or approximately 32 milliseconds. If the current rises too slowly, a stable arc will not be established. Figure 2 (top) shows a typical current oscillograph trace for a stud weld. The welding current rises steeply to a peak of 1000 amp, then drops to 700 amp as the machine slows down.

4 **High Short-Time Current Output.** Current output required is three to six times that required for other manual and automatic welding methods, and the duty cycle is only 5 to 15%, instead of 60 to 100%.

Terminal Voltage and Arc Voltage. Figure 2 (bottom) shows a typical voltage oscillograph trace for a stud weld. (The traces in Fig. 2 were made using a motor-generator set; the voltage characteristics of other types of direct-current power units would be similar.) The voltage at the terminals of the machine was 80 volts, until welding current was drawn. When welding current started to flow, the terminal voltage dropped to 50 volts. After the weld was completed, the terminal voltage dropped to less than 20 volts, then increased rapidly to a very high value because of the inductance in the machine, and then dropped to slightly below the normal open-circuit voltage. The voltage then slowly increased to its original open-circuit value, as the machine regained full speed.

The lower voltage trace in Fig. 2 (bottom) is the arc voltage, which depends on arc length. It is usually 30 to 35 volts. The trace shows that there was arc voltage before the welding current started to flow. This is pilot arc voltage. The difference between load voltage and arc voltage is a result of voltage drop in the cables, connectors, ground connection, and contactor. In Fig. 2, there was a 20-volt drop in the circuit between the machine and the welding arc.

Output Rating vs Stud Diameter. A 400-amp NEMA-rated direct-current welding machine is used for studs up to 7⁄16 in. in diameter. A 600-amp machine will weld studs of ½-in. diameter. Two 400-amp machines connected in parallel are needed for ⅝-in.-diam studs, and two 600-amp machines connected in parallel are needed for ¾-in.-diam studs. A 1-in.-diam stud requires a 2000-amp machine.

In some applications, studs welded by a machine with a transformer-rectifier would have to be 1⁄16 in. in diameter smaller than studs welded by a motor-generator machine of the same rating.

Cables. The size and length of welding cables and ground cables affect the power available at the welding gun. Figure 3 shows that, for a given length of cable, the welding current can be increased about 10% by using a cable of the next larger diameter. Also, for a given size of cable, the current at the gun decreases as the length of the cable is increased.

Studs are specially manufactured, and the weld end is flux-loaded, when necessary, and equipped with a porcelain or ceramic ferrule. The ferrule shields and controls the welding arc, concentrates the heat of the arc in the weld area, and also acts as a dam to control the flow of the molten metal and to restrict it to the weld area.

Table 2. Comparison of Arc and Capacitor-Discharge Stud Welding of Aluminum Alloy Studs to Teflon-Coated and Natural-Finish Aluminum Alloy Base Metal

Item	Arc stud welding	Capacitor-discharge stud welding: Initial-contact; initial-gap	Capacitor-discharge stud welding: Drawn-arc

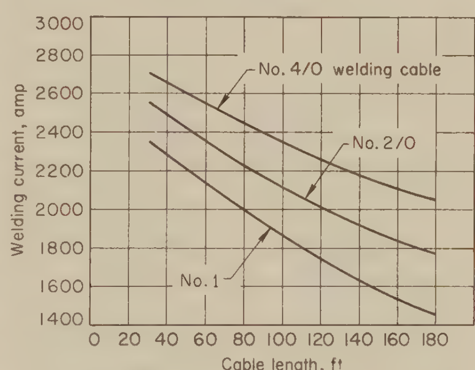
Angle from perpendicular, max(c)	10°	0°	2°
Angle with special chuck, max(d)	25°	0°	2°
Weld quality, rough or textured surface	Excellent	Fair	Excellent

(a) Without damaging Teflon coating. (b) Without damaging finish. (c) Angle at which stud can be off perpendicular to surface of base metal and produce a good weld. (d) Angle to gun motion.

The flux acts as an arc stabilizer, and as a deoxidizing agent when steel is welded. It is held at the center of the weld base within 0.010 in. of true position. Except for special applications, flux is not needed for studs less than ¼ in. in diameter.

Studs come in various styles, lengths and diameters (or widths and thicknesses), and compositions. They are frequently custom designed.



Data were determined by welding studs with a special 2000-amp machine that was operated at the highest setting. Cable length is combined length of welding cable and ground cable. Amperage is average for 60 cycles or 1 second.

Fig. 3. Effect of cable size and length on welding current that is available at the welding gun

Because a stud must extend through the ferrule an amount equal to the burn-off (⅛ to 3⁄16 in., depending on the diameter), minimum stud length usually is about ¾ in. When automatic feeding systems are used, maximum length is about 1 in. Amount of burn-off must be considered when the finished length of the stud is important.

The weld base of a stud can be larger or smaller than the body, and can be of any shape. Rectangular fasteners should have a width-to-thickness ratio no greater than 5 to 1. Fasteners having a weld base with a greater ratio weld inconsistently and are not recommended.

On round studs, the weld-base diameter generally should be no more than five times the base-metal thickness, but a ratio of about 3 to 1 is needed for making a weld that is stronger than the stud and causes no burn-through or excessive distortion of the base metal. The minimum base-metal thicknesses and starting conditions for arc stud welding of low-carbon steel and aluminum alloys are given in Table 3.

The end of a stud with a round weld base is convex or conical. Rectangular fasteners have tapered tips, the apex being at the center of the width dimension. This shape helps to initiate the arc at the center of the stud, permitting the arc to spread equally along the surface to be heated. Also, if the

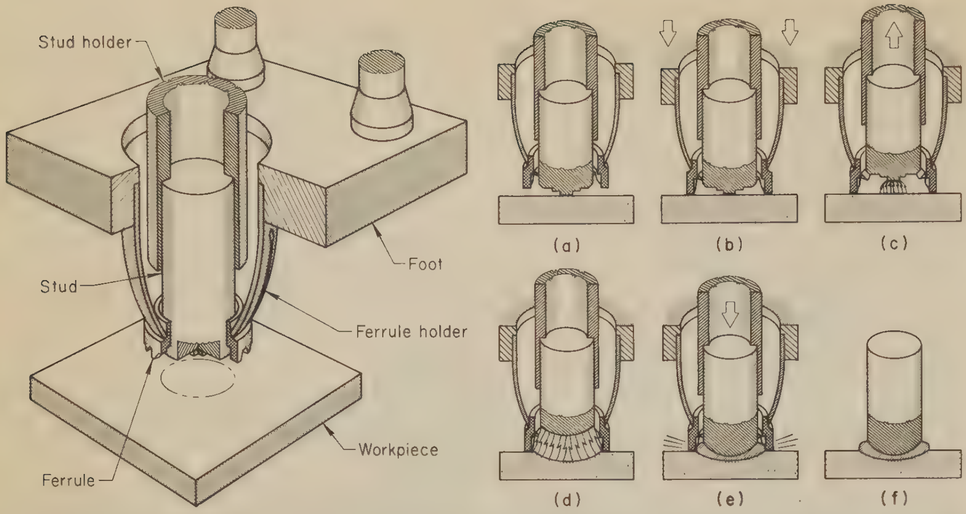
(a) These are starting conditions and must be adjusted to welding conditions and strength requirements. (b) Based on 60 cycles per second. (c) Minimum of 65 volts open-circuit voltage recommended. Amperage is actual and does not necessarily correspond to power supply dial settings. When stainless steel studs are welded, amperage is increased 10%. (d) Shielding gas not needed for stud welding steel. Generally, argon is used for stud welding aluminum alloys.



(*a*) First, the stud is located on the workpiece. (*b*) Force is applied so that the spring within the gun is compressed until the ferrule is seated firmly on the workpiece. (*c*) When the welding current is turned on, the solenoid in the welding gun is energized, the stud is automatically lifted, and an arc between the face of the stud and the workpiece is initiated. (*d*) With the stud in the lifted position, arcing spreads across the face of the stud and the heat of the arc melts an area on the workpiece and produces a weld puddle under the stud, and also melts a small portion of the face of the stud. (*e*) When the welding current is stopped, the solenoid is de-energized and the face of the stud is plunged, by spring pressure, into the weld puddle. (*f*) Finished weld; note shape of fillet formed by the ferrule.

Fig. 4. Sequence of steps in arc stud welding

stud is held a few degrees from perpendicular to the surface of the base metal, initial contact still will be made and the arc will be drawn at the center of the stud, instead of on the periphery.

Fasteners are sometimes coated with cadmium, zinc or other plating materials. Plating must be removed from the weld base of all studs more than $\frac{3}{16}$ in. in diameter, to prevent contamination of the weld.

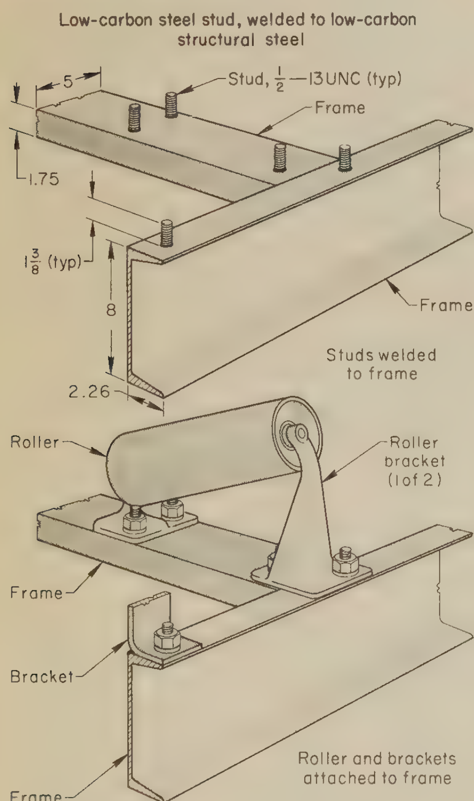


Fig. 5. Brackets fastened to a belt-loader frame made of heavy structural sections, using studs rather than through-bolts (Example 168)

Stud Location. The method of locating a stud depends on the stud and the accuracy required. For manual welding, centerpunch marks or scribed lines are used. The tip of the stud or the flux is placed on these marks. Where greater accuracy is needed, a template with holes of slightly larger diameter than the ferrule diameter is used. Spacers about $\frac{3}{32}$ in. thick must be inserted between the template and the workpiece to allow gases generated during welding to escape. (Example 170 on page 172 describes the use of a locating template.)

In production setups, the welding tool can be bench mounted and the studs located on the workpiece by means of fixtures or indexing tables.

Procedure. The stud is placed in the stud holder of the welding gun, and the ferrule is placed in the ferrule holder, which is adjusted during setup so that the stud will extend $\frac{1}{8}$ to $\frac{3}{16}$ in. beyond the ferrule. Figure 4 shows the steps in arc stud welding.

A controlling device limits arc time (the number of cycles the arc is allowed to burn), according to a predetermined setting. At the end of the arcing period, the timing device shuts off the welding current, de-energizes the solenoid, and plunges the end of the stud into the small volume of molten metal (the weld puddle, or weld pool) in the base metal. When the weld puddle solidifies, the weld is complete. Because the weld solidifies almost instantly, the gun can be moved to the next weld position without delay. The welding gun is then removed and the ferrule is broken off. A shielding gas is sometimes used when nonferrous alloys are being stud welded.

The duration of the welding cycle depends on the weld-base diameter, or cross-sectional area, of the stud and on the metals being joined. Table 3 lists typical welding conditions for low-carbon steel studs with weld-base diameters of 0.187 ($\frac{3}{16}$) to 1 in. and for aluminum alloy studs 0.250 to 0.500 in. in diameter.

Studs can be welded in the flat, overhead or vertical position. The highest weld quality is produced in the flat and overhead positions.

Examples of Practice. Often, product appearance is improved and assembly costs are reduced by using stud welding. Studs are surface mounted to one side of a workpiece without holes or reverse-side marking. In the following example, product appearance was improved by eliminating bolt heads, and assembly time was reduced because of elimination of the drilling operation.

Example 168. Change From Bolting to Stud Welding for Attachment of Conveyor Support Brackets to a Frame (Fig. 5)

End-welded studs were used for attaching conveyor support brackets to the frame of a mobile belt loader, as shown in Fig. 5. The studs, $1\frac{3}{8}$ in. long, with $\frac{1}{2}$–13 UNC threads, were made of low-carbon steel, and the frame was made of channel-shape structural steel sections. A portable arc stud welding gun was used. Weld time per stud was about 30 cycles, and welding current was about 800 amp.

A total of 92 studs was required for attaching the brackets, which had originally been attached by bolting. Changing to studs eliminated drilling of these holes, the through-bolts, and the tapered washers that were used under the bolt heads, and assembly was faster, because fastening was from one side only and it was not necessary to hold the bolt heads while the nuts were being tightened. Stud welding also eliminated bolt heads showing on the outer surfaces and simplified maintenance.

Hood covers and hydraulic hose clamps were also attached to the loader, using an additional 91 studs, which were $\frac{5}{16}$ and $\frac{3}{8}$ in. in diameter. By using the 183 studs, material and assembly costs were reduced \$40 per unit, or \$4800 per year for a production of 120 units.

Although Table 1 indicates that the capacitor-discharge method is preferred for stud welding of aluminum, arc stud welding was selected in the following

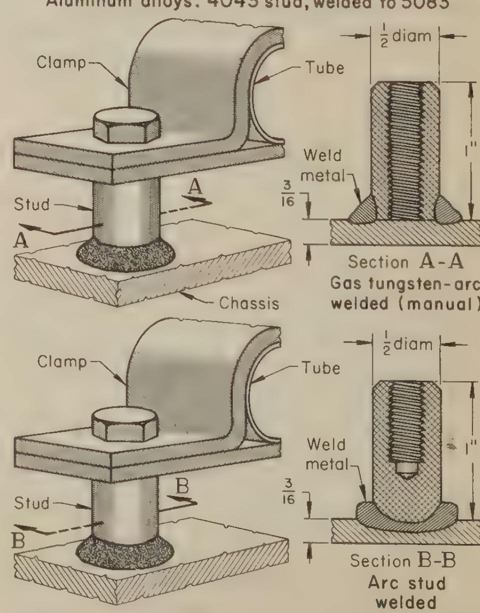

Fig. 6. Aluminum alloy studs attached by arc stud welding, instead of by gas tungsten-arc welding, to an aluminum alloy chassis for an amphibious vehicle (Example 169)

example because of the large weld-base diameter of the stud and because suitable motor-generator equipment was available.

Example 169. Arc Stud Welding of ½ and 7/16-In.-Diam Aluminum Alloy 4043 Studs (Fig. 6)

Tapped aluminum alloy 4043 studs secured clamps for attaching hydraulic, air, oil, and electrical lines to an aluminum alloy 5083 chassis for an amphibious military vehicle. The studs were ½ in. in diameter by 1 or 1½ in. long and tapped with ¼–20 UNC–2B threads, as shown in Fig. 6, or 7/16 in. in diameter by 1 or 1½ in. long and tapped with 10–32 UNF–2B threads.

Originally, the studs were fastened to the chassis by manual gas tungsten-arc welding, but the position and spacing of many of the pads made manual welding difficult and time consuming.

Processing was changed to stud welding, and the arc process was chosen because of the stud weld-base diameter. Also, the 400-amp motor-generator that was used as the power supply for gas tungsten-arc welding provided current with a drooping volt-ampere characteristic and could be used for arc stud welding. Argon shielding gas was used to protect the aluminum alloy base metal and stud.

To prepare for stud welding, the surface of the chassis was cleaned with a stainless steel wire brush just before welding. The studs could not be tapped through because the full base was needed for arc initiation and a full-strength weld.

The plunge adjustment of the gun was critical for good welds. To preload the main plunging spring properly, the stud extended ⅛ to 3/16 in. beyond the gas adapter.

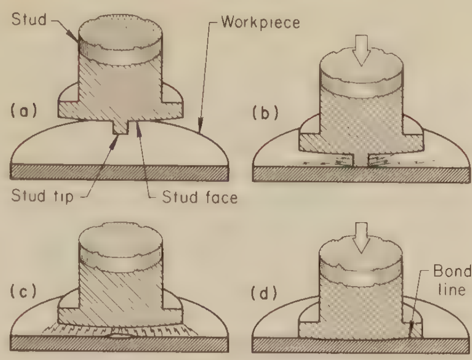
Welding time for the ½-in.-diam stud was 40 ± 2 cycles and the welding current was 640 amp. For the 7/16-in.-diam stud, the welding time was 30 ± 2 cycles and welding current was 570 amp. Reverse polarity was used for both diameters of the studs.

Production time for welding was reduced 60% by the use of stud welding instead of manual gas tungsten-arc welding.

Capacitor-Discharge Stud Welding

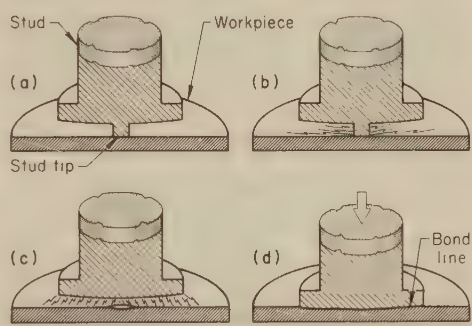
Capacitor-discharge stud welding uses the heat from an arc produced by the rapid discharge of a capacitor. A small tip or projection on the end of the stud is suddenly disintegrated and an arc is initiated. This produces a thin film of molten metal on the end of the stud and on the workpiece adjacent to the stud. The stud is forced into the molten puddle of metal, which extinguishes the arc and completes the weld. Flux is not needed in welding steel; argon shielding sometimes is used in welding aluminum alloys by the drawn-arc method.

There are three methods of capacitor-discharge stud welding: the initial-gap, initial-contact, and drawn-arc methods. The initial-gap and initial-contact methods have a weld time of 3 to 6 milliseconds, which prevents heat buildup and permits welding of fasteners about 5/32 in. in diameter to a steel base metal as thin as 0.030 in. without pronounced distortion, discoloration or burn-through. Weld penetration is slight, which permits many dissimilar metals to be welded with acceptable strength and metallurgical structure. Also, paint, plating or plastic coating on the surface opposite the weld is not damaged. Teflon coating on the inner surface of 0.040-in.-thick aluminum pans is not damaged when studs are welded to the outer surface. Small fastener-component cups made of low-carbon steel, stainless steel, aluminum alloy, or copper alloy have been capacitor-discharge welded to various base metals.



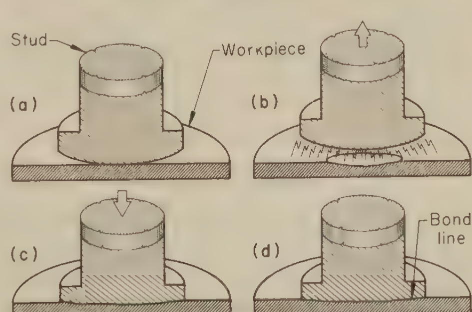
(*a*) The stud is initially positioned above the workpiece. (*b*) When the unit is triggered, the stud holder is released and plunges the stud to the workpiece with the capacitor-discharge voltage impressed on the stud. When the stud tip contacts the workpiece, welding current starts to flow and an arc is formed. (*c*) The tip disintegrates when it contacts the workpiece. Arcing between the stud and the workpiece melts the face of the stud and the workpiece surface opposite the stud face to a very shallow depth. (*d*) The stud is plunged into the puddle of molten metal, to complete the weld.

Fig. 7. Sequence of steps in initial-gap capacitor-discharge stud welding



(*a*) The stud is initially in contact with the workpiece. (*b*) When the welding current is turned on, the tip softens and disintegrates, and the arc is initiated. (*c*) Arcing between the stud and the workpiece melts the face of the stud and the workpiece surface opposite the stud face to a very shallow depth. (*d*) The stud is plunged into the puddle of molten metal, by spring pressure, to complete the weld.

Fig. 8. Sequence of steps in initial-contact capacitor-discharge stud welding



(*a*) The stud is initially in contact with the workpiece. (*b*) When the current is turned on, the current surges into the stud tip, and the stud is then immediately raised, to draw the arc. The heat of the arc melts the face of the stud and the workpiece surface opposite the stud face to a very shallow depth. (*c*) When the welding current is turned off, the solenoid in the gun is de-energized and the stud plunges into the puddle of molten metal. (*d*) Finished weld, with little or no fillet.

Fig. 9. Sequence of steps in drawn-arc capacitor-discharge stud welding

The drawn-arc method has an arc time of 6 to 12 milliseconds; it is the method best suited for base metals that have light rust, mill scale, or surface irregularities.

Straight polarity (stud negative, workpiece positive) is used for capacitor-discharge welding.

Procedures and characteristics of the three types of capacitor-discharge stud welding are described below.

Initial-Gap Welding. In this method, the stud is positioned away from the surface of the workpiece, as shown in Fig. 7. The gun has a solenoid that holds the stud away from the workpiece and a means for moving the stud toward the workpiece rapidly.

When the gun is triggered, the stud holder is released and plunges toward the workpiece with the capacitor-discharge voltage impressed on the stud. As the stud tip contacts the workpiece, welding current starts to flow and an arc is formed that disintegrates the tip. The arc melts metal on the face of the stud and on the workpiece surface opposite the stud. Continued movement of the stud extinguishes the arc and forges the stud into the workpiece. Welding force is usually 5 to 7 lb.

The high-intensity arc has a duration of 3 to 6 milliseconds, and the melted surface layer on each part is only a few thousandths of an inch thick. Because of the brief energy span, the reverse side of the workpiece is almost never marked. There is very little weld spatter at the base of the stud, and a clean weld is produced.

Initial-Contact Welding. In this method, the stud is initially placed in contact with the workpiece as shown in Fig. 8. The gun does not contain a solenoid, but has a means for moving the stud toward the workpiece rapidly. When the gun is triggered, the welding current disintegrates the tip on the stud and an arc is initiated. This causes metal to be melted on the face of the stud and in the area on the workpiece opposite the stud. A welding force of 5 to 7 lb plunges the stud into the molten puddle of metal, which extinguishes the arc and completes the weld.

As in the initial-gap method, the high-intensity arc has a duration of 3 to 6 milliseconds, and the melted surface layer on each part is only a few thousandths of an inch thick. The weld is completed with little reverse-side marking.

Drawn-Arc Welding. In this method, the stud is initially in contact with the workpiece and is then withdrawn to initiate the arc, as shown in Fig. 9. The gun is fitted with a solenoid to withdraw the stud and has a means for moving the stud toward the workpiece rapidly. Welding force is usually 10 to 12 lb.

The high-intensity arc has a duration of 6 to 12 milliseconds; therefore, the layer of molten metal on the stud and workpiece is slightly thicker than for the other capacitor-discharge methods. Also, the work surface can be more rough, pitted and scale coated than for the other two methods.

The power supply is an electrostatic storage system in which the weld energy is stored at low voltage in capacitors having a high capacitance. Because energy is stored, power requirements are low. For portable or hand-held guns, the capacitors are charged by a 115-volt, alternating-current, single-phase power supply. Production models or bench models operate on 230 to 460-volt, alternating-current, single-phase or three-phase power. The output rating of the capacitors ranges from 40,000 to 200,000 microfarads.

Solid-state control units supply signals for several purposes: to energize the solenoid in the welding gun for the initial-gap and drawn-arc methods; to initiate the pilot arc; to de-energize

the solenoid when applicable; and to discharge the required welding current from a bank of capacitors. Precise timing of functions makes possible the exact timing sequence required for maximum performance under a given set of conditions, or for a wide range of conditions. Because of the short, precise timing needed, electromechanical or electrical controls are unsatisfactory for capacitor-discharge stud welding.

Studs can have a shank of any shape, but the weld base must be round. Most studs have a flanged or enlarged base. (A larger weld base provides a stronger weld.) The weld-base diameter of the stud generally ranges from 1/16 to 5/16 in. The maximum diameter is usually 3/8 in.

For the initial-gap and the initial-contact methods, the weld end is provided with a tip that is carefully designed for each application. The tip is small and cylindrical or conical. These tips are used to initiate the arc. Studs for the drawn-arc method have a pointed or convex shape on the end to be welded. This shape helps to initiate the arc at the center of the stud and prevents arcing at the periphery of the stud when it is held one or two degrees from perpendicular with the workpiece. Studs for the drawn-arc method are similar to round-weld-base studs used for arc stud welding, but they have a larger nose radius (flatter tip), because no flux is used and there is less melting at the end of the stud.

In addition to the tip, only a small amount of metal is melted from the stud, which means that the welded length is almost the same as the unwelded length. Standard studs have a minimum length of 3/8 in., but studs for automotive trim are 5/32 in. long.

Standardization of stud size is desirable for efficiency in production-line operations on related or similar items. In Example 172, aluminum studs were standardized so that they could be used for attaching handles to more than one type of utensil.

Stud Location. The method of locating studs depends on several factors, such as the accuracy requirements, whether the welding gun is fixed or portable, the production rate, and the size and shape of the workpiece.

Accuracy of location when the welding gun is portable depends on the care in laying out the workpiece. The use of templates with bushings can result in locational tolerances of ±0.020 in. or less. Because the tips on the weld end of the studs used for the initial-contact and initial-gap methods are carefully designed to maintain the required arc, centerpunch marks cannot be used; very lightly scribed lines are suggested when use of templates is uneconomical.

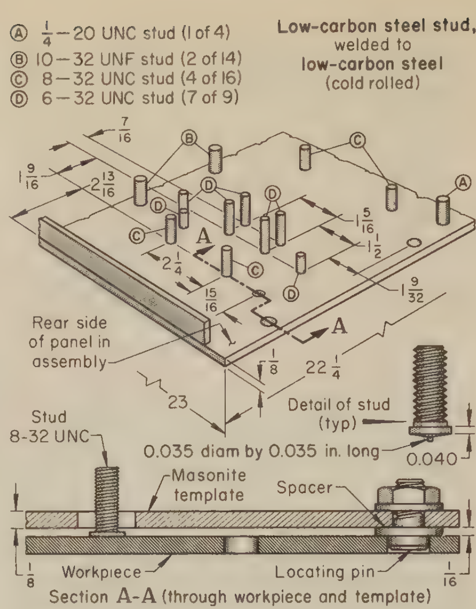


Fig. 10. Mounting base on which studs for electrical components were capacitor-discharge stud welded, and the locating template used (Example 170)

In the following example, a masonite template located the studs to a tolerance of ±1/32 in.

Example 170. Capacitor-Discharge Stud Welding of Mounting Studs to an Electrical Panel (Fig. 10)

The mounting base for the power-supply components of a small telephone system was a 22¼-by-23-by-⅛-in. panel of cold rolled low-carbon steel (Fig. 10). Originally, holes were drilled in the panel, and then machine screws were inserted and held by an assembler from the front of the panel while a second man positioned the components and secured them with nuts from the rear.

Processing was changed to initial-contact capacitor-discharge stud welding, and 43 low-carbon steel studs were welded to the panel. Components were then placed over the studs and secured with nuts from the rear of the panel by one assembler.

The studs, which had a flanged weld base, were 3/8, 1/2 and 5/8 in. long and had full-length threads. Nine studs had 6–32 UNC threads; sixteen had 8–32 UNC threads; fourteen had 10–32 UNF threads; and four had ¼–20 UNC threads.

For welding, the panel, with the ground cable attached, was placed flat on a workbench. A masonite template with locating holes spaced as needed located the studs to a tolerance of ±1/32 in. (Fig. 10). The holes were color coded according to the stud length and diameter, and fit the nose of the welding gun. Spacers 1/16 in. thick between the template and panel prevented template damage from arcing and also permitted the gases developed during welding to escape.

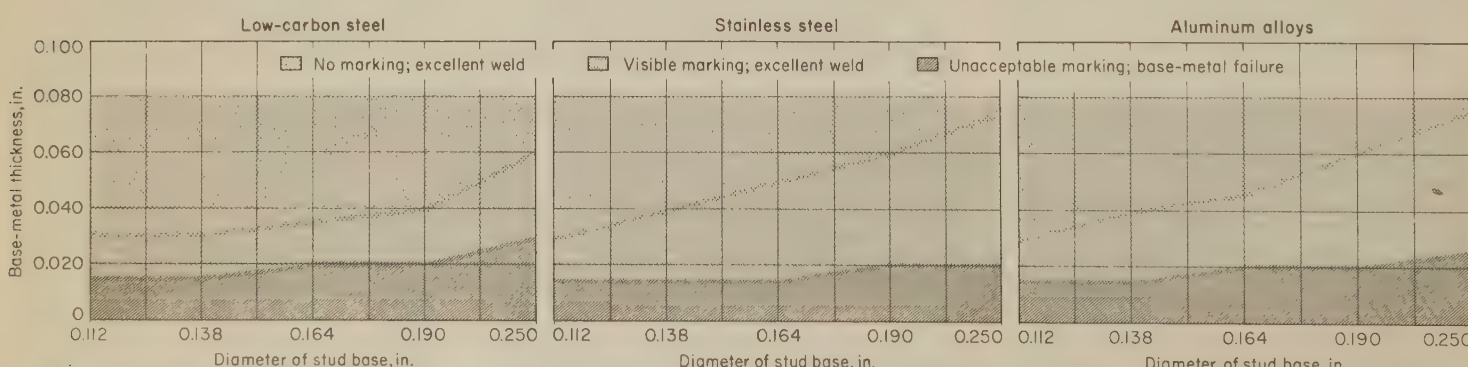
The 10-amp power supply had a nominal available capacitance of 65,000 microfarads, and was charged by 115-volt, single-phase alternating current. The capacitor-discharge output voltage was changed for each stud diameter; otherwise, excessive spatter occurred when the smaller studs were welded with the same voltage used for the ¼-in.-diam studs.

Total welding time was about 3 sec per stud; production was 15 panels per hour.

Production units equipped with various types of workholding and locating tooling can provide tolerances of ±0.008 in. or less. Precise location requires high-quality welding equipment, tooling and fasteners.

Base-metal thickness vs stud size is of interest when the appearance of the product is a prime consideration. Reverse-side marking is the principal effect involved in appearance. In some applications, especially where the largest possible stud diameter is desired for a given base-metal thickness, slight-to-heavy reverse-side marking is acceptable. Figure 11 shows the degree of reverse-side marking that occurs on the base metal for different stud-base diameters when welding similar combinations of low-carbon steel, stainless steel, and aluminum alloys. The data shown in Fig. 11 were compiled by welding both flanged and nonflanged studs to the base metal in a bench-type automatic or semiautomatic stud welder, using the initial-gap capacitor-discharge method.

Honeycomb panels in which face sheets are brazed to the core occasionally have small unbonded areas that can be repaired by passing a stud through the cover sheet and core and then capacitor-discharge stud welding one end to the inner surface of the lower sheet, as described in the following example. The other end of the stud is then gas tungsten-arc welded to the outer surface of the top sheet. This type of repair can be used when the underside of the panel is not accessible,



Degree of reverse-side marking that occurs on the base metal for different stud diameters when welding similar combinations of low-carbon steel, stainless steel, and aluminum alloy. The areas are separated by bands rather than sharp lines, because the point at which a combination will produce reverse-side marking or base-metal failure is difficult to determine with precision.

Fig. 11. Effect of stud diameter and base-metal thickness on reverse-side marking in initial-gap capacitor-discharge stud welding

or when a through hole and weld on the underside can cause a leak — for instance, when the face sheet forms part of a fuel-tank enclosure. When feasible, plain pins are used that extend through the honeycomb panel and are gas tungsten-arc welded to the exposed faces of the panel.

Example 171. Repair of Stainless Steel Honeycomb Panels by Capacitor-Discharge Welding (Fig. 12)

The unbonded area in the honeycomb panel shown in Fig. 12 was repaired by stud welding one end of a ⅛-in.-diam type 321 stainless steel stud to the inner surface of the 0.040-in.-thick PH 15-7 Mo stainless steel bottom sheet. The other end of the stud was subsequently gas tungsten-arc welded to the top sheet.

A portable capacitor-discharge welding gun, with the controls set for the initial-gap method, was used. Both cables were uncoiled and extended so that welding current would be consistent. Straight-polarity direct current was used.

Extreme care was taken in preparing the panel for stud welding. The location of the stud on the top sheet was marked by a small centerpunch indentation, and then a small pilot drill was used to make a hole through the top sheet and the core. Next, the hole was enlarged to 5⁄32 in. in diameter, to within 1⁄16 in. of the bottom sheet. Drill stops prevented drilling too deep, which would have damaged the inner face of the bottom sheet. A flat-bottom drill and a flat end-mill were then used to remove the remaining core and any brazing alloy on the bottom sheet. Drill chips and pieces of the core and brazing alloy were removed with an electromagnet and a vacuum nozzle small enough to enter the hole. The depth of the hole was measured with a depth micrometer, so that the stud welding gun could be set for the proper initial gap of 0.085 in.

After the hole had been properly prepared, a plastic insulator, which insulated the top sheet and core from the stud, was placed in the hole (Fig. 12). The stud, which was held by the stud holder in the gun, was then positioned in the insulator. The gun was held so that the stud was perpendicular to the surface to which it was to be welded.

After stud welding, a gas tungsten arc was used to cut off the portion of the stud extending beyond the top sheet. Cutting the stud to length with a saw would have damaged the stud weld unless special precautions were taken.

The top of the stud was then gas tungsten-arc welded to the top sheet, and the bead was ground flush, if this was required by the application.

Several sample welds were made and tested to determine whether the proper machine settings had been selected. The sample stud weld and the production weld were tested by applying a torque wrench to a special stud-gripping tool. A minimum torque of 10 in.-lb was specified.

The minimum honeycomb facing-sheet thicknesses and torque values for studs of various diameters are:

Stud-base diameter, in.	Minimum sheet thickness, in.	Minimum torque, in.-lb
1⁄16	0.008	1
3⁄32	0.012	4
⅛	0.018	10
3⁄16	0.025	30
¼	0.035	75

A backing block of copper must be used to minimize burn-through and prevent distortion if sheet thickness is less than 0.030 in.

Cooking Utensils. Studs are welded to cooking utensils and lids made of copper, stainless steel, and natural-finish or coated aluminum alloys for attaching handles and legs. The studs can be round, hexagonal, square, rectangular, or trapezoidal, and stud length can vary from as short as can be held in a stud holder to 2 in. Studs are drilled and tapped, drilled for self-tapping screws, slotted, or supplied with threaded extensions.

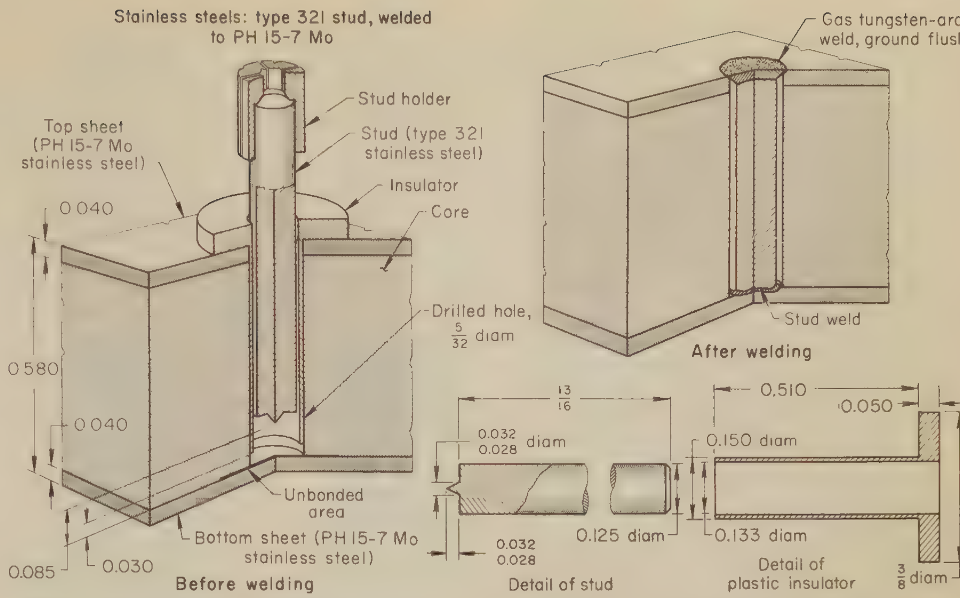


Fig. 12. Stainless steel honeycomb panel that was repaired by capacitor-discharge stud welding and subsequent gas tungsten-arc welding to close the hole (Example 171)

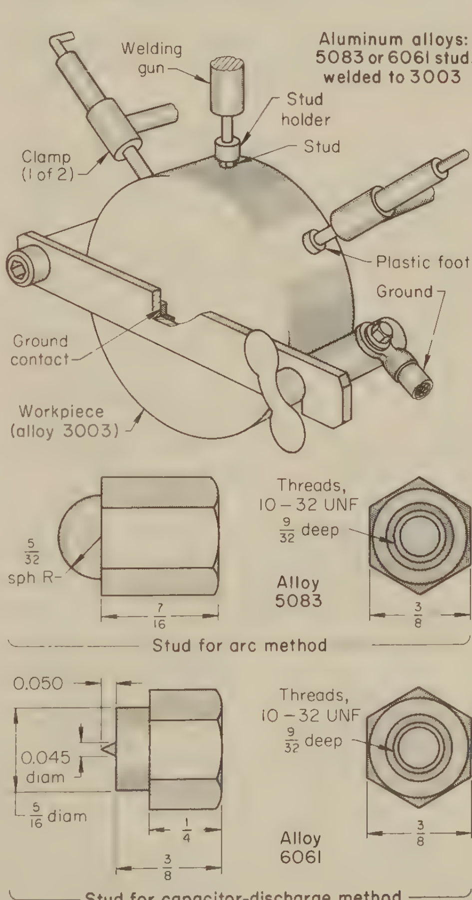

Fig. 13. Tooling arrangement for welding a female stud made of aluminum alloy to an aluminum alloy cooking utensil. Capacitor-discharge stud welding replaced arc stud welding, which had replaced brazing. (Example 172)

Formerly, handles were attached to utensils by riveting, brazing, or resistance spot welding. Knobs were attached to lids by spot welding or by machine screws through a hole in the lid. The introduction of Teflon-lined pans and colored enameled pans made riveting and spot welding undesirable, and stud welding was used. A comparison of arc and capacitor-discharge stud welding for attaching aluminum alloy studs to Teflon-coated and natural-finish aluminum alloys is given in Table 2.

In the example that follows, aluminum studs were arc stud welded to cooking utensils made of aluminum without discoloring the inner surface or distorting the sidewalls. However, when the wall thickness was reduced and a Teflon coating was added to the inner surface of the utensil, the studs were capacitor-discharge stud welded, because weld penetration was less than with arc stud welding.

Example 172. Attaching Studs to Aluminum Cooking Utensils by Arc and Capacitor-Discharge Stud Welding (Fig. 13)

When aluminum alloy 5083 studs were arc stud welded to the body of ⅛-in.-thick alloy 3003 utensils, a setup similar to that shown in Fig. 13 was used. The workpieces were cleaned by vapor degreasing before stud welding.

The arc stud welding machine had a power rating of 85 kva. The secondary welding current was 220 amp. Argon shielding gas and ceramic ferrules were used to control weld quality. Burn-off of the studs was about 3⁄32 in. Air-operated clamps were used on each side of the gun, for fixturing, as shown in Fig. 13. The surfaces of the clamps contacting the workpiece were made of plastic or some other nonconductor of electricity, to prevent arcing at the contact points. The ground connection was made by a shoe on the bottom of the pan where pits produced by arcing would be less noticeable or objectionable.

Welding time was 12 cycles, and one operator could weld 300 studs (300 utensils) per hour using a column-mounted gun and a cast epoxy locating fixture. The relative position of the gun and fixture was adjustable, to ensure correct location of the stud on the pan body. Maintaining a production rate of 300 utensils per hour in

brazing (the operation previously used) had required three brazers, one man for removing flux, three buffers, and one part-time worker who resized the utensils that were distorted by the brazing operation.

The process was changed to initial-gap capacitor-discharge stud welding when the thickness of the pan was reduced and a Teflon coating was applied to the inner surface. Weld penetration was less than for arc stud welding, and thus the Teflon coating was not damaged; also, the heat-affected zone was smaller. Studs of aluminum alloy 6061 were used, and were standardized so that they could be used on several types of utensils.

The input power to the capacitors was 440-volt, 20-amp, three-phase, 60-cycle alternating current. The capacitors had a maximum rating of 200,000 microfarads. Welding time was 4 milliseconds, and the production rate was 900 pans per hour. The gap between the stud and pan was not critical and was set at 1½ in. for ease of loading and unloading the fixture. The fixture used for capacitor-discharge stud welding was similar to that used for arc stud welding.

The handle assembly, which consisted of an aluminum ferrule, a plastic handle, and a threaded bolt, was accurately tightened by an air-operated torque wrench.

At the beginning of each shift, or when restarting the machine after a long shutdown, sample welds were made and torque tested to destruction. During production, studs were nondestructively tested at a predetermined torque at random intervals.

Both stud welding methods provided a joint as strong as those made by riveting, brazing, and spot welding.

Metals Welded

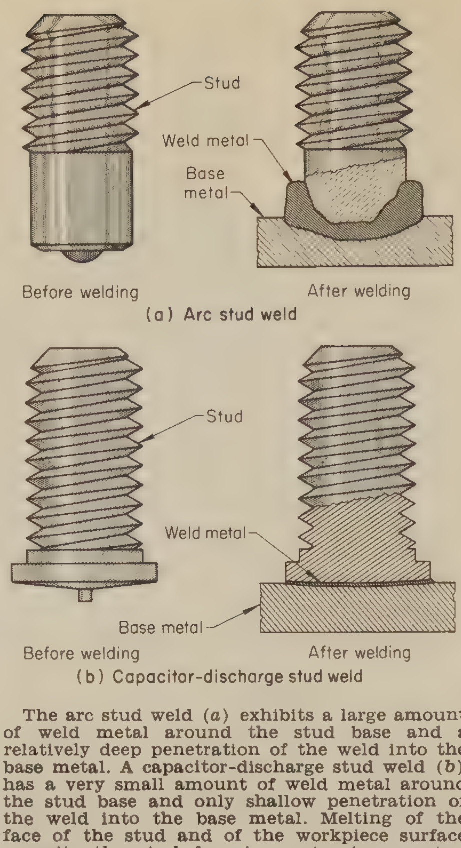
All metals that are readily welded by other arc welding processes are suitable as base metals for stud welding, with proper selection of stud metal. The electrical resistivity and melting temperature of the parts to be joined have little effect on the weld, if both parts are electrical conductors. Table 4 lists typical combinations of base metal and stud metal that have been welded.

Stud welding of various base metals is discussed in the following sections.

Carbon steel workpieces with a carbon content of 0.30% or less usually can be stud welded without preheating. Provided the diameter of the stud is in proper relation to the thickness of the base metal, steel with more than 0.30% C, in thicknesses of less than ⅛ in., can be stud welded without preheating, because of the lower quenching effect of the base metal.

Stud welding of the medium-carbon steels (1030 to 1050) generally is successful, provided the correct preheating and postheating procedures are followed, as discussed next for high-carbon steels.

High-Carbon Steel. In stud welding steel with 0.45% C or more, martensite, a hard, brittle constituent, forms in the steel base metal under the stud. In effect, the base metal has been spot hardened, and the hardening is usually accompanied by cracking. In welding plain carbon steel of high carbon content, preheating of the base metal is suggested because it prevents formation of cracks. Postheating is less effective because cracks have already formed, but it will prevent the propagation of cracks. Depending on the carbon content of the steel base metal, a typical preheating temperature is 700 F and a typical postheating temperature is 1200 F. The hardenable alloy steels are either preheated or postheated, or both, depending on the product requirements.



The arc stud weld (*a*) exhibits a large amount of weld metal around the stud base and a relatively deep penetration of the weld into the base metal. A capacitor-discharge stud weld (*b*) has a very small amount of weld metal around the stud base and only shallow penetration of the weld into the base metal. Melting of the face of the stud and of the workpiece surface opposite the stud face is greater in arc stud welding than in capacitor-discharge stud welding.

Fig. 14. Sections through low-carbon steel studs that were arc and capacitor-discharge stud welded to low-carbon steel base metals

When considering stud welding of high-carbon steel, sample pieces should be welded experimentally, to determine whether the operation is feasible.

Table 4. Typical Combinations of Base Metal and Stud Metal for Stud Welding

Base metal	Stud metal
Arc Stud Welding	
Low-carbon steel, 1006 to 1025	Low-carbon steel(a); stainless steel, series 300(b)
Stainless steel, series 300(b), 405, 410 and 430	Low-carbon steel(a); stainless steel, series 300(b)
Aluminum alloys, 5000 series	Aluminum alloy 5086
Capacitor-Discharge Stud Welding	
Low-carbon steel, 1006 to 1025	Low-carbon steel(a); stainless steel, series 300(b); copper alloys 260 and 268
Stainless steel, series 300(b) and 400	Low-carbon steel(a); stainless steel, series 300(b); copper alloys 260 and 268
Aluminum alloys, 1100, 3000 series, 5000 series, 6061 and 6063	Aluminum alloys 1100 and 5086
ETP copper, lead-free brass and rolled copper	Low-carbon steel(a); stainless steel, series 300(b); copper alloys 260 and 268
Zinc alloys (die cast)	Aluminum alloys 1100 and 5086

(a) 0.23% C max, 0.60% Mn max, 0.04% P max and 0.05% S max. (b) Except for the free-machining type 303 stainless steel.

Low-alloy high-strength steels and most structural steels with a carbon content of more than 0.15% may require moderate preheating, to obtain required toughness in the weld area. An oxy-fuel gas heating torch can be used, because only a localized preheated zone is needed.

Some heat treatable structural steels are sufficiently hardenable in the heat-affected zone to be sensitive to underbead cracking. For maximum toughness, preheating at 600 to 700 F is necessary.

Galvanized Steel. In the construction of buildings and bridges, arc stud welding can be used to weld low-carbon steel shear connectors and concrete anchors directly to steel beams by burning through the galvanized metal decking, without prepunching it. Steel decking up to 0.064 in. thick that is black or bare, or has been electrogalvanized, or has been hot dip galvanized and wiped and has a coating of 0.50 oz of zinc per square foot can be burned through with ½, ⅝ or ¾-in.-diam studs, provided enough welding current is used. Hot dip galvanized sheet 0.040 in. thick coated with 1¼ oz of zinc per square foot also can be burned through. Steel decking 0.060 in. thick coated with a weldable grade of paint (two coats on the bottom side only or one coat on each side) can be burned through using ½-in.-diam studs. Painted sheets that are 0.048 in. thick can be burned through with ⅝ and ¾-in.-diam studs. Specially designed ferrules are used for all coated metals.

The areas on the steel beams to which the studs are to be welded should be cleaned of scale, rust or dirt by wire brushing or grinding, and the steel decking should be free of dirt, water, snow and ice.

Ductwork and other products of galvanized steel can have low-carbon steel studs welded to them. Such studs are used to support insulation, wiring and piping; the welds have adequate strength for this purpose.

Stainless Steel. The austenitic stainless steels 302, 304, 305, 309, 310, 316, 321 and 347 can be arc and capacitor-discharge stud welded. Martensitic stainless steels are subject to air hardening and usually are brittle in the weld area and heat-affected zone unless annealed after welding.

The power requirements for welding stainless steel studs are about 10% greater than those required for welding carbon steel studs.

Stainless steel studs can be welded to stainless steel and to low-carbon steel base metals. Because of dilution of chromium from a stainless steel stud by a low-carbon steel base metal, the resulting weld metal may have a high hardness, especially if the carbon content of the base metal is more than 0.20%. Such difficulties can be minimized by using fully annealed studs with a higher chromium-nickel content. Free-machining stainless steel studs are not readily stud welded.

Aluminum alloys can be welded by both the arc and capacitor-discharge methods, but more are welded by the capacitor-discharge method.

Aluminum alloys of the 1100, 3000 and 5000 series generally are excellent for stud welding; alloys of the 4000 and 6000 series are acceptable; alloys of the 2000 series are poor.

The power supply, welding gun, and controls are the same as those used for steel. Argon or helium shielding gas is required. Reverse-polarity direct current (stud positive, workpiece negative) is used.

Studs are made of aluminum-magnesium alloys, including 5086, 5356 and 6061, and of alloy 1100. The aluminum-magnesium alloys have high strength and good ductility and are metallurgically compatible with most of the other aluminum alloys.

A longer arc is needed for welding aluminum alloy studs than for welding steel studs. A cylindrical or conical projection on the end of the stud helps to initiate the arc and to establish the longer arc.

Longer weld times and lower welding currents are used for welding aluminum alloys than for welding low-carbon steel, as shown in Table 3.

Magnesium alloys have been arc stud welded in a test program. High-strength welds were made with a gas shield and reverse-polarity direct current. Ferrules were not used. Helium shielding gas was preferred over argon, because it provided a wider range of welding times and higher-strength welds. (For data, refer to: L. F. Lockwood, Gas-Shielded Stud Welding of Magnesium, *Welding Journal*, April 1967.)

Zinc alloy die-cast parts can have fasteners stud welded to them instead of cast integrally. The fasteners can be welded to the parts without destroying the decorative coatings that have been previously applied. In the automotive industry, stud welding has been used for attaching fasteners to emblems, dashboards and taillight brackets that were zinc alloy die cast.

Studs of aluminum alloy 1100-H18 are most successful, but studs of aluminum alloy 5086, copper alloys, low-carbon steel, and stainless steel have been used for limited applications, or where greater stud strength was needed. In one application, a ¼-in.-diam aluminum alloy stud was stud welded to a zinc die-cast part with a capacitor-discharge machine set for 150 volts and 100,000 microfarads. Peak amperage was 7000. Weld time was 5 milliseconds. (Source: E. J. Fay, Welding Fasteners to Zinc Die Castings, paper presented at Third National Die Casting Exposition and Congress, Detroit, Nov 17-20, 1964)

Inspection and Quality Control

Stud welds are inspected visually or mechanically.

Visual inspection depends on an inspector's interpretation of the fillet around the stud base. An arc stud weld has a pronounced fillet; a capacitor-discharge weld has a very small fillet.

A section through a satisfactory arc stud weld is shown in Fig. 14(a). Much of the molten metal in the weld puddle was forced out from under the stud and retained by the ferrule, but some metal remained at the base of the stud. Heat-affected zones occur in both the stud and the base metal.

A section through a capacitor-discharge weld (Fig. 14b) shows a very small fillet. The heat-affected zones on the stud and in the base metal are very shallow, but the weld is sound.

A satisfactory fillet on an arc stud weld and some typical defective welds are shown in Fig. 15. A well-formed fillet is shown in Fig. 15(a). Figure 15(b) shows an incomplete weld that resulted because a malfunction in the gun prevented plunging of the stud at the end of arcing. If the gun is not held perpendicular to the surface of the workpiece, a partial fillet can result, because of cocking of the ferrule, which allows weld metal to escape, as shown in Fig. 15(c). A plunge that is too short will result in a partial fillet because not enough metal is extruded from the weld puddle, as shown in Fig. 15(d). A partial weld can also result when foreign material is present that impedes melting during arcing. The results when temperature is too low and too high are shown, respectively, in Fig. 15(e) and (f). The electrical connections, power setting, time cycle and arc length should be checked when a cold weld occurs. The power setting or the time cycle, or both, should be decreased when temperature is too high.

In a good weld formed by the capacitor-discharge method, the stud is perpendicular to the workpiece, with very little weld spatter around the base and a weld fillet that is very thin and even (see Fig. 14b). Incomplete welds can result from a malfunction of the gun or from an inadequate plunge, as in arc stud welding. If the welding tool is not held perpendicular to the workpiece, the stud will be tilted and a partial weld will be produced at the edge of the stud contacting the workpiece.

A cold weld is produced when the base of the stud is not melted to the edge and only a small area in the center of the stud is fused. This can be corrected by increasing the power-discharge setting. Excessive weld spatter and weld metal encasing the base is called a hot weld; it is usually caused by a power-discharge setting that is too high. A hot weld usually burns through thin sheet.

Mechanical testing of studs usually is done before starting a production run, to determine whether satisfactory welding schedules have been developed, and before each shift and during a production run, to ensure that welding conditions have not changed.

Stud welds are tested by applying torque until a predetermined torque load is reached or until failure occurs. The torque load applied and the number of studs tested depend on the application requirements.

Stud welds are also tested by bending. The stud is struck with a hammer or bent with a short length of tube placed over it. If the weld is good, any failure will occur in the shank of the stud or in the base metal. Some applications specify that the stud be bent 45° to 90° from its axis without failure; for other applications, a bend of 10° to 15° is adequate.

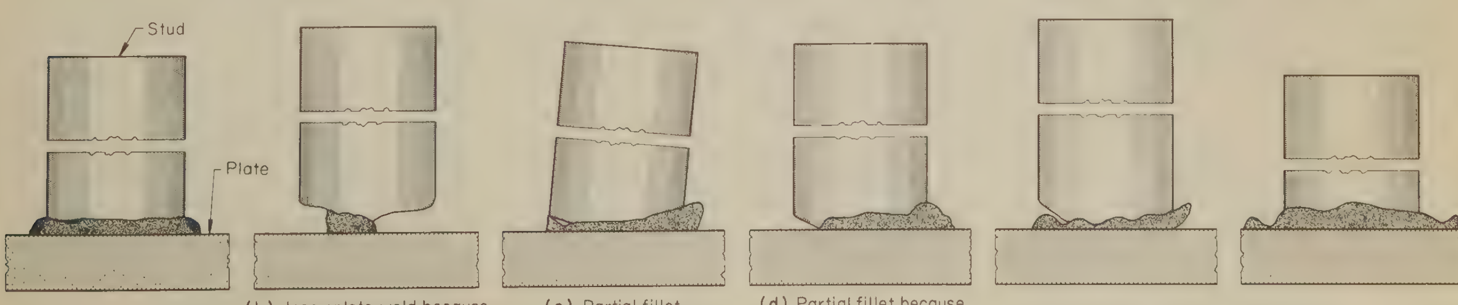
Aluminum and brass studs should not be bent with a hammer; a tube-type bending tool should be used.

Because bend tests can damage the studs so that they are usable only in very low-stress applications, bending should be done on samples, not on production parts. However, there are some applications in which the stud can be bent and used as is, or can be bent, straightened and then used — provided that no failure of the stud, the base metal or the weld occurred during the bend test or during straightening.

Stud Welding vs Alternative Processes

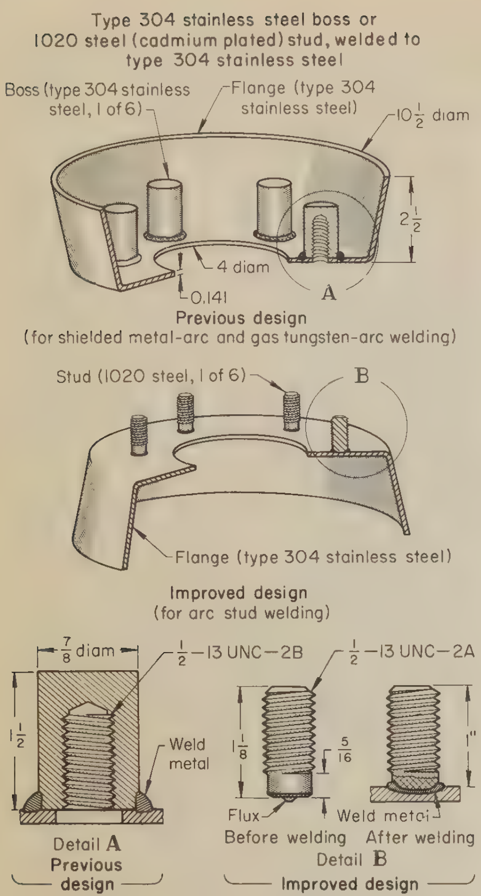
Stud welding is frequently selected over other processes because of good appearance of the workpiece, accessibility of the workpiece surface, requirements for airtight and watertight joints, and the need for complete fusion to minimize electrical resistance and to obtain good heat transfer.

Arc stud welding replaced gas tungsten-arc welding in Example 169. In Example 170, capacitor-discharge welded studs were used instead of screws and nuts. Arc stud welding replaced brazing in Example 172, but was replaced by capacitor-discharge stud welding when the base metal was changed.



(a) Well-formed fillet (b) Incomplete weld because of malfunction in gun (c) Partial fillet because of tilted gun (d) Partial fillet because plunge too short (e) Cold weld (f) Hot weld

Fig. 15. Well-formed fillet on an arc stud weld (left) and typical fillet defects. Capacitor-discharge welded studs have similar characteristics (see text for discussion).



Item	Gas tungsten-arc welding	Arc stud welding
Cost per Piece		
Fabrication:		
Setup	$0.035	$0.016
Operating	1.592	0.041
Assembly:		
Setup	0.032	0.004
Operating(a)	0.787	0.167
Material	4.188(b)	0.675(c)
Total cost per piece	$6.634	$0.903
Total savings per piece		$5.731

(a) Includes welding and testing for air leaks or strength of weld. (b) Includes cost of six screws, six bosses, and welding supplies. (c) Includes cost of six studs and nuts.

Fig. 16. Stainless steel valve-outlet flange for which weld quality was improved by changing from shielded metal-arc to gas tungsten-arc welding, then to arc stud welding. Costs were greatly reduced when flange was redesigned for arc stud welding. (Example 173)

In manual arc welding, slag inclusions and start-and-stop overlaps affect weld quality and can cause porosity. For airtight joints, porosity cannot be tolerated. In the next example, stud welding improved weld quality, provided a strong joint, and reduced cost by more than 85%.

Example 173. Cost Comparison for Gas Tungsten-Arc Welding vs Stud Welding of Fasteners to Valve Outlet Flanges (Fig. 16)

The type 304 stainless steel drain-valve outlet flange shown as the Previous design in Fig. 16 was made by welding six tapped bosses ⅞ in. in diameter by 1½ in. long to the flange. Originally, welding was done by the shielded metal-arc process, using ⅛-in.-diam E308-16 stainless steel electrodes.

The flanges were placed in a combination welding-and-leak-test fixture, and the bosses were welded to the inner surface of the flange, as shown in Fig. 16 (Previous design). Dowel pins with small holes for the passage of compressed air for testing purposes were used to locate the flange and the bosses on a 6¼-in.-diam bolt circle. The pins extended through the flange and into the tapped holes in the bosses. Before the workpiece was removed from the fixture, the welds were air tested for leaks with the aid of a soap solution.

Welds made by the shielded metal-arc process were not of uniform quality and slag entrapment and start-and-stop overlaps occurred. Weld quality was improved by changing to manual gas tungsten-arc welding, but greater operator skill was needed and welding costs were higher.

Arc stud welding was then recommended. Because of engineering requirements, the following changes and tests were made before stud welding was adopted:

1. A fillet about ⅝ in. in diameter that formed around the base of the stud in arc stud welding interfered with leakproof sealing of the valve to the outlet flange, even though a 3/32-in.-thick cork gasket was used between the parts. To overcome this drawback, the hole size in the valve flange was changed from 9/16 to ⅝ in. in diameter.
2. The original specification called for studs of type 304 stainless steel. After tests showed that cadmium-plated low-carbon steel studs were as resistant as stainless steel studs to the particular service environment, the use of cadmium-plated cold drawn 1020 steel studs and nuts was approved. This contributed to a lower material cost.
3. Torque and tension tests were made on sample welds to determine that they had adequate strength, because field failures could occur at weld joints not strong enough to withstand the torque needed to tighten the flange to the valve, and a broken stud would be difficult to replace in the field.

Studs with a weld-base diameter of 7/16 in. and with flux attached to the tip were arc stud welded to the outer surface of the flange, as shown in Fig. 16 (Improved design). The flange was clamped to an indexing fixture that was positioned beneath a column-mounted stud welding gun. Because the stock thickness (0.141 in.) was such that burn-through could occur, the fixture also served as a backing and chill.

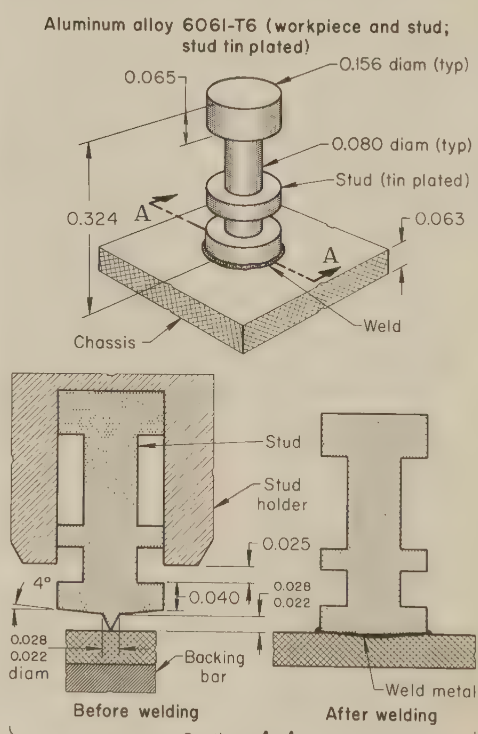


Fig. 17. Tin-plated 6061-T6 stud that was capacitor-discharge stud welded to a 6061-T6 electronic chassis (Example 174)

The power-supply unit had an output rating of 1500 amp. The stud, with flux attached to the tip, extended 3/32 to ⅛ in. below the ferrule when both were inserted in the gun.

Stud welding resulted in improved appearance because only a small heat spot showed on the inner surface of the flange. Also, a leak test was unnecessary because there were no holes in the flange.

Based on a production-lot size of 400 units, the average welding time was 2.87 minutes per piece.

Costs for gas tungsten-arc welding and stud welding are compared in the table accompanying Fig. 16. Savings per unit for stud welding was $5.73, or a yearly total savings of $13,385 for 2336 flanges.

Low-resistance electrical connections and low-cost, reliable joints are required for chassis for electronic equipment. With the aluminum alloys frequently used for the chassis, low-temperature soldering techniques seldom provide the necessary joint reliability. In the following example, tin-plated aluminum connectors were capacitor-discharge stud welded to a chassis, instead of being secured mechanically, to improve joint reliability, and reduce production time and cost.

Example 174. Capacitor-Discharge Welding of Studs to an Aluminum Electronic Chassis (Fig. 17)

Originally, the assembly shown in Fig. 17 was made by mechanically securing the stud to the chassis. Both components were made of aluminum alloy 6061-T6. A better joining method was required when the size of the electronic chassis was reduced, production quantities were increased, and more-reliable electrical connections were needed.

Initial-contact capacitor-discharge stud welding was selected because it provided a strong joint that was free from inclusions and had low electrical resistance. By using tin-plated aluminum studs, a means for making reliable solder connections was provided. Specifications for the chassis stated that the studs were to be perpendicular to the surface within ±1°. Weld spatter was to extend no more than 1/32 in. beyond the diameter of the stud.

The studs were made of alloy 6061-T6 to the dimensions shown in Fig. 17 and were tin plated to a thickness of about 0.002 in. before the welding operation. Cleaning of the studs before welding was not required, but the chassis was acid cleaned to remove surface oxide.

The welding machine, which had an input rating of 110-volt alternating current, had two capacitors, with a total capacitance of 16,000 microfarads. The gun was column mounted, and the chassis was manually positioned for each stud. The machine platen served as a backing, to prevent deflection of the thin sheet and to minimize burn-through.

An air cylinder with an applied air pressure of 60.5 psi held the tip of the stud against the chassis during initiation of the arc, and was used to plunge the stud into the weld puddle after the conical tip disintegrated. The stud holder was made of beryllium copper.

Weld quality was checked during the production run by making four shear samples and testing them to destruction. The minimum acceptable load in shear was 210 lb, but many of the studs withstood a shear load of 340 to 450 lb. Failure in the weld joint was unacceptable. The tin plating on the stud did not affect weld quality unless the plating thickness was excessive.

To determine whether an adequate bond had been made, a 10-lb load was applied to the top of the stud and parallel to the sheet surface. If there was visible movement, the stud was removed and a new one was welded in the same place.

Production rate was 100 welds per hour, with a rejection rate of less than 2%. The cost of each stud was about 3¢.

Percussion Welding

PERCUSSION WELDING is an arc welding process in which the heat is obtained from an arc produced by a rapid discharge of electrical energy, and force is percussively applied during or immediately after the electrical discharge. A shallow layer of metal on the contact surfaces of the workpieces is melted by the heat of the arc produced between them, and one of the workpieces is impacted against the other, extinguishing the arc, expelling molten metal, and completing the weld.

Arc initiation, arc time, and welding force are controlled and synchronized automatically. The power supply usually is a welding transformer or a capacitor (or bank of capacitors). The welding force (forging force) is applied by electromagnetic devices, electromechanical devices, cam-actuated direct drive, springs or gravity.

The heat input is intense, but extremely brief and localized, and enables the percussion welding of one small component to another, of a small component to a larger one, and of dissimilar metals that differ considerably in electrical resistivity and melting temperature. The electrical resistivity of the parts being welded does not noticeably affect the amount of heat generated at the joint. The arc supplies the heat for welding.

The workholding clamp, jaws or chuck of the welding head need not be a good electrical conductor, as in resistance welding, because the amount of current passed is comparatively small and the duration of current flow is extremely brief. The holder material is usually selected primarily for strength and wear resistance; hardened steel is often used.

Relation of Percussion Welding to Stud Welding

Percussion welding and stud welding (described in the preceding article in this volume) are similar in three important respects:

1. Welding heat is obtained from an arc.
2. Force is applied percussively.
3. Arc-starting methods used in the several variations of the two processes are closely similar.

Percussion welding and stud welding differ in various aspects of equipment, technique and process variables. The similarities and differences among the commonly used methods of percussion welding and stud welding are compared in Table 1. Although a clear-cut distinction exists between percussion welding and arc stud welding, there are close similarities among the capacitor-discharge methods of percussion and stud welding.

Percussion welding is principally used for making electrical connections and electrical contact devices; the chief use of stud welding is for joining studs or similar shapes to larger parts for fastening other components.

The examples and most of the text for this article were supplied by members of five Metals Handbook welding committees.

Applicability

Percussion welding can be used to join like and unlike metals that are not usually capable of being flash welded or stud welded.

The process is used for welding fine wire leads to filaments in lamps and to terminals of electrical and electronic components where a reliable joint is needed to withstand shock, vibration and extended service at elevated temperature. It is used in making telephone equipment and other electronic and electrical devices, and for attaching large-area contacts to switch components. Percussion welds can be made a few thousandths of an inch away from glass seals or other heat-sensitive materials without damage to these materials, because the total heat input is small and can be made highly localized.

Percussion welding can be used for butt joints between two wires or between a wire and a rod, and for T-joints between a wire and a workpiece with either a flat or a curved surface. The workpiece can be massive, or it can be thin sheet metal, as in a chassis or a terminal. Stranded wire, as well as solid wire, can be percussion welded in joints of these types. Flat workpieces of any shape can be percussion welded to mating flat surfaces with the aid of an arc-starting nib or projection on one of the members.

Design and Size of Workpieces. The workpieces must be separate; the ends of a continuous workpiece cannot be joined to make a ring. One of the components of the assembly must be designed so that it can be clamped securely in a welding head and be impacted against a stationary component without slippage.

Capacitor-discharge percussion welding (see page 179) can be used to butt weld wires of similar diameters or of greatly different diameters. For some metals, wire diameter can be as small as about 0.005 in.

A wire can be capacitor-discharge percussion welded to a workpiece having a large surface area. In Examples 176 and 177, a 0.020-in.-diam wire was butt welded to a 0.040-in.-diam wire. Welding a 0.032-in.-diam wire to a section of ½-in.-diam tubing that had a wall thickness of 0.062 in. is described in Example 178.

Magnetic-force percussion welding (see page 185) can join flat workpieces with a weld area of 0.04 to 0.70 sq in. in production. An arc-starting nib or projection must be provided on one of the workpieces. Example 180 describes the welding of a contact 0.71 in. square (weld area of 0.50 sq in.).

Workpiece Condition. Heat treated, cold worked or prefinished metals are virtually unaffected by the heat of percussion welding, because the heat-affected zone is very shallow. As discussed in the section on Arc Time and Heat-Affected Zone, on page 178, the heat input is so concentrated at the weld interface and of such short duration that metal more than a few thousandths of an inch away from the weld interface is not affected by the welding heat.

Cleaning is not critical for the production of a sound percussion weld, because at least a thin layer of metal is melted from each workpiece and expelled from the joint.

Metals Welded

Almost any like or unlike metals or alloys can be joined by percussion welding. Work metals of widely dissimilar composition, melting temperature, electrical conductivity, and thermal conductivity can be readily welded together.

Like metals joined include copper alloys, aluminum alloys, nickel alloys, low-carbon steels, medium-carbon steels, and stainless steels. Various combinations of these alloys also have been joined.

Gold, silver, copper-tungsten, silver-tungsten, and silver – cadmium oxide have been percussion welded to copper alloys for commonly used assemblies for electrical contacts.

Copper is routinely percussion welded to molybdenum. Although true welds between these two metals had formerly been considered impossible because of mutual insolubility, electron-beam microprobe analysis has shown copper penetration of 0.0004 in. into molybdenum at the weld interface.

Thermocouple alloys and low-expansion alloys have been percussion welded to molybdenum and other metals. Welds between molybdenum wires, between Cb-1Zr wires, between 85Zr-15Cb wires, and between tantalum wires have been made in air, with a stream of argon gas directed at the joint during welding.

In applications where diffusion during prolonged service at high temperature would produce weak or brittle structures in direct joints between dissimilar metals (for instance, in joints between copper and stainless steel for continuous service at 1200 F), transition joints that include a compatible third metal have been used to prevent this condition.

Percussion welding schedules for joining dissimilar metals are based primarily on the melting temperatures of the metals being joined, although the thermal and electrical conductivities of work metals and the shape and size of workpieces also must be considered. (Table 2 gives conditions for and results of capacitor-discharge percussion welding of several combinations of wire-to-wire and wire-to-stainless plate. Wire size was 0.015 and 0.150 in. in diameter and 0.040 in. square.)

Table 1. Comparison of Process Variables in Percussion and Stud Welding

Item	Percussion welding				Stud welding			
	Capacitor-discharge method			Magnetic-force method	Arc method(a)	Capacitor-discharge method		
	Low-voltage		High-voltage					
Power supply	Capacitor	Capacitor	Capacitor	Transformer(b)	Rectifier(c)	Capacitor	Capacitor	Capacitor
Current supplied to arc	Dc	Dc	Dc	Ac	Dc	Dc	Dc	Dc
Voltage, v	50 to 150	12 to 120	1000 to 3000	10 to 35	60 to 100	100 to 200(d)	100 to 200(d)	100 to 200(d)
Arc-starting method	Nib plus dc voltage (initial gap)	High-frequency ac pulse plus dc voltage(e)	Dc voltage (initial gap)	Nib plus first half-cycle of ac (initial contact)	Nib plus dc voltage (draw arc after contact)	Nib plus dc voltage (initial gap)	Nib plus dc voltage (initial contact, no retraction)	Dc voltage (draw arc by retracting after contact)
Arc time, milliseconds	0.15 to 1	1 max	1 max	8 max	100 to 1000	3 to 6	3 to 6	6 to 12

(a) A ferrule is used to confine the molten metal in this method; flux may be used, depending on workpiece and size. (b) Resistance welding transformer. (c) Arc-welding type of rectifier or motor-generator; no energy storage. (d) Approximate. (e) Initial gap.

Power Supply

Three types of power-supply units, as described below, are used for percussion welding. The first two, low-voltage and high-voltage capacitors, are energy-storage devices that are charged by direct current from a rectifier or motor-generator. The third type — a resistance welding transformer — uses an input of 60-cycle alternating current, and does not involve storage of electrical energy.

Low-voltage capacitors that have high capacitance are used as power supplies in capacitor-discharge percussion welding. The capacitor is charged by direct current from a rectifier or motor-generator, and the welding energy is stored at about 50 to 150 volts (or, occasionally, up to 300 volts) and later discharged to make the weld.

These capacitors are similar to those used to supply power for capacitor-discharge stud welding, but are discharged in about a fourth to a sixth of the time taken by the capacitors used in stud welding. The low voltage makes this type of power supply appropriate for use with hand-held percussion welding guns, for which protection from high voltage would be difficult to provide. Low-voltage capacitors are also used with bench-mounted heads in percussion welding systems that are less expensive than those using high voltage, and that are adaptable to mechanized high-speed production. (See Low-Voltage Capacitor-Discharge Percussion Welding, page 180.)

High-voltage capacitors that have low capacitance are also used to supply power for capacitor-discharge percussion welding. They function the same as low-voltage capacitors, but store the welding energy at 1000 to 3000 volts (or, occasionally, up to 6000 volts).

High-voltage capacitors can produce a more uniform arc discharge, and the use of this type of power supply is one way of avoiding the need for an arc-starting nib. The high voltage allows more latitude in controlling operating variables. However, for hand-held equipment, it is more difficult and costly to provide operator protection against voltages above 1000 volts than against those below 150 to 300 volts. (See "High-Voltage Capacitor-Discharge Percussion Welding", page 184.)

Resistance welding transformers used as power-supply units for magnetic-force percussion welding supply 60-cycle alternating current at low voltage. They are used at a lower impedance and deliver current at a higher voltage (10 to 35 volts) than those used in ordinary resistance welding.

Two transformers are used, as explained in the section on Magnetic-Force Percussion Welding, page 185. The weld is made during the first half-cycle of current flow; thus this system functions essentially like a low-voltage direct-current system without an auxiliary energy-storage device.

Arc Time and Heat-Affected Zone

Arc time is the interval beginning when the arc is initiated and ending when one workpiece strikes the other and the arc is quenched.

Factors affecting arc time include the work metal or combination of work metals, mass of the moving workpiece and moving parts of the machine, nib dimensions, welding voltage and current, welding force, and synchronization of arc initiation with the application of welding force.

The shortest arc time that will permit the formation of a sound metallurgical bond with some penetration into both workpieces is generally used, in order to minimize heating effects on adjacent areas of the workpieces. Typical arc times in percussion welding are up to 1 millisecond for capacitor-discharge welding, and up to 8 milliseconds when using a transformer, as in magnetic-force percussion welding.

Because of the short arc time, the heat-affected zone is very shallow. For capacitor-discharge welding, it is often only about 0.0015 to 0.005 in. In percussion welds between metals that have widely different melting temperatures, the heat-affected zone may be only a few millionths of an inch in the higher-melting metal and 0.015 to 0.025 in. in the lower-melting metal. (See Example 176, on welding of molybdenum to Dumet.)

Because the capacitor-discharge method permits a shorter arc time, this method can be expected to produce somewhat shallower heat-affected zones in a given joint than the magnetic-force method can.

Welding Energy

The charge on the capacitor (or bank of capacitors) and the voltage give an approximate measure of the welding energy expended at the joint in the arc discharge. This energy can be calculated by the following equation:

$$E = \frac{1}{2}Cv^2$$

where E is energy in watt-seconds (joules), C is capacitance in farads, and v is voltage.

The amount of energy used in making a percussion weld depends on the cross-sectional area of the joint, the properties of the work metal or metals, and the depth to which metal is melted on the workpieces.

In welding copper to copper alloy 710 (copper nickel, 20%) in Example 175, welding energy per weld was 2.5 watt-sec, which was equivalent to an energy density of about 8000 watt-sec per square inch of weld cross section. In joining molybdenum to Dumet in Example 176, the welding energy was 5.0 watt-sec per weld, or 16,000 watt-sec per square inch. About 25,000 watt-sec of energy per square inch was needed in joining a platinum-rhodium alloy to copper in Example 177, in which 8 watt-sec was used. In all three of these examples, the weld interface was 0.020 in. in diameter, for a cross-sectional area of 0.000314 sq in.

Welding Current

The welding current pattern (or arc-discharge pattern) in percussion welding varies with the application, and is not usually measured. However, current peaks of 400 and 350 amp, equivalent to more than 1 million amperes per square inch of weld contact area, are reported in Example 175 for capacitor-discharge percussion welding of copper to copper alloy 710 (copper nickel, 20%); and a maximum current density of 855,000 amp per square inch was observed in magnetic-force percussion welding a ⅜-by-5⁄16-in. Ag-CdO contact to a brass terminal, in an operation similar to Example 180.

Figure 2 on page 181 shows a schematic representation of the changes in welding current during capacitor-discharge percussion welding of wires.

A peak current density in the neighborhood of 300,000 amp per square inch is obtained when a low voltage of 80 to 90 volts is used in capacitor-discharge percussion welding of steel to steel, steel to copper, aluminum to aluminum, and brass to aluminum.

Polarity is of no consequence in making percussion butt welds between members made of the same metal and having the same cross section, but can affect results in other types of percussion welds. When the members have different cross sections or different melting points, and the amount of heat input is a critical factor in obtaining a sound weld, the member for which a greater amount of heat input is needed (the member having the larger cross section or higher melting point or thermal conductivity) is ordinarily given a positive polarity.

Table 2. Conditions for and Results of Percussion Welding of Seven Combinations of Work Metals(a)

Workpieces welded	Wire size	Welding voltage, v	Resistance, ohms(b)	Initial gap, in.(c)	Tensile strength, psi	Location of failure
Chromel wire to Alumel wire	0.015-in. diam	130	1.0	⅜	77,300	Alumel
Copper wire to Nichrome wire	0.015-in. diam	160	1.5	⅜	39,100	Copper
Copper wire to stainless plate	0.015-in. diam	150	1.0	1¼	40,000	Copper

(a) The welding machine was similar to that used in Example 178. The capacitor bank had a variable output rated at 20 to 400 microfarads and 600 volts max. The series resistor was a 0 to 7.5-ohm, 50-watt stepless potentiometer. The effective weight of the cantilever was about 6 oz, but additional weight could be added, if needed. (b) Setting of potentiometer. (c) Distance of fall of wire (workpiece) attached to pivoted arm.

The selection of polarity is of special importance in the percussion welding of unlike metals that differ greatly in melting temperature, and is used to minimize the depth of melting, as well as the depth of the heat-affected zone, in the lower-melting metal.

When alternating current is used in magnetic-force percussion welding of work metals for which polarity affects weld quality, sometimes the transformer core must be defluxed during loading time, to ensure the correct polarity. This is done automatically on some machines by passing the second half-cycle at reduced current through the transformer in the direction opposite to that of the first (welding) half-cycle.

Welding Force

The force used in percussion welding is difficult to measure, because it is dynamic rather than static and depends on the velocity and mass of the moving workpiece and moving parts of the machine. Peak loading of 15,000 to 30,000 psi has been observed in dynamic measurements for capacitor-discharge percussion welding.

To produce good welds, the welding force must be adjusted empirically until the desired weld quality is obtained. Welding force can be supplied by an electromagnet, gravity, a cam-actuated direct drive, or a spring, depending on the percussion welding method and the size, shape and arrangement of the parts being welded. It must be great enough to accelerate one of the parts being welded and the moving parts of the machine to a high velocity within the short gap characteristic of percussion welding.

An impact velocity of 80 to 150 in. per second has been used with spring drive in low-voltage percussion welding of wires up to about 0.010 in. in diameter. Velocity was 90 to 100 in. per second in Example 175. A range of 10 to 60 in. per second has been used in joining wires only a few mils in diameter. The application of the percussive force and the welding current must be precisely coordinated.

Because a force-applying component may rebound and put a tensile load on the weld metal while it is solidifying, a means of damping the rebound must be provided. Damping is particularly critical in the welding of small parts.

Arc Starting

Three methods of starting the arc are used in percussion welding.

In one method, the arc is started by applying to the parts being welded a direct-current voltage high enough to overcome the resistance of the air in the gap between the parts as one moves toward the other. The air is ionized, and the flow of welding current is started. This method is used in high-voltage capacitor-discharge percussion welding.

Another method involves superimposing an auxiliary high-frequency, high-voltage alternating current on a low-voltage direct current across the gap between the workpieces. The high-frequency alternating current ionizes the air in the gap, and the low-voltage direct current maintains the arc. This method is used in some low-voltage capacitor-discharge percussion welding; it eliminates the need for preparing a nib on one of the workpieces.

In a third method, a starter nib is prepared on one of the workpieces by cutting it at an angle, or in the shape of a chisel tip or other projection, or by attaching or forming a projection on it. Either a low-voltage direct current (in some low-voltage capacitor-discharge percussion welding) or the first half-cycle of low-voltage alternating current from a transformer (in magnetic-force percussion welding) will create enough heat to melt the nib. It is heated so rapidly when the arc forms that it explodes and molten particles are expelled from between the work surfaces at high velocity. These particles help to form the electric arc, which then spreads progressively over the workpiece surfaces at the interface of the joint being welded.

Capacitor-Discharge Percussion Welding

In capacitor-discharge percussion welding, a direct current with a low voltage of about 50 to 150 volts (or, occasionally, up to 300 volts) or a direct current with a high voltage of 1000 to 3000 volts (or, occasionally, up to 6000 volts) is supplied by a capacitor or bank of capacitors. (See the section on Power Supply, on page 178.)

In low-voltage welding, arc starting is accomplished with the aid of a nib (see "Nib-Starter Machines", page 180) or a high-frequency pulse of alternating current (see "High-Frequency-Start Machines", page 181). In high-voltage welding, no auxiliary arc starter is needed.

The mechanism of arc starting at voltages below the ionization potential of air (about 450 volts) is not clearly understood, but is believed to involve a cold cathode discharge. Arc starting is less consistent below 450 volts than at higher voltages, particularly in welding workpieces of large diameter.

Because arc equilibrium conditions are not achieved in the short interval of the arc discharge, the repeatability of percussion welds is affected by variations in arc-starting behavior, and hence is related to the voltage used. Voltages near 450 volts are not usually selected, as small variations in the operating conditions could change the mechanism of arc starting.

The use of a nib or a high-frequency current pulse at low voltages greatly improves the consistency of arc starting. With close control of the welding conditions, the quality of welds produced in low-voltage systems can be uniformly high, with the incidence of defective welds often being 0.1% or less.

Arc starting ordinarily takes place just before the workpieces come into contact, at a separation of about 0.0002 to 0.0004 in., in low-voltage systems in which a starter nib is used. The discharge takes place across a gap of typically 0.010 to 0.030 in. in low-voltage systems in which a high-frequency pulse is used. In studies of percussion welding of workpieces 0.040 in. in diameter using a voltage of 1300 volts, the arc discharge began when the gap between workpieces was 0.004 to 0.006 in.

Sequence of Steps. In operation, first a capacitor (or bank of capacitors) is charged by direct current from a rectifier or motor-generator, and then one of the parts being welded is advanced toward the other and rapidly accelerated. When the two parts are close enough, the capacitor discharges and explodes the nib (arc starter), if one is used. The intense arc formed between the parts by the discharge heats the work surface of each part to the melting temperature in a fraction of a millisecond. Then, as one part is impacted against the other at high velocity, molten metal is expelled from the joint and the parts are forged together to complete a weld. The sequence of steps in capacitor-discharge percussion welding is shown in a simplified way in Fig. 1.

Control. Close control of voltage, capacitance, impact velocity and limiting resistance is important for producing a good weld. The voltage and capacitance determine the amount of energy stored in the system, and hence the heating capacity of the arc. Impact velocity (along with the mass of the moving workpiece and clamping members of the machine) determines the amount of forging energy. The limiting resistance generally is adjustable and controls the peak discharge current.

These four factors interact to determine the arc duration and the timing

with respect to arc discharge. The approach of the workpieces serves as a switch to trigger the arc discharge.

Usually, conditions are adjusted to give the shortest arc time that will permit consistent production of welds having the desired properties. If the parts being welded are forced together too soon, the arc is extinguished before the work surfaces of both parts are melted. If the impact is delayed too long after arc initiation, the melted interfaces may solidify too soon to permit expulsion of excess molten metal.

Preparation of workpieces for capacitor-discharge percussion welding varies widely, depending on the application. If a nib is needed for arc starting, a shear or cutter usually serves to produce the desired tip configuration.

Displacement, Current and Voltage. The changes in displacement of the moving workpiece, welding current, and voltage across the weld that take place during capacitor-discharge percussion welding, based on oscillograph records for the welding of wires, are shown schematically in Fig. 2.

Displacement of the moving workpiece in the direction of travel proceeds at a uniform rate during the arc discharge and while molten metal is being expelled, but is slowed as the forging action takes place. Displacement continues beyond the final displacement on the completed weldment because of deflection of the mechanical system and the workpieces. The maximum displacement because of deflection is reached after about 3 milliseconds, and the oscillations are damped rapidly, becoming insignificant after a reverse-oscillation peak that occurs after an additional interval of approximately 5 milliseconds.

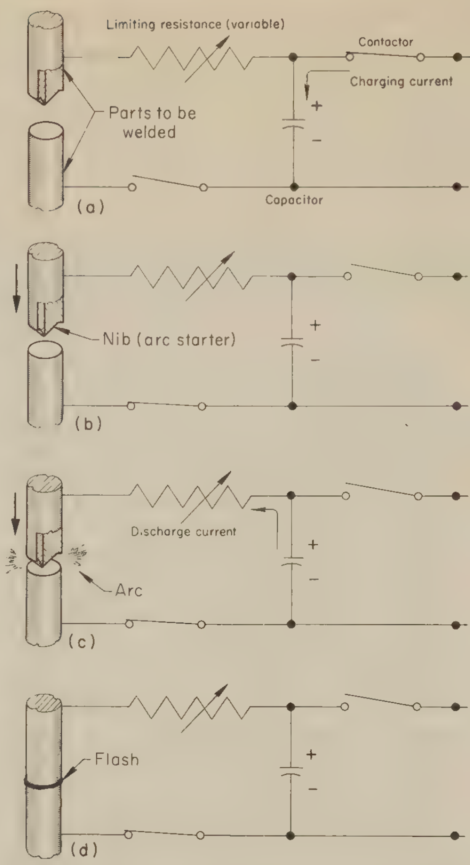
Peak welding current is achieved almost immediately on arc initiation, and the current then decays rapidly during the arc discharge. As shown in Fig. 2, the current increases to a secondary peak on contact of the workpieces, because of the sudden drop in electrical resistance, and then tapers off to zero in an additional 3 to 5 milliseconds.

Voltage across the weld decreases very rapidly to a fraction of its initial open-circuit value when the arc is initiated by the close approach of the moving workpiece to the stationary workpiece, and then decreases less rapidly as the arc discharge continues. When the arc is extinguished on contact of the workpieces, after a typical arc time of 0.25 to 1.15 milliseconds, the voltage decreases instantly to nearly zero.

The magnitude and rate of change of displacement, current and voltage vary with the size and nature of the workpieces and the characteristics of the welding equipment. Figure 2 is based on the welding of 0.015 to 0.040-in.-diam wire of various materials, including Dumet, nickel, nickel-plated steel, and copper-plated steel.

Low-Voltage Capacitor-Discharge Percussion Welding

Low-voltage capacitor-discharge percussion welding is done on many types of equipment. Simple and relatively inexpensive machines are used for low production (see the section on Low-Production Welding in Nib-Starter Machines, page 183). Commercially available and specially designed machines of widely varying capability, complexity and cost are used for welding in intermediate to large quantities, and generally can be adapted for use with specially designed work-handling equipment for semiautomatic or automatic high-volume production.



(a) Contactor is momentarily closed to charge the capacitor. (b) One of the parts to be welded is advanced toward the other and rapidly accelerated. (c) The arc forms across the gap just before the parts meet, melting the work surface of each part, and exploding the nib (arc starter), if one is used. (d) The arc is extinguished as one part is impacted against the other, expelling molten metal as flash and forging the parts together to complete the weld.

Fig. 1. Simplified representation of sequence of steps in capacitor-discharge percussion welding

The amount of energy stored in the capacitor bank to make a weld is usually regulated by selection of the number of capacitors charged and by charging to a controlled voltage. The initial-gap technique is used throughout. Except for machines that use a high-frequency pulse of alternating current for arc starting, the approach of the workpieces initiates the arc.

Machines for low-voltage capacitor-discharge percussion welding can be classified on the basis of the arc-starting technique as nib-starter and high-frequency-start machines.

Nib-Starter Machines. In one type of machine for low-voltage capacitor-discharge percussion welding, a nib is used for arc starting (see the section on Arc Starting). This machine usually consists of a portable power supply and either a hand-held gun or a bench-mounted welding head, but these components can also be built into a specially designed integral machine. Voltages of from 50 to 150 volts are usually employed for welding with the bench-mounted machine; for operator safety, the voltage used with the hand-held gun is ordinarily about 50 volts.

The bench-mounted machines and integral machines are readily adaptable to mechanization for high-speed, high-volume welding operations, but the hand-held gun has the advantage of portability. Otherwise, the machines operate in much the same manner.

The machines have two sets of jaws — one set movable and the other stationary — with provision for precise alignment of the two sets of jaws and for setting of the initial gap. One workpiece, usually a wire, is held in the movable jaws; and the second workpiece, usually a terminal, is held in the stationary jaws. Some hand-held guns are made to hold only the movable wire (workpiece); this type of gun is held against the stationary workpiece, and is suitable for welding to large, approximately flat workpieces. Wire size is about 0.006 to 0.100 in. in diameter; terminals are usually at least 0.006 in. thick.

When the switch is actuated, the wire moves toward the terminal at high velocity. Impact velocity varies with the wire size and the mass of the moving jaws, but is ordinarily between 80 and 150 in. per second (see the section on Welding Force, page 179). Total arc time is about 0.15 to 1.0 millisecond.

The basic electrical system for nib-starter low-voltage capacitor-discharge machines is shown schematically in Fig. 3. The limiting resistor controls the peak discharge current during welding. Another resistor is used as charging ballast, to limit the peak charging rate. Moving the switch to the welding position (as in Fig. 3) isolates the rectifier and charging circuit from the capacitor bank and discharge circuit. In repetitive welding, the switch remains in this position long enough for the weld to be completed, whereupon it is returned to the charging position to allow recharging of the capacitor bank. The switching is controlled automatically, often by a system of cams.

Nib-starter machines vary in details of construction and many are designed for specific welding applications.

The driving force for propelling one of the workpieces in such equipment is provided by springs, cams (or cams plus levers), or electromagnets. Timing is automatic for some or all machine functions. Rotating cams on a central shaft are often used to actuate switches, relays or other devices, as well as to provide machine motions directly. Solid-state timers or other types of timing devices are used in some machines.

Precise alignment is important; for example, when wires of 0.010-in. diameter are welded, a misalignment of 0.002 in. can reduce weld size and cause poor welds if wires deflect on impact.

Three examples in this article describe low-voltage capacitor-discharge percussion welding using nib-starter machines. A hand-held low-voltage gun

was used in Example 175 for welding of tinned copper leads to copper alloy 710 (copper nickel, 20%) terminals on a relay. A specially designed machine was used in Example 176 to join Dumet wire to molybdenum; cam drive was used to accelerate the Dumet wire in this operation. Another type of specially designed machine, with the driving force provided to the movable workpiece by an electromagnet, welded copper wire to a platinum-rhodium alloy in Example 177.

Production rate is usually limited by the time needed for loading and unloading the workpieces or for other work-handling operations. With manual loading and unloading, the production rate for a single welding head is often about 200 to 500 welds per hour.

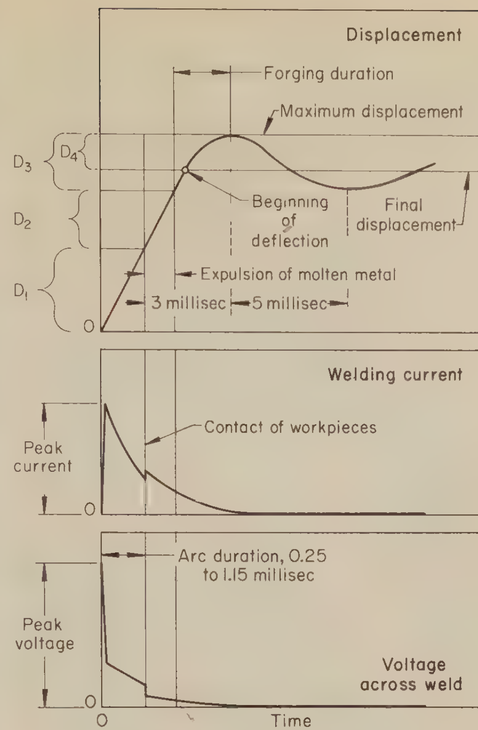
In fully mechanized welding, the repetition rate of the machine can become a limiting factor for the production rate in welds per head. The charging time for the capacitor bank usually is an approximate measure of the total weld cycle time, which can vary from about 0.2 to 1 sec or more, corresponding to production rates of 18,000 and 3600 welds per hour, respectively.

In Example 175, the production rate was 200 welds per hour with manual loading and unloading of a hand-held gun, but 12,000 welds were made per head per hour on similar parts in a fully automatic six-head machine. In Example 176, the production rate per welding head was 6000 to 10,000 welds per hour in a completely mechanized operation. Studs were fed from a vibratory feeder, and wire was fed from a spool and automatically cut off after each weld. In Example 177, 80 welds (40 assemblies) per hour were made in a bench-mounted machine with manual loading and unloading.

High-Frequency-Start Machines. In the second commonly used type of machine for low-voltage capacitor-discharge percussion welding, a high-frequency, high-voltage pulse of alternating current serves as an arc starter by ionizing the air in the gap between the workpieces. This machine, like the nib-starter machine, usually consists of a portable power supply and either a hand-held gun or a bench-mounted welding head. These components can also be built into a specially designed integral machine. Suitability for mechanization and arrangements for holding and aligning the workpieces in this machine are similar to the nib-starter machine.

The main application is in welding a wire to another wire, to a pin terminal or to a large flat surface. Solid wires about 0.100 in. to less than 0.005 in. in diameter, or stranded wires as small as 0.010 in. in over-all diameter (four strands of 0.004-in.-diam wire), are welded. Special provisions are made for damping the rebound on impact in welding the smaller-diameter wires.

This type of machine differs from the nib-starter type in the following respects: (*a*) there is no need to prepare a nib on the wire by an angle cut or other means, and the wire can be cut off square or in any convenient shape that gives reproducible dimensions; (*b*) timing of machine function is done with solid-state devices that have a switching time of 0.001 to 0.002 milliseconds; (*c*) the driving force to propel the moving workpiece is provided by a solenoid or electromagnet; and (*d*) the approach of the workpieces does not initiate the arc.



D_1 = Displacement during arc discharge
D_2 = Displacement during expulsion of molten metal
D_3 = Displacement during forging and deflection
D_4 = Displacement during deflection

Diagrams are based on oscillograph records made in studies on the welding of wires (see text). (Source: Irving Bradley, Use of Percussive Welding in Electronics, *Electro-Technology*, Sept 1968, p 72)

Fig. 2. Changes in the displacement of the moving workpiece, welding current, and voltage across a weld during capacitor-discharge percussion welding

A simple form of the high-frequency-start machine (system A) has a basic electrical system like that shown in Fig. 3, but with the limiting resistor replaced by an autotransformer, to which a solenoid and a high-frequency pulse generator (toroid) are connected in series. When the work has been loaded in the preset position with the desired gap, the operator closes a switch to make the weld. The switch (as in Fig. 3) moves to the weld position, closing the discharge circuit from the capacitor bank through the autotransformer and toroid to the weld gap. A high-frequency pulse bridges the weld gap during the first half-cycle of the pulse, ionizing the air in the gap. The arc discharge across the gap then starts, about 0.010 to 0.015 milliseconds after the operating switch is closed. The flow of current through the solenoid actuates it to propel the movable workpiece toward the stationary workpiece at high velocity. Total time elapsed at the beginning of the forging action is typically 1¼ to 2 milliseconds.

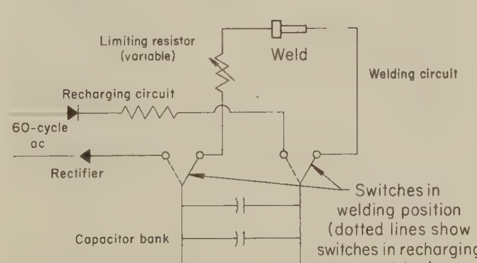


Fig. 3. Basic electrical system for nib-starter low-voltage capacitor-discharge percussion welding machines (typical)

Contact of the parts extinguishes the arc. The switch remains in the weld position for a total time of about 6 to 15 milliseconds, to allow completion of the weld and nearly complete decay of the welding current and voltage, and then automatically moves to the charge position. The capacitor bank is then recharged by the rectifier to the desired preset voltage, and the machine is ready to repeat the welding operation, after a total time of 1.5 sec or less for a complete welding sequence.

The major fraction of the weld cycle time is the charging time, which depends on the characteristics of the charging unit and the capacitor bank and the amount of energy in the charge. Maximum charging time for the type of equipment described is less than 1.5 sec.

In this form of high-frequency-start machine, two basic adjustments are used to optimize weld properties. Heat input to the weld is adjusted by selecting the number of capacitors to be charged and setting the charging voltage. Impact velocity (and timing) is adjusted by setting the gap. However, the adjustment of heat input also affects impact velocity (and timing) by changing the amount of current passed through the solenoid. Thus, heat input and impact velocity (and timing) cannot be changed independently by routine adjustments.

A more versatile form of the high-frequency-start machine (system B) has greater capacitance and has the solenoid, heat input and arc initiation independently powered. Thus the high-frequency pulse can be timed to occur at some definite point during workpiece travel. The independent control of arc initiation, heat input and impact velocity thus provided gives system B greater flexibility in balancing the heating effect at the weld against the forging action. This feature, and the greater capacitance, makes it possible to weld a wider range of sizes of wire with system B. A comparison of characteristics of the two systems, and of diameters of wire that can be welded by each system, is as follows:

	System A	System B
Capacitance, max .	800 mfd	4000 mfd
Solenoid connection	Series	Parallel
Voltage, v	12-75	12-120
Gap, in.	0.008-0.010	0.015-0.020
Wire diam, in.	0.015-0.070	0.004-0.102

System B allows a greater variety of metal combinations to be welded.

Intermediate and High-Production Welding in Nib-Starter Machines

The equipment and techniques described for low-voltage capacitor-discharge percussion welding have many applications in joining wire leads to

wires, pins or terminals in the telephone, electronics, electrical equipment, and lamp industries. Three applications involving different workpiece materials, variations in equipment design and operation, and different production rates are described in the three examples that follow. The first of these describes the welding of tinned copper leads to copper alloy 710 (copper nickel, 20%) terminals on a relay, using a hand-held gun for a production rate of about 200 welds per hour. Although copper can be readily brazed to copper alloys, the manufacture of terminal boards precludes the use of a heat input as great as that needed for brazing. The intense but localized heat in percussion welding penetrates only a few thousandths of an inch into the workpieces and melts the mating surfaces without producing a significant heat-affected zone.

Example 175. Capacitor-Discharge Percussion Welding of Tinned Copper Leads to Copper Alloy Terminals on a Relay (Fig. 4)

Leads made of 0.020-in.-diam annealed and tinned copper wire, which was insulated, were capacitor-discharge percussion welded to copper alloy 710 (copper nickel, 20%) terminals on a relay, in the setup shown in Fig. 4 and under the conditions shown in the accompanying table. In this arrangement, the copper wire was connected to the positive terminal.

The gun was a low-voltage, hand-held, motor-operated type and functioned in two stages. In the first stage, the stripped end of the copper wire was positioned in the wire jaw, with the insulation against the outer surface of the jaw, as shown in Fig. 4. The wire was then clamped, and the gun was cocked. The terminal jaw of the gun was then placed over a terminal; the initial gap between the wire and the terminal was 0.040 to 0.050 in. (Fig. 4). The weld was completed in the second stage by triggering the gun and thus actuating the driving force and completing the welding circuit to the workpieces.

A featheredge formed on the end of the wire by the use of a special cutter, as shown in Fig. 4, was used to start the arc as the wire approached the terminal.

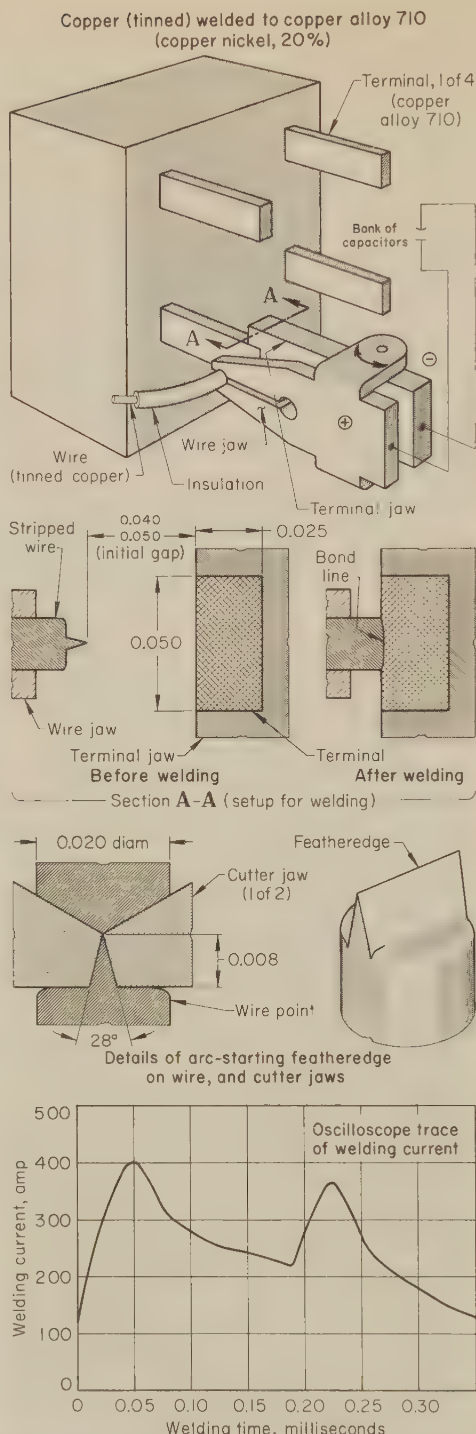
An oscilloscope trace (Fig. 4) of the capacitor discharge during welding showed a peak current of about 400 amp at about 0.05 millisecond after initiation. A second peak of about 350 amp occurred at about 0.22 millisecond, or just after the arc had been extinguished by full contact of the wire and the terminal.

The melted layer produced on the lead and the terminal at the joint and expelled from the interface by the forging action was 0.005 to 0.015 in. thick. The heat-affected zone on each side of the bond line in the completed weld was typically 0.002 to 0.003 in. deep.

Weld strength was tested in two ways. A straight pull, at 90° to the terminal, usually broke the wire outside the weld area. When the wire was bent 90° and pulled parallel to the terminal (pull-bend test), the breaking load was about 1 lb less than the wire strength.

The same technique, except that the welding was done with either a hand-held gun or a fully automatic bench-mounted welding head, was used in percussion welding of copper wires (component leads) 0.006 to 0.102 in. in diameter to terminals of copper, brass, tinned brass, nickel-silver, aluminum, low-carbon steel, or high-carbon steel that were 0.006 in. thick or thicker.

Depending on the size and composition of the parts being welded, capacitance ranged from about 500 to 50,000 microfarads at an operating voltage of 50 volts, which was preferred over high voltage for safety and better control of welding-energy input.



Power supply	Bank of capacitors
Gun	Hand held(a)
Capacitance	2000 mfd
Voltage	50 v
Initial gap	0.040 to 0.050 in.
Velocity of wire	90 to 100 ips
Arc time	Approx 0.2 millisecond
Welding force	3 lb
Melted layer(b)	0.005 to 0.015 in.
Energy per weld	2.5 watt-sec
Energy density(c)	8000 watt-sec/sq in.
Production per hour	Approx 200 welds

(a) Low-voltage, motor-operated gun. (b) Combined thickness of the melted layer on the wire and the terminal, which was expelled from the weld interface ("burn-off" or "meltback"). (c) Computed for the area of the weld.

Fig. 4. Setup for capacitor-discharge percussion welding of a tinned copper wire to a copper alloy relay terminal for conditions in table, details of arc-starting featheredge on the wire, and oscilloscope trace of welding current (Example 175)

The copper wire, because of its high thermal conductivity, was connected to the positive terminal in these applications. The heat-affected zone on each side of the bond line was typically 0.002 to 0.003 in. deep, with an extreme range of about 0.0015 to 0.008 in.

No special cleaning was required. Production per hour varied from about 200 connections per gun for manual operation to about 72,000 connections when using a fully automatic bench-mounted machine that had six separate welding units to make six welds at once. Charging time for the capacitor banks was about 0.2 sec.

When dissimilar metals with widely different melting temperatures are capacitor-discharge percussion welded, the relatively high heat input to the joint can produce a large amount of upsetting. These metals are usually difficult to join by other welding processes, because the metal having the higher melting point may not melt or alloy with the metal having the lower melting point. Percussion welding minimizes this difficulty, because of the almost immediate localized input of welding heat.

In the following example, wires of molybdenum and Dumet (copper-clad 58Fe-42Ni) were capacitor-discharge percussion welded in a high-production operation (350 million assemblies per year). This was the combined output from a number of fully automatic machines, each of which made 6000 to 10,000 welds per hour, averaging about 500,000 welds per machine per week.

This combination of wires is difficult to weld with reliability by other welding processes because of the difference in melting temperatures of molybdenum (4730 F) and the Dumet core (2900 F).

Example 176. High-Production Capacitor-Discharge Percussion Butt Welding of Molybdenum and Dumet Wires (Fig. 5)

The molybdenum wire stud and the Dumet (copper-clad 58Fe-42Ni) wire lead shown in Fig. 5 were capacitor-discharge percussion butt welded under the conditions shown in the accompanying table. The copper cladding on this size of Dumet wire was about 0.001 in. thick (17 to 26% by weight of the wire).

The welding machine, which was of special design, had a six-station rotary table that included one welding station. All the machine motions and electrical contacts were controlled by cams. The studs were fed automatically to the welding machine from a vibratory feeder. A wire-feeding device fed the Dumet wire from a spool, through a guide tube, and past a cutoff blade. Production was 350 million assemblies per year, using a number of these special welding machines.

The steps in welding were as follows:

1 Studs were fed from the feeder through a tube to the machine.
2 A stud was gripped by clamp jaws and held in position for welding.
3 Dumet wire from the spool was impacted into the stud, welded and cut off to a length of 1.605 ± 0.010 in. for the weldment of wire plus stud, and at an angle of 28° to 30°, as shown in Fig. 5. The cutoff provided a nib for the next weld.
4 A pickup arm removed the welded assembly from the clamp jaws and dropped it into a chute leading to an inspection area. The same pickup arm discarded assemblies joined by potentially weak welds on signal from a weld discriminator.

The depth to which the Dumet wire was heated in welding provided a relatively large amount of plastic metal. This metal was upset in welding and, as a result, the weld diameter was nearly equal to the diameter of the molybdenum stud, as shown in the welded assembly in Fig. 5. In the completed weld, the weld metal layer was only a few millionths of an inch thick. The heat-affected zone in the molybdenum was typically about 0.00001 in.; that in the Dumet was about 0.025 in. Sound welds could not be made at the production rates used unless the heat-affected zone in the Dumet was at least 0.018 in.

After welding, an inspector removed the assemblies that had welds with visible defects such as spikes, overwelds or heavy carbon deposits. In addition, electronic weld discriminators that monitored voltage versus current wave patterns inspected each assembly during the welding operation and automatically removed the workpieces that had potentially weak welds.

Weld quality was then tested on a random basis by 10-lb axial loading, which the welds had to withstand, and a bend test in which the assembly had to survive six bend cycles for satisfactory evaluation.

Figure 5 shows the setup for the bend test. The molybdenum stud was chucked into a fixture that could be turned to stress the weld. A 1-lb weight was suspended on the Dumet lead wire and the fixture was then rotated 90° (Fig. 5), to the bend position. Returning the fixture to the starting position completed one bend cycle. A frequency distribution for the number of bends to failure for 566 welded assemblies in a sample lot of 567 assemblies is given in Fig. 5. (One of the workpieces failed in the wire, instead of at the weld.) This distribution, which is typical of other sample lots, illustrates normal performance.

An acceptable quality level (AQL) of 0.5% and a 1% LTPD (lot tolerance per cent defective) plan were enforced.

Mechanical testing was supplemented by microscopic examination of etched sections through welded joints, at a magnification of 1300 diameters.

In the following example, capacitor-discharge percussion welding produced a reliable and inexpensive joint between wires having different diameters and melting points. A specially designed bench-mounted machine was used with manual loading and unloading for a production rate of 40 assemblies (80 welds) per hour. Driving force for the movable workpiece was provided by an electromagnet.

Example 177. Capacitor-Discharge Percussion Butt Welding of a 60Pt-40Rh Wire to Copper Wires (Fig. 6)

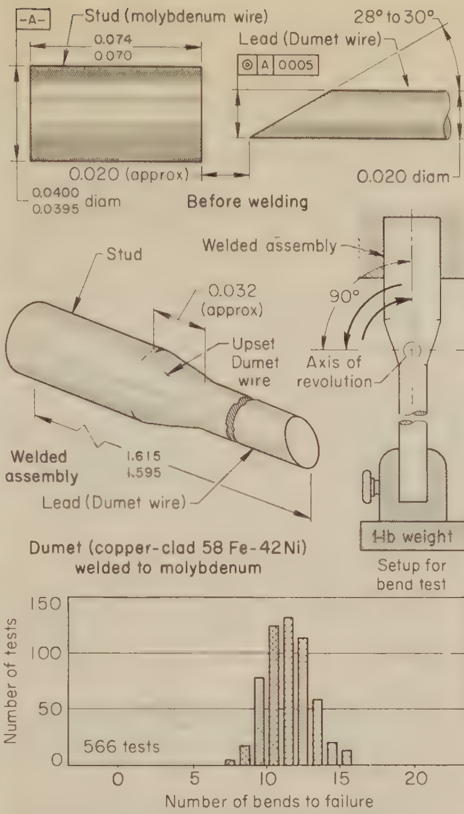
Both ends of a 0.020-in.-diam annealed 60Pt-40Rh wire were capacitor-discharge percussion butt welded to 0.040-in.-diam hard drawn and tinned copper wires 0.50 in. long, in the assembly of the resistance brazing tip shown in Fig. 6(a). The ends of the copper were cut off square, and the Pt-Rh wire was cut at an angle to provide a nib at each end to start the arc. (The brazing tip was used to resistance braze fine copper wires to copper terminals, as described in Example 603 in the article on Resistance Brazing in this volume.) Figure 6(b) shows the welded assembly.

A diagram of operating fundamentals of the welding machine is shown in Fig. 6(c). The electrical circuit included the wires to be welded, two sets of gripper jaws and an electromagnet. The sets of gripper jaws held the wires in alignment for welding. One set of jaws was mounted on an adjustable carriage having a manual advance mechanism, and the other set was mounted on an armature, or lever, that was moved by the electromagnet when it was energized. The gap between the electromagnet and the armature was 0.010 in.

Power was supplied from a bank of capacitors that could be charged to a preselected energy level at a potential of 30 to 80 volts and had a maximum capacitance of 3000 microfarads. The capacitor bank was charged with direct current from a rectifier that drew a current of 2 amp from the 115-volt, 60-cycle alternating-current power line.

In operation, jaws mounted on the adjustable carriage clamped a precut length of 60Pt-40Rh wire so that it extended 1/16 to 3/32 in. beyond the jaws. This wire had positive polarity for the welding operation. Another set of jaws clamped a precut length of copper wire so that it extended 1/8 in. beyond the jaws. The carriage then was advanced to bring the ends of the wires together, striking an arc between them.

As the capacitors, which had been charged to a preselected energy level, discharged through the arc, the arc caused meltback of the wires, and the flow of current through the electromagnet (see Fig. 6c) energized it. The energized electromagnet then closed the gap between it and the armature, and impacted the Pt-Rh wire against the copper wire to complete the weld.



Welding machine	Special design(a)
Input power to charging unit	20 to 50 watts(b)
Capacitance	4000 mfd
Welding current	200 amp
Voltage	50 v
Initial gap	0.020 ± 0.005 in.
Driving force, max	Approx 2.0 lb
Welding force	1 to 2 lb
Energy per weld	5.0 watt-sec
Energy density	16,000 watt-sec/sq in.
Arc time	2 milliseconds
Production per hour	6000 to 10,000 assemblies
Production per year	350,000,000 assemblies(c)
Cost per 1000 assemblies	Approx $2.50

(a) Equipped with a six-station rotary table, including one welding station (see text); single-station automatic machines were also used, with suitable modification of procedure. (b) Single-phase, 60-cycle alternating current. (c) Using a number of machines, most of which were single-station machines, all at about the same hourly production rate.

Fig. 5. Molybdenum wire stud and Dumet wire lead that were capacitor-discharge percussion butt welded, setup for bend test of welded assemblies, and frequency distribution of bends to destruction for 566 assemblies (Example 176)

The subassembly was removed from the gripper jaws and reversed end-to-end to make the second weld. A second length of copper wire was clamped in the jaws at the right in Fig. 6(c) and the Pt-Rh wire of the subassembly was clamped in the jaws of the carriage. The procedure used to weld the subassembly was then repeated to produce the assembly shown in Fig. 6(b).

Weld quality was then tested by manually bending the welded assembly near each joint, through a 90° bend. If the weld was not acceptable, machine settings were adjusted and the wires were rewelded, until acceptable welds were made. This method of determining proper machine settings was used because production quantity was small.

After welding, the assembly was manually bent to a U-shape (Fig. 6a).

The depth of the heat-affected zone on either side of the bond line was 0.005 in. or less. The total energy used in making one weld was approximately 8 watt-sec. Arc time per weld was about 0.1 millisecond. Production rate was 40 assemblies per hour.

Low-Production Welding in Nib-Starter Machines

The simplest type of low-production percussion welding equipment uses a nib for arc starting and has a gravity-operated cantilever arm, which is pivoted on a low-friction bearing, to provide the welding force. A machine of this type, which was built from commercially available electrical and mechanical devices by the user for welding of metallographic specimens, is described in Example 178.

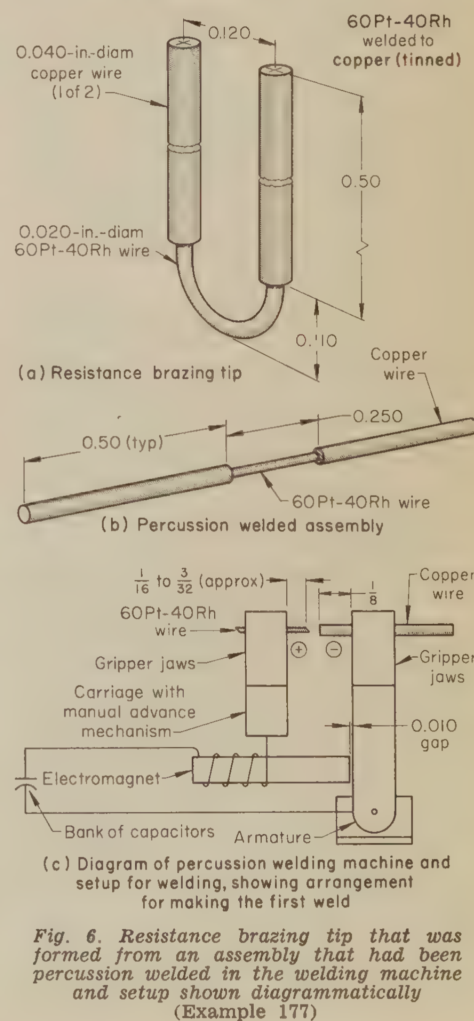


Fig. 6. Resistance brazing tip that was formed from an assembly that had been percussion welded in the welding machine and setup shown diagrammatically (Example 177)

Another user-built machine of this general type was used to weld wires of various materials and sizes for electronics applications. The versatility of this simple machine is illustrated in Table 2, where the conditions and results for welding seven combinations of work metals are given.

The circuit was essentially like that shown in Fig. 3. The power for welding was supplied from a bank of 20 electrolytic capacitors rated at 20 microfarads each and 600 volts max. The capacitors were connected in parallel for a total capacitance of 400 microfarads, arranged so that all or a fraction of the bank could be used, as desired. The limiting resistor was a stepless 0 to 7.5-ohm, 50-watt potentiometer. A rectifier rated at 0 to 500 volts and 100 milliamp max was used to charge the capacitor bank.

The movable workpiece was held in a pin vise mounted on a gravity-operated cantilever arm, which pivoted on a low-friction bearing. Effective weight of the cantilever was 6 oz, but additional weights could be added if needed. Precise alignment of the workpieces for welding was accomplished by positioning the lower workpiece with the aid of a compound table having screw-operated travel in two directions, while observing the workpieces through a magnifying glass. Cutting the wires (the workpieces) with ordinary wire cutters produced a chisel-type tip, which functioned as an arc starter.

Excellent welds were obtained on difficult-to-weld metal combinations, as shown in Table 2. In addition, this equipment provided the capability of welding precisely located wires in areas with limited accessibility.

Percussion welding machines like that just described, although not efficient for medium or high production, can perform many joining operations on small parts that would be very difficult, time consuming, or costly if performed by other means.

Example 178 describes the percussion welding of a 0.032-in.-diam type 304 stainless steel support wire to a typical metallographic specimen of Inconel 600. The equipment, which was assembled by the user, and the procedure described were used also in welding stainless steel support wires to metallographic specimens of many different shapes, sizes and metals, including titanium and zirconium. The welding of stainless steel wires to all metals tried over a period of several years was successful. This technique can also be used for joining a lead wire for electrolytic etching to a metallograph specimen after mounting the specimen in plastic.

Limited heat input is important in this application, in which the microstructure of the specimen had to be kept unchanged well away from the surface to be examined.

The machine was designed and built by the user from readily available mechanical and electrical equipment. The mechanism supporting the welding head was a standard part of a commercial percussion welder. Other advantages were that little or no operator skill was required, and that the time for setting up and welding a specimen was typically less than 1 min.

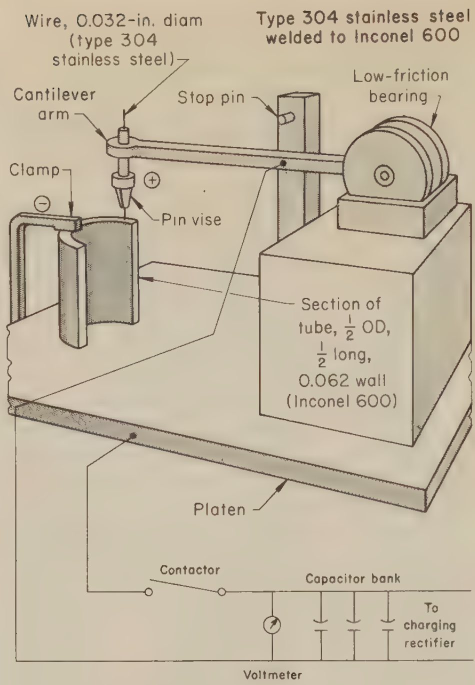

Fig. 7. Setup for capacitor-discharge percussion welding of a type 304 stainless steel support wire to an Inconel 600 metallographic specimen (Example 178)

Example 178. Capacitor-Discharge Percussion Welding of a Stainless Steel Support Wire to an Inconel Specimen (Fig. 7)

Figure 7 shows the setup for capacitor-discharge percussion welding of a 0.032-in.-diam type 304 stainless steel wire to a section of a 0.062-in.-wall Inconel 600 tube that was ½ in. in outside diameter and ½ in. long. The tube section was to be nickel plated to protect the edges during subsequent polishing for use as a metallographic specimen, and the wire provided support and electrical connection for the electroplating operation.

A gravity-operated cantilever arm, which pivoted on a low-friction bearing and was supported by a stop pin (Fig. 7), was a standard part of a commercial percussion welding machine and provided the welding force. The starting height could be adjusted to change the velocity and impact momentum. A pin vise mounted to the cantilever arm held the wire above the tube.

The power-supply unit was a 1200-microfarad, 450-volt bank of capacitors, which was charged to about 75 to 100 volts by a rectifier (not shown). Closing the arc-resistant contactor shown in Fig. 7 energized an electromagnet (not shown), withdrawing the stop pin and allowing the arm to drop. Closing this contactor also opened a switch between the charging rectifier and the capacitor bank, and completed the discharge circuit from the capacitor bank to the two workpieces, permitting the arc discharge to take place at the correct interval before impact.

The stainless steel wire had positive polarity for the welding operation. The wire was cut with hand wire cutters in preparation for the welding operation. The cutters produced a chisel-shape tip on the wire, which acted as an arc starter. The shape of the tip was not considered to be critical.

The static weight of the cantilever arm, measured at the point where the wire was held, was 57 grams. The arm was positioned to drop the wire about ⅛ in. The charge on the capacitors was 75 to 100 volts. Melting of the end of the stainless steel wire was so slight that no flash was evident around the wire.

In operation, the tube was manually positioned and clamped, because positioning of the wire was not critical. The charging time on the capacitors (and, hence, the voltage) was adjusted to change the energy input to the specimen until a visually good weld was obtained. Operators did not need special skill or experience. The total time for setting up and welding a specimen was typically less than 1 min.

The welded joint was strong and had good electrical conductivity. The heat-affected zone was very small, and thus the microstructure of the specimen was unchanged a few mils from the weld.

High-Voltage Capacitor-Discharge Percussion Welding

High voltage, usually 1000 to 3000 volts (but occasionally up to about 6000 volts), is used only in bench-mounted machines or specially designed integral machines for capacitor-discharge percussion welding. The difficulty and expense of providing protection for the operator against high voltage precludes the use of hand-held guns in high-voltage systems.

Applications are similar to those described for low-voltage welding, but the diameter of the smaller workpiece in high-voltage production welding does not ordinarily exceed about 0.060 in. (compared with about 0.040-in. diameter in low-voltage systems). Maximum diameter of the smaller workpiece is about 0.70 in. (compared with about 0.10 in. in low-voltage systems). No nib or other arc-starting aid is needed; the tip of the moving workpiece can have any convenient shape.

The welding operation is generally very much like that described for nib-starter machines in the section on Low-Voltage Capacitor-Discharge Percussion Welding (page 180), and the basic electrical system is like that shown schematically in Fig. 3.

The amount of energy stored in the capacitor bank to make a weld is usually regulated by selection of the number of capacitors charged and by charging to a controlled voltage. The initial-gap technique is used throughout, and the approach of the workpieces initiates the arc discharge. Impact velocity in high-voltage welding is typically about 40 in. per second for wire 0.040 in. in diameter.

The machines are usually of special design to suit the application, and are intended for semiautomatic or fully automatic operation in intermediate to high-production welding.

In fully mechanized systems, charging time for the capacitor bank may be a limiting factor for the number of welds made per minute by a single welding head. A charging time of 300 milliseconds, corresponding to a maximum production rate of 120 welds per minute for a single welding head and capacitance of 75 to 240 microfarads, is typical.

Some machines are fitted with more than one welding head, each with its capacitor bank, to increase production rate. Each capacitor bank is recharged during loading and unloading time.

The example that follows describes the high-voltage capacitor-discharge percussion welding of electrical contacts to connector wires in high-speed automatic production, using a programed-feed dual-head machine.

Example 179. Programed High-Voltage Percussion Welding of Three Types of Electrical Contacts to Closely Spaced Connector Wires (Fig. 8)

Copper alloy 715 (copper nickel, 30%) electrical contact blocks were percussion welded to 0.040-in.-diam copper alloy 770 (nickel silver, 55-18) wires by high-voltage capacitor discharge in specially designed high-production automatic welding equipment. In welding, a contact block, 0.101 by 0.073 by 0.042 in., was propelled against the square-cut end of a connector wire, attaching the face of the block to the wire end.

Percussion welding was selected because it permitted minimal heat input to the joint, avoided problems in heat balance from the size difference between the workpieces, was compatible with the close spacing (0.110-in. centers) of the wires, and, because of its short repetition time, was suitable for high-speed automatic machines.

The machine was built and put into service before the development of low-voltage capacitor-discharge techniques for percussion welding, and has been used for this welding application for more than 15 years with excellent results. This high-voltage operation has had the advantages of simplicity of operation, high reliability of welds, and operation without an arc starter on the end of wires or by using a high frequency current.

Figure 8 shows the welded assembly, which was part of a telephone-type wire-spring relay. Contact blocks were welded to the square-cut ends of some or all of the 12 nickel silver connector wires, which projected about 0.200 in. from their encasing phenolic frame; two wires received no contact blocks in the assembly shown.

A contact block and connector wire in position for welding, and a completed weldment, are shown in Section A-A of Fig. 8, and the design details of the three different types of contacts used in a single assembly are also shown in Fig. 8. Contact blocks with palladium on both top and bottom were used as "transfer" contacts in the operation of the relay; those with palladium on either the top or bottom only, as "make" or "break" contacts, respectively.

All welding-machine functions were controlled and actuated through a main drive and camshaft. Phenolic block – wire subassemblies (workpieces) were moved along a straight-line conveyor to the welding station, with the wires horizontal and at 90° to the direction of travel.

The machine had two welding heads, arranged side-by-side, spaced on 0.720-in. centers, that made welds simultaneously. One welding head made the welds on wires 1 to 6; and the second, on wires 7 to 12 (see view of welded assembly in Fig. 8).

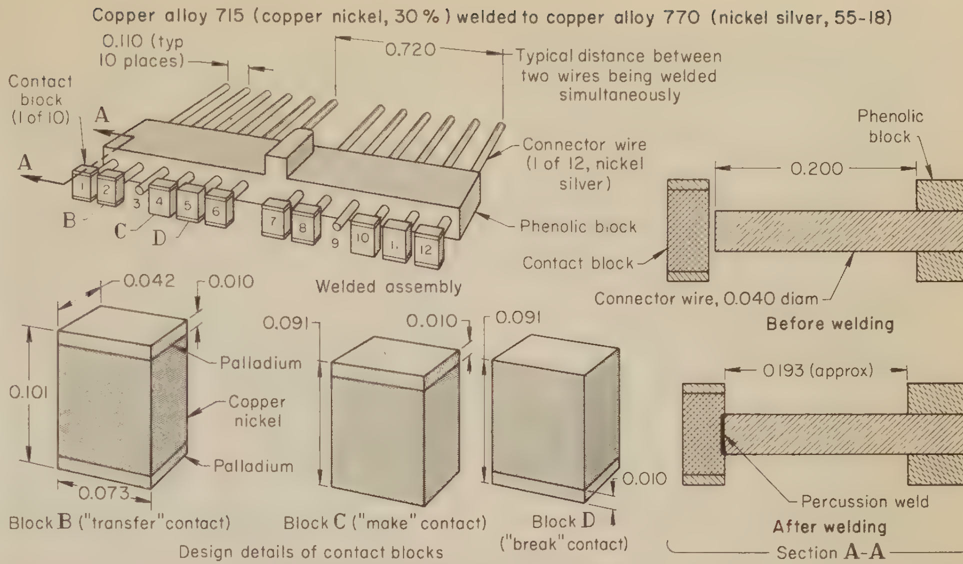
At each cycle of the machine, the workpiece at the welding station was stepped along to move the next wire into welding position. At each cycle during which a weld was to be made, a contact of the type specified for the wire at the welding position was fed into welding position in each welding head.

A selective hitch-feed mechanism for each head fed contact tape to an automatic cutter, according to a preset program for the relay, from one of three reels that contained coils of the three types of contact material. No tape was fed to the cutter for wires that were not to receive a contact.

At each cycle, transfer fingers operated to move a contact from the cutter to the load position, and to move a contact from the load position to the weld position (jaws of the welding head). One contact-cutting-and-feeding mechanism served the welding head for wires 1 to 6; and a second, the welding head for wires 7 to 12.

In making a weld, the jaws holding a contact were released from the cocked position by cam action and propelled toward the wire by a spring. Velocity at impact was about 40 in. per second. The mass of 30 grams (jaws plus contact block) produced an impact force of about 30 lb.

Welding power was supplied to each welding head directly from a 75-microfarad



Welding machine	Special design(a)	Arc time	0.1 to 0.4 millisecond
Capacitance	75 mfd	Burn-off, total	0.005 to 0.010 in.
Voltage	1300 v	Heat-affected zone	0.001 to 0.002 in.(c)
Initial gap	0.150 in.	Breaking load of weld	150 to 160 lb
Velocity at impact	40 ips	Charging time	Approx 0.3 sec
Welding force	Approx 30 lb(b)	Production rate	120 welds per minute(d)

(a) Dual-head, cam-controlled from main drive shaft; selective automatic cutoff and feed of contact blocks from three reels of different contact stock (see text). (b) Mass of moving jaws and workpiece was 30 grams. (c) Including a maximum thickness of about 0.001 in. of weld metal. (d) For each of the two welding heads.

The machine automatically cut the contacts from coiled "tape" of three different types, and fed contacts and wire subassemblies to a dual-head welding machine in a programed sequence to produce the desired arrangement of contacts. The machine also was programed to omit the welding of contacts to specified wires.

Fig. 8. High-voltage percussion welded assembly of copper nickel – palladium contacts to closely spaced nickel silver connector wires mounted in a phenolic block for a telephone-type relay, and details of joint and the three types of contacts (Example 179)

capacitor charged to a potential of 1300 volts. As the contact block approached the wire, an arc was established between them at a gap of a few thousandths of an inch. Portions of the abutting surfaces of both the wire and the contact base metal were melted and expelled from the arc zone before the molten surfaces were forced together in firm contact. (Normally, the total amount of metal melted and expelled is 0.005 to 0.010 in.)

Arc time was 0.1 to 0.4 millisecond. Nearly all the heated metal was expelled from the joint during the welding operation, so that a heat-affected zone of about 0.001 to 0.002 in. remained.

Welds were made at the rate of 240 per minute, 120 per minute for each welding head and capacitor. Each capacitor was charged for each weld by a separate thyratron-tube rectifier; the two rectifiers operated from a common source of high-voltage current. The charging time was approximately 0.3 sec.

With routine control of the operating conditions in production, the welds were highly reliable. Less than 0.1% of the relays produced had unacceptable welds.

Visual examination for defective welds was made in production by the machine operator. In addition, the retraction of the welding-head jaws from a welded contact block exerted a pull of 2 lb on the block, thus providing a check for very weak welds or unwelded contact blocks.

Weld strength was tested on a statistical sampling of production welds with a "hook-pull" gage, which applied a combined tension and bending force to the weld. Samples tested in straight tension for comparison showed that a hook-pull force of 50 to 60 lb was equivalent to 150 to 160 lb of straight tension. In the tension samples, failure occurred more frequently in the wire than in the weld.

Protection for personnel against high voltage was provided in the machine by door interlock switches, solenoid-release shorting bars, and bleeder resistors on the capacitors. Safety from mechanical jams was provided by a slip clutch on the main drive and by a pull-out clutch and automatic stop switch in the transfer drive mechanism for the block – wire assembly.

Magnetic-Force Percussion Welding

In magnetic-force percussion welding, a resistance welding transformer supplies the welding current at a voltage of about 10 to 35 volts. This transformer has lower impedance and higher secondary voltage than the transformers ordinarily used in resistance welding. The system functions like a low-voltage direct-current system without an auxiliary energy-storage device, because the weld is made during the first half-cycle of current flow of a 60-cycle alternating current.

Welding force is developed by an electromagnet, and the magnitude of this force, which is controlled by a separate transformer, can be varied without affecting the welding current. The welding force needed depends on the size and composition of the parts being welded, as these determine the response of the parts to heating.

The arc starter usually is a nib or a projection on one of the parts to be welded. For welding elongated parts, two nibs are sometimes necessary. An air cylinder holds the workpieces together at low pressure while a current path is established through the nib.

A magnetic-force percussion welding machine is similar to a press-type

resistance welding machine. Figure 9 shows a diagram of the machine. The six-step sequence of operations in welding in this machine is given in Example 180 below.

The diameter and height of an arc-starting nib or projection depend on the application. The diameter must be large enough to prevent the nib or projection from collapsing under the initial pressure, but it must not be large enough to permit the nib or projection to carry the welding current. The height determines the gap between the workpieces to be welded and the arc voltage that is necessary to explode the nib.

Arc time is up to 8 milliseconds, and is governed by the amount of energy discharged, the magnitude of the magnetic force, and the dimensions of the arc-starting nib. The interval between initiation of the arc and application of the magnetic force has an influence on the arc time and also on the resulting weld quality.

Weld areas of 0.04 to 0.70 sq in. can be welded in production. Some meltback (besides the explosive removal of the nib) occurs at the weld interface and, in most applications, some flash must be removed. Weld metal is not always completely expelled from the joint (see Example 180).

Applications. Magnetic-force percussion welding is used in joining silver – cadmium oxide to brass, cadmium-plated brass or copper; copper to copper; copper to silver-tungsten; and copper to silver – cadmium oxide (see Example 180).

One manufacturer uses this process for joining tungsten and molybdenum tips to RWMA class 2 copper shanks in making resistance welding electrodes, to extend the useful temperature range at which they can be used. Electrodes 0.482 and 0.625 in. in diameter have been made in this way, instead of by the customary brazing method.

In the following example, a change was made from brazing to magnetic-force percussion welding, to improve joint integrity and to prevent an undesirable annealed structure in an electrical-contact assembly. Production was 60 welds per minute for automatic, dial-feed welding, and 7 welds per minute for manual loading and unloading.

Example 180. Change From Silver Brazing to Magnetic-Force Percussion Welding for an Electrical Contact Assembly (Fig. 9)

Originally, two silver – cadmium oxide contacts and a copper backing strip were silver brazed, to make part of a switching device used in electrical equipment. A contact and the copper backing strip are shown in Fig. 9. Processing was changed to magnetic-force percussion welding because (*a*) the brazed joint, even for the best brazing conditions, contained voids, and (*b*) the comparatively large heat input in brazing produced an undesirable annealed structure in the workpieces. The percussion welded joints, which had a weld bond covering more than 80% of the mating surfaces, had good electrical and mechanical properties, and the properties of the welded assembly immediately adjacent to the bond line were unaffected by the heat input in welding.

In addition, the production rate by percussion welding was 4 times (using manual feed) or 36 times (using automatic feed) that by resistance brazing, the faster of two previously used silver brazing methods.

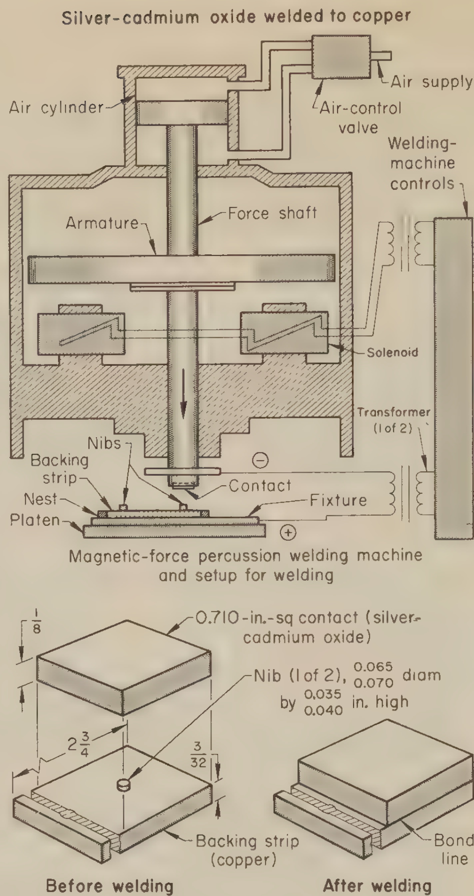


Fig. 9. Silver – cadmium oxide contact and copper backing strip that were magnetic-force percussion welded in the machine and setup shown (Example 180)

The percussion welding rate was 10 times (manual) or 90 times (automatic) that by induction silver brazing.

Before welding, two nibs (arc starters) were coined into the copper strip, as shown in Fig. 9. One nib was used in welding each contact. Each nib was located on the backing strip so that it would touch the center of a contact at the start of welding.

The copper backing strips were given a flash plating (0.0002 in. max) of tin shortly before welding. The silver – cadmium oxide contacts were received clean, in sealed cans. If difficulties occurred, the contacts were dipped in dilute hydrochloric acid or in hydrochloric-nitric acid and then thoroughly rinsed in hot and cold water.

The welding machine and setup for welding the first contact to the backing strip are shown in Fig. 9. The machine had two transformers. One supplied the welding current; the other supplied current to the solenoid that applied the welding force. Air pressure in the air cylinder applied the force to bring the contact against the nib on the backing strip and an initial low force to hold it there. Both the initial force and the welding force were applied through the force shaft. The fixture was of class 12 electrode material (copper-tungsten). An automatic dial feed was used, or loading and unloading were done manually.

The sequence of operations in welding each contact was as follows:

1 A contact and backing strip were securely clamped in position in the machine.
2 The start button was pushed, to initiate the welding cycle and automatically actuate and time the next three operations.
3 The contact was brought against the appropriate nib on the backing strip, by the force shaft, and initial force was applied to hold it there.
4 The flow of the welding current was started, the nib disintegrated and arcing spread across the interface.
5 The solenoid was energized and produced a high synchronized force on the force shaft, which closed the gap and exerted the welding force on the parts being joined.
6 The welded assembly was removed from the machine.

Steps 2 through 5 were interlocked so that (after the initial force had been applied and the welding current had been started) the solenoid actuated the force shaft at approximately the time the arc was initiated. Welding voltage was 20 to 30 volts, and maximum current was 100,000 to 125,000 amp.

In welding, a total thickness of about 0.010 in. was melted at the interface of the workpieces and expelled from the joint, usually in approximately equal amounts because the two materials have the same conductivity and do not differ greatly in melting temperature. Thickness of weld metal remaining in the completed joint did not ordinarily exceed 0.005 to 0.007 in. The heat-affected zone in the copper backing strip had a maximum thickness of about 0.005 in., and no heat-affected zone was visible in the silver – cadmium oxide contacts when viewed in section at a magnification of 1500 diameters.

Flash was expelled from the weld zone at high velocity. It eroded some sections of the tooling and produced buildup on others. As a result, the fixtures were checked and necessary maintenance performed at intervals of 10,000 assemblies.

Ultrasonic testing and metallographic examination were used in qualifying the welds. A group of 10 to 25 parts was used to set up the machine. During production, 3% of the welds were tear tested, 2% at the machine by the operator and 1% by the inspection department. Metallographic examination was used in troubleshooting, when results of routine tear tests were difficult to interpret.

The arc time was a half-cycle of 60-cycle alternating current (8 milliseconds). When loading and unloading were done manually, production rate was 400 welds (200 assemblies) per hour. When an automatic dial feed was used, production rate was 3600 welds (1800 assemblies) per hour.

In the previous production method, brazed assemblies were made by carbon-electrode resistance brazing at 100 joints (50 assemblies) per hour and induction brazing at 40 joints (20 assemblies) per hour.

The approximate cost for the basic percussion welding machine, including tooling for manual loading and unloading, was about $17,000. Cost for the completely automated machine was about $50,000.

Safety

Hazards to an operator or anyone near percussion welding equipment are as follows:

1 The noise level is high for welding large parts that have nib-type arc starters — for parts about ½ in. in diameter, it is similar to the noise from firing a 12-gage shotgun.
2 Weld flash and molten particles may be expelled from the joint at high velocity.
3 Highly toxic vapors are released in the welding of some metals — for example, silver – cadmium oxide.

In general, the severity of the hazards is approximately in proportion to the area of the weld, and is minimal for the welding of fine wires. Hazards from noise and weld flash can be minimized by shielding the weld area. Toxic vapors can be drawn off by an exhaust system. All three hazards can be minimized by enclosing the operation in a well-ventilated cabinet.

The operator should be protected from the welding voltage, particularly when high-voltage capacitors are used (see last paragraph in Example 179).

ARC WELDING OF METALS OTHER THAN LOW-CARBON STEEL

CONTENTS

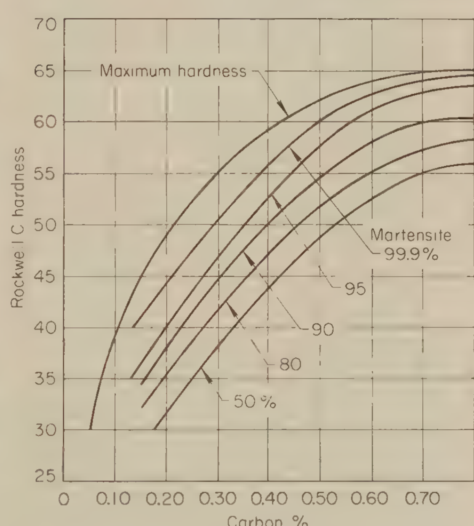
Arc Welding of Hardenable Carbon Steels

*By the ASM Committee on Welding of Hardenable Steel**

THE STEELS discussed in this article are the plain carbon steels that contain enough carbon to be hardenable during rapid cooling from welding temperatures. Hardening is caused by the formation of martensite. The greater the carbon content of the steel, the harder will be the martensite formed in that steel. Only very rapid cooling will produce 100% martensite and maximum attainable hardness. The effect of carbon content, and of the amount of martensite formed, on the hardness of carbon steel is shown in Fig. 1.

In most arc welding applications involving carbon steel, the cooling rate of the weld metal and the heat-affected zone is too low to develop the *maximum* hardness that steel of a specific carbon content can attain, because the hardenability of the steel is low. Nevertheless, an undesirable amount of hardening can occur, and the control of this hardening, together with the avoidance of cracking, constitutes the important difference between welding of low-carbon (mild) steel and hardenable carbon steel of medium or high carbon content.

In resistance welding, it is often possible to develop maximum or near-maximum hardness in a carbon steel, because a small volume of heated steel (the weld nugget) is cooled very rapidly by the large mass of cold metal that surrounds the nugget on all sides. Similar conditions can prevail during the arc welding of thick sections; a small bead of weld metal can be cooled so fast by the large volume of surrounding cold base metal that high hardness develops in the weld zone. Thus, the hardness of the weld zone of a carbon steel weldment depends on both the carbon content and the section thickness of the base metal.



Source of data: Curve for maximum hardness from Burns, Moore and Archer, Trans ASM, 26, 14, 1938; remainder of data from Hodge and Orehoski, Trans AIME, 167, 627, 1946

Fig. 1. Effect of carbon content on the hardness of carbon steel cooled rapidly to produce specific percentages of martensite, and (top line) the maximum hardness obtainable in severe water quenching of small specimens of carbon steel

Hardenability is the property that determines the depth and distribution of hardness induced by rapid cooling. Because the hardenability of carbon steels is low compared with that of alloy steels, carbon steels are generally less difficult to weld than are alloy steels of the same carbon content. In the welding of alloy steels, maximum hardness often is developed in the heat-affected base metal even when the cooling rate is low, because of the high hardenability of alloy steels (see the article on Arc Welding of Alloy Steels, page 200 in this volume).

As the carbon content of plain carbon steel is increased, the hardenability (as well as the hardness) increases. This is shown by the end-quench maximum

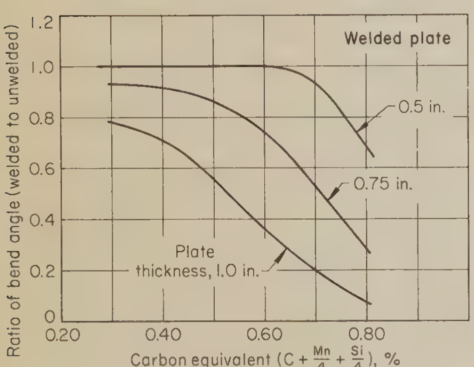
Fig. 2. Maximum hardenability of carbon steels, as determined by the standard end-quench test



Ratio (welded to unwelded) of bend angle for normalized steel plates. A high value of the ratio indicates high weldability. Derived from data on notch-bend tests by Stout and Doty ("Weldability of Steels", Welding Research Council, 1953).

Fig. 3. Effect of carbon equivalent and plate thickness on the weldability of carbon steels as indicated by notch-bend tests

hardenability curves for five plain carbon steels plotted in Fig. 2; comparing the five steels at 1 in. from the quenched end of the hardenability specimen (which corresponds to a cooling rate of 10 F per second at 1300 F), the hardness increases from Rockwell C 21 for 1038H steel to Rockwell C 40 for 1080 steel. Cooling rates of 10 F per second are not uncommon in arc welding, and if the hardness shown for a particular steel at the 1-in. position in Fig. 2 is unacceptable (or is associated with cracking), measures must be taken to avoid the development of this hardness, or to decrease it, as discussed later in this article.

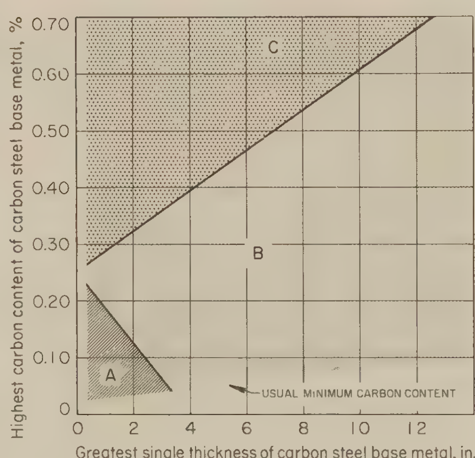
Classification of Carbon Steels

Specific carbon contents that separate low, medium and high-carbon steels are arbitrary.

Low-carbon steels, considered here as those containing less than 0.25% carbon, are generally easy to join by any arc welding process. The arc welding of these steels is discussed in detail in the first six articles in this volume (pages 1 to 147). Welds of acceptable quality can usually be produced without the need for preheating, postheating, or special welding techniques, provided the sections being welded are less than 1 in. thick and there is no severe joint restraint. Electrode selection is seldom critical for welding low-carbon steel.

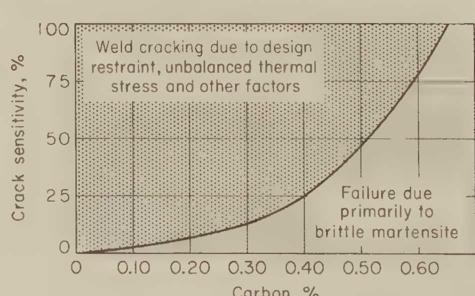
Medium-carbon steels, considered here as those containing 0.25 to 0.50% carbon, can also be satisfactorily welded by all of the arc welding processes, but because of the formation of greater amounts of martensite in the weld zone, and the higher hardness of the martensite, preheating or postheating, or both, are often necessary.

For joints and arc welding methods in which the weld zone is rapidly cooled, preheating is effective in minimizing hard, brittle martensitic areas. By postweld heating, it is possible to restore ductility in the heat-affected zones. Modifications in welding procedure — for example, the use of a larger V-groove or multiple passes — will also decrease the cooling rate and the probability of weld cracking. In multiple-pass welding, it is good practice to deposit the final weld bead in such a fashion that it is surrounded on both sides by weld metal from previous passes. By so doing, the heat-affected zones that resulted from the deposition of the previous-pass weld beads are tempered by the heat from the final-pass bead.



A—Neither preheating nor postweld stress relieving is usually required.
B—Preheating is usually required; postweld stress relieving is not usually required.
C—Both preheating and postweld stress relieving are usually required.

Fig. 4. Combined influence of base-metal thickness and carbon content on weldability, expressed in terms of the need for preheating and postweld stress relieving as defined in the list above (J. Heuschkel)



Summary of an investigation in a large fabricating plant to determine causes of cracking in carbon steel weldments. Brittle martensite was a minor cause of weld cracking in steels of lower carbon content but the major contributor for steels in the higher carbon range.

Fig. 5. Effect of carbon content on the cause of weld cracking in carbon steels

Selection of electrodes for arc welding becomes more critical as the carbon content of the steel increases. Steels with higher carbon content are more susceptible to cracking caused by hydrogen; therefore, low-hydrogen electrodes are ordinarily used in shielded metal-arc welding. As the carbon content of the steel being welded approaches 0.50%, the use of low-hydrogen conditions becomes mandatory.

High-carbon steels, with more than 0.50% carbon, are difficult to weld because of their susceptibility to weld cracking. The arc welding of these steels is more critical than is gas welding. Excessive hardness and brittleness are probable.

For best results in shielded metal-arc welding, the use of low-hydrogen electrodes is mandatory. Similarly, for other arc welding processes, low-hydrogen conditions are mandatory. Both preheating and postweld stress relieving or tempering are usually required. Austenitic stainless steel electrodes are sometimes used for welding high-carbon steel, to obtain greater notch toughness in the joint. However, the heat-affected zone may still be hard and brittle, and preheating and postweld stress relieving may be necessary.

Successful welding of high-carbon steel requires the development of specific welding procedures for each application. Composition, thickness and configuration of the component parts, and the service requirements, must be considered. For each application, the welding procedure should be qualified by tests before it is adopted.

Weldability

Weldability is a measure of the ability to make sound, strong welds. For a given joint, the chief factors influencing the making of good welds are steel composition, heat input, and rate of cooling. Heat input and rate of cooling are characteristics of the welding process and the technique used; they are also influenced by the dimensions of the sections being welded. For carbon steels, the carbon and manganese contents largely determine the extent and magnitude of hardening under given heating and cooling conditions.

The higher-carbon, higher-manganese grades of carbon steel can be welded satisfactorily if they are preheated and postheated. Sometimes peening of the hot weld bead is helpful, but many codes do not permit the use of peening, because it is difficult to control.

In the absence of procedures for controlling the rate of cooling and for eliminating high gradients of temperature and stress, cracks are likely to occur in both the weld metal and the base metal. In addition, the ductility and notch toughness of the base metal may be greatly reduced.

Carbon equivalent is sometimes used as a rough guide in the evaluation of weldability. However, the section size

being welded has an important influence on the combined effect of carbon and manganese contents on weldability, because of its relation to heat input and cooling rate. Figure 3 shows the effect of section thickness and carbon equivalent on weldability, as expressed in terms of notch-bend test results.

Several different equations for expressing carbon equivalent are in common use. The one shown as the horizontal legend of Fig. 3 (C + Mn/4 + Si/4), which considers only carbon, manganese and silicon, is appropriate for most carbon steels. Another well-known equation for expressing carbon equivalent that is sometimes used for carbon steel considers, in addition to manganese, residual (or higher) amounts of chromium and molybdenum — the two elements that are most likely to affect hardenability and weldability when present in small amounts. The equation is as follows:

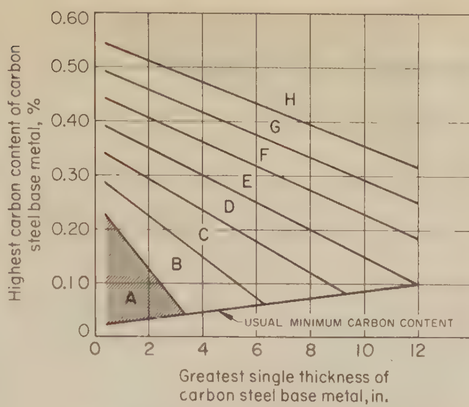
$$\text{Carbon equivalent} = \text{C} + \frac{\text{Mn}}{6} + \frac{\text{Cr}}{5} + \frac{\text{Mo}}{4}$$

This equation yields considerably lower carbon equivalents than the equation used in Fig. 3. For example, for a steel containing 0.35 C, 0.80 Mn, 0.20 Si, and only trace amounts of chromium and molybdenum, the carbon equivalent is 0.60% by the equation of Fig. 3 and 0.48% by the equation that neglects silicon but includes chromium and molybdenum.

Although a carbon equivalent is sometimes useful in planning welding procedures, its value is limited because only the chemical composition of the steel is considered. Section thickness and joint restraint are of equal, or greater, importance. Figure 4 relates carbon content and section thickness to weldability, expressed in terms of the need for preheating and postweld stress relieving. Combinations of carbon content and section thickness in the lower left portion of the chart (area A) are easily weldable. Combinations in area B usually require preheating, and those in area C usually require both preheating and postweld stress relieving. The use of low-hydrogen electrodes can offset, to some extent, the requirement for preheating, by shifting upward the lines that separate the three zones.

Weld Cracking

Susceptibility to weld cracking increases as the number of unfavorable welding conditions increases. For example, 1065 steel welded with an E7024 electrode (not classified as a low-hydrogen electrode), without preheat or postheat, performed satisfactorily when joint restraint was low and cycle loading of the weldment in service was limited. The heat-affected zone exhibited a region of martensite about 1/16 in. thick, but no cracking. However, when the section thickness was doubled, the thickness of the martensite zone increased, and cracking resulted. Changing to a low-hydrogen electrode (E7018) did not prevent cracking of the thicker section. The use of a 600 F preheat prevented cracking by retarding the rate of cooling and thereby reducing the amount of martensite formed.



Area	Range of preheating and interpass temperatures, F: Welding with high-hydrogen electrodes(a)	Welding with low-hydrogen electrodes
A	50 to 100	50 to 100
B	100 to 200	50 to 100
C	200 to 300	100 to 200
D	250 to 400	150 to 300
E	300 to 500	200 to 400
F	350 to 600	250 to 500
G	400 to 700	300 to 600
H	450 to 800	400 to 800

(a) In practice, it is usually considered mandatory to use low-hydrogen electrodes for welding steels containing 0.50% carbon or more.

Fig. 6. Effect of base-metal carbon content and thickness on preheating and interpass temperatures for shielded metal-arc welding of carbon steel (J. Heuschkel)

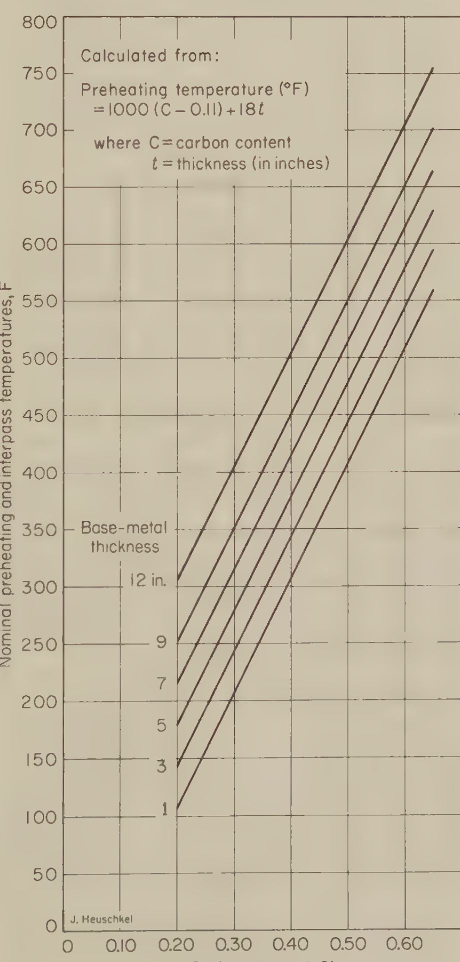


Fig. 7. Effect of base-metal carbon content on preheating and interpass temperatures for six section thicknesses of carbon steel welded by the shielded metal-arc process

Weld cracking is correlated with carbon content in Fig. 5, which summarizes a study made in one plant of a variety of welded components. Cracks occurring in weldments made of steels of lower carbon content were attributed chiefly to design restraint and unbalanced thermal stresses. In weldments made of steels of high carbon content, hardening (brittle martensite) was the major cause of weld cracking.

Underbead cracking can occur in any steel, but is most likely to occur in steels containing more than 0.20% carbon. High restraint, unbalanced thermal stresses, improper welding sequence in restrained designs, and inadequate penetration to the root of the joint are common causes of underbead cracking. However, the primary cause of underbead cracking is moisture — in the electrode covering (shielded metal-arc welding), in the flux (submerged-arc welding), on the base metal, or in the atmosphere. Moisture causes atomic hydrogen to form in the arc. Grease, oil and other hydrocarbons are also sources of hydrogen. The weld metal, because it is molten, will pick up more hydrogen than will the base metal, but both will absorb hydrogen at elevated temperatures. Because hydrogen also diffuses out at high temperatures, keeping the weldment at the preheat temperature or using a postweld heat treatment immediately after welding will help to prevent cracking. However, use of low-hydrogen electrodes in shielded metal-arc welding, or low-hydrogen conditions in other arc welding processes, will minimize the amount of hydrogen that contacts the weld.

Preheating and Interpass Temperature

Preheating an assembly for welding is intended primarily to prevent cracking in the weld or in the heat-affected zone. With preheating, the hardness in the heat-affected zone will usually be lower, because cooling rate is slower, and residual stress and distortion will be minimized. Many code-governed weldments have mandatory requirements, and specific conditions, for preheating.

The need for preheating of carbon steel is based not on carbon content alone, but rather on the combination of carbon, manganese, silicon and residual alloy contents along with various aspects of joint configuration — chiefly section thickness. Likewise, the selection of a preheating temperature is determined largely by this combination. Figures 6 and 7 relate the selection of preheating and interpass temperatures to carbon content and section thickness. The data and experience from which these graphs were developed were obtained with shielded metal-arc welding. Similar relations would apply to gas metal-arc and flux-cored arc welding. Less restrictive relations would sometimes be applicable for submerged-arc welding, which characteristically involves lower cooling rates for a given joint.

Welding at low ambient temperature (especially below room temperature) can cause cracking, and preheating to a safe-to-weld temperature is usually

the easiest and most effective preventive. If there is doubt concerning the composition of the steel being welded, preheating should be at a temperature conservatively on the high side. The use of low-hydrogen electrodes will frequently eliminate the need for preheating of thinner sections.

Bead size is also related to preheating. Small beads cool faster than large beads. Increasing the size of the bead by reducing travel speed, for example, increases heat input for a given length of weld, which results in a slower cooling rate, thus producing less martensite and lower hardness in the heat-affected zone. In some applications, the need for preheating has been eliminated by control of bead size.

Multiple-pass welding can sometimes reduce or eliminate the need for preheating. In certain applications where cracking has occurred when welding was done with a single pass and with no preheating, changing to multiple-pass welding has prevented cracking (without preheating). Under these conditions, the first pass serves as a preheat for the second pass, and the second pass as a preheat for the third. Each filler pass also provides some postheating effect for earlier passes.

Methods of Preheating. Ideally, a weldment is preheated in a furnace, but sometimes no furnace is available or the weldment is of such size or shape that furnace heating is not feasible. Under these conditions, preheating is usually done with gas torches, and temperature-sensitive crayons (or a surface pyrometer) are used for monitoring temperature.

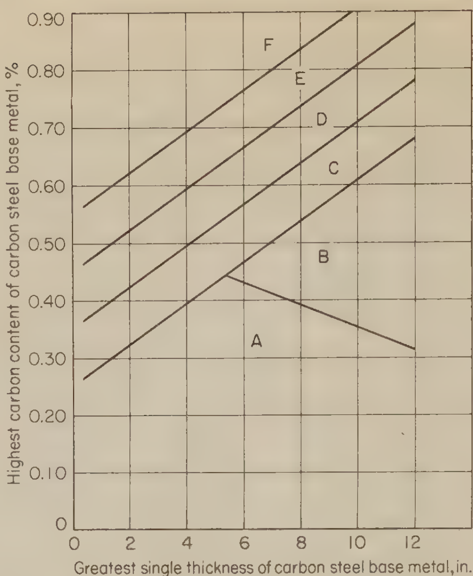
When preheating is done with torches, regardless of the temperature selected, the heat should be applied at one face of the joint and measured at the opposite face to ensure that the joint is heated through, or the preheating temperature should extend for a distance of 3 in. in each direction from the joint to be welded.

Interpass Temperature. In multiple-pass welding, if preheating is needed it is usually equally necessary to maintain a minimum interpass temperature equal to the minimum preheating temperature. However, if welding conditions are changed, such as a change in process or electrode, after deposition of the first bead, the interpass temperature should be adjusted to suit the new conditions. Suggested preheating and interpass temperatures, based on carbon content and thickness of the base metal, are given in Fig. 6 and 7.

In many automatic welding processes (especially in submerged-arc welding), enough heat is supplied to the joint so that additional heating between passes may not be required.

Postweld Stress Relieving

Stress relieving or tempering after welding of hardenable carbon steel is often desirable, and in some applications it is mandatory. Many codes define the conditions under which stress relieving is required, and the time and temperature of the stress-relieving cycle. The times and temperatures prescribed in these codes can be used for noncode applications of the same steels.



A—Postweld heating seldom is required.
B—Postweld heating is required only for dimensional stability, as when parts are to be finish machined after welding.
C—Postweld stress relief is highly desirable for repetitively loaded or shock-loaded structures and for restrained joints having a thickness greater than 1 in.
D—Postweld stress relief is required for all repetitively loaded or shock-loaded structures, for all restrained joints, and for all thicknesses over 2 in. It is also desirable for statically loaded structures.
E—Postweld stress relief is recommended for all applications. No intermediate cooldown should be permitted for restrained structures or for base metal having a thickness greater than 2 in.
F—Same as E, except hazards are greater.

Fig. 8. Effect of base-metal thickness and carbon content on requirements for postweld stress relieving or tempering of carbon steels (J. Heuschkel)

Although other variables, such as joint restraint, influence the need for postweld stress relieving, the principal factors are the same as for preheating — that is, base-metal thickness and carbon content. In Fig. 4, area C defines the combinations of base-metal thickness and carbon content for which postweld stress relieving is usually required. A more detailed chart for postweld stress relieving is presented in Fig. 8. The six areas into which Fig. 8 is divided take into account various conditions of welding and service that relate to the need for stress relieving, as explained below the graph.

The temperatures generally used for stress relieving of medium-carbon steels range from 1100 to 1200 F. The time at temperature is usually 1 hr per inch of maximum base-metal thickness, up to a maximum of 8 hr.

It is generally desirable to place the weldment in the stress-relieving furnace before it cools below the minimum preheat or interpass temperature, although this is not always feasible and is seldom considered mandatory for plain carbon steels. The heating and cooling of a weldment in a furnace during stress relieving must be at a gradual rate that will minimize the temperature gradient across the section thickness. A general formula for heating and cooling rates has not been found suitable for all shapes and materials. Section VIII of the ASME Boiler and Pressure Vessel Code defines the conditions under which postweld heat treatment must be applied for stress relieving of unfired pressure vessels.

Stress relief of weldments requires that the weldment be properly supported during the stress-relieving heat treatment, to prevent excessive distortion from relaxation of stresses.

Local reheating will soften hard zones, just as placing the entire weldment in a furnace will, but it may not reduce residual stresses. In order to stress relieve by localized reheating, the temperature gradient must be controlled and restriction of movement minimized. Local reheating can be dangerous if misapplied. A cycle of local heating and cooling can intensify residual stresses rather than relieve them.

Joint Preparation

Careful preparation of the weld joint is important. The joint edges can be sheared, machined, ground, chipped, gas cut or arc cut to the desired shape.

Cold working of the metal adjacent to a joint, either in preparing the joint or in cold forming after edge preparation, can cause cracks that can propagate and become large fractures. Gas cutting of high-carbon steels produces a heat-affected zone of hard, brittle metal, the hardness and depth of which increase with increasing carbon equivalent. The effects of gas cutting on medium-carbon steel, and the use of preheating and postheating to obtain an edge with the desired properties, are described on pages 284 to 287 in the article on Gas Cutting, in Volume 4 of this Handbook. Annealing or normalizing may be necessary following gas cutting, to restore the original structure of the steel.

Before welding, irregularities such as nicks, cracks and gouges that could act as stress raisers must be ground out, and grease, paint, surface scale, oxide, water and other foreign material must be removed. Because some carbon steels are sensitive to underbead cracking from hydrogen, water in any form — moisture in scale, humid atmosphere, rain, snow — should be removed, and a low-hydrogen electrode is recommended.

In the example that follows, cracking of weld metal was prevented by two methods of joint preparation. Because large, heavy-section pieces were being welded, preheating and postweld stress relief were not feasible, but cracking was avoided either by reducing joint restraint or by increasing the size and strength of weld metal.

Example 181. Two Methods of Joint Preparation That Prevented Weld Cracking Due to Joint Restraint and Loss of Ductility (Fig. 9)

Weld cracking occurred when heavy 1045 steel channel sections 10 to 20 ft long (see Fig. 9) were joined back-to-back with single-pass welds made by the shielded metal-arc process, using low-carbon steel filler metal (E6010). The cracking was ascribed to: (*a*) the restraint of the heavy sections (36.5 lb per foot) on the welds during cooling and contraction; (*b*) loss of weld ductility due to carbon enrichment of the weld metal by the 1045 steel base metal; (*c*) rapid chilling of the weld metal by the large mass of surrounding base metal; and (*d*) small cross-sectional area of the bead.

In an attempt to prevent cracking, low-hydrogen electrodes, including E7016 and the higher-strength E12018, and 35Cr-15Ni electrodes were tried, but results were little better than those obtained with E6010. Cracking always occurred through the centerline of the weld, which indicated lack of strength or ductility, or both, rather than hydrogen embrittlement.

Next, a revision in joint preparation for welding was made. Two methods were equally effective in preventing weld cracking. In one (method A in Fig. 9), the channel sections were separated by copper wires, 1/16 in. in diameter and 9 in. long, which were placed perpendicular to the channel flanges at 2-ft intervals. To hold the wires and the channels in proper position for welding, strong tack welds were placed near each wire. Both sides of the joint were shielded metal-arc welded with E6010 or E6011 electrodes, working from the center toward the ends. Because of the length of the channels, welding was alternated from side to side every few feet, to avoid cambering. The weld beads were deposited in a single pass, with deep penetration of the base metal. As the welds cooled, the soft copper yielded sufficiently to reduce shrinkage stress.

The other method used to avoid weld cracking (shown as method B in Fig. 9) involved the use of intermittent V-groove welds 4 in. long, spaced on 8-in. centers; joint edges were chamfered to form a 60° V-groove of 1/4-in. minimum depth. After the channels had been placed back-to-back, clamped and tack welded, they were shielded metal-arc welded with low-carbon steel electrodes of the E60*xx* or E70*xx* class. The welds were single-pass welds, deposited from the center toward the ends. Each 4-in. weld was allowed to cool before the next one was begun. To avoid cambering, welding was alternated from side to side after every two welds. Because the V-grooves increased the cross-sectional area of the welds, weld strength and ductility were increased sufficiently to enable the weld to withstand stresses developed by joint restraint and to prevent cracking. Although some of the ductility gained by depositing a greater amount of weld metal undoubtedly resulted from a lesser amount of carbon pickup from the base metal, it was mostly because a greater amount of hot metal was available for elongation or compression.

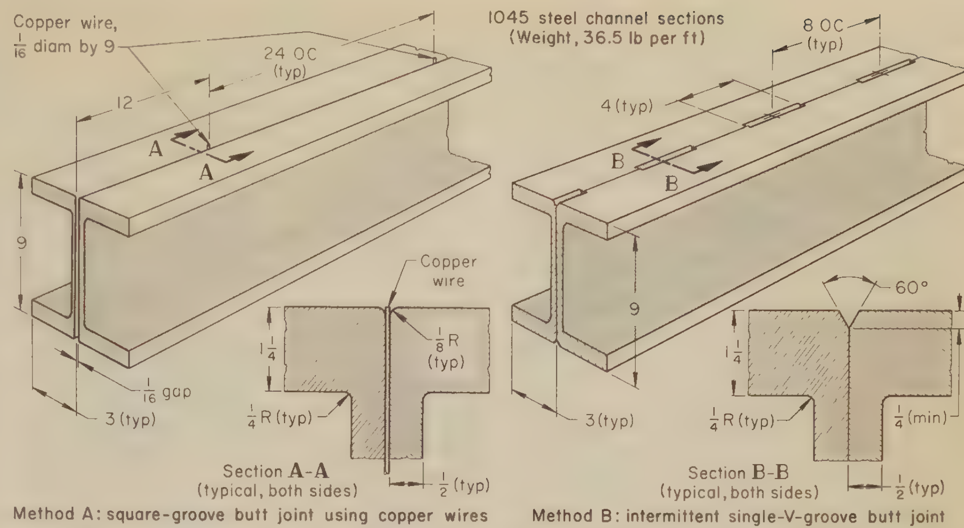


Fig. 9. Two methods of joint preparation for shielded metal-arc welding of heavy channel sections back-to-back, to avoid weld cracking due to joint restraint and insufficient weld ductility (Example 181)

Shielded Metal-Arc Welding

Shielded metal-arc welding is used extensively for joining hardenable carbon steel. In general, the equipment, techniques and difficulties discussed in the article on Shielded Metal-Arc Welding, pages 1 to 23, apply to the welding of hardenable carbon steel.

The use of low-hydrogen electrodes is important in welding hardenable carbon steel. Electrodes with flux coverings that contain cellulose will release hydrogen, which, when absorbed in the hardened zone of a weld, can cause underbead cracks, especially in steel with a high carbon equivalent. Cracking is minimized by the use of low-hydrogen electrodes, by proper storing and drying procedures, by minimizing carbon pickup from the base metal, by selection of electrodes and welding techniques that minimize melting of the base metal, by preheating, and by maintaining an appropriate interpass temperature (see Fig. 6 and 7).

Transferring the weldment to a furnace for postweld stress relieving while it is at or above the interpass temperature is desirable for steels of higher carbon content or higher hardenability.

Large tonnages of hardenable carbon steels are used for applications where weld integrity is imperative, and various welding codes and standards have been developed for these applications. The heating requirements set forth in these codes can be used for applications that are not governed by codes.

Electrodes. The type and size of electrode selected depend on the composition of the steel, its thickness, joint preparation, welding position, and available welding current. Not all of the electrodes covered by AWS specifications A5.1-69 and A5.5-69, which apply to low-carbon steel and low-alloy steel covered electrodes, respectively, are suited for welding hardenable carbon steel. Although hardenable carbon steels are sometimes welded with cellulose-type (high-hydrogen) covered electrodes such as E6010, low-hydrogen electrodes are generally preferred. Among the electrodes most often used are E7015, E7016, E7018, E8016-C1, E8016-C3, E8018-C1, E8018-C3, E10016-D2 and E10018-D2. Of this group, E7018 electrodes are the ones most used. Ranges of welding current for use with various sizes of the above electrodes are given in Table 1.

E7015 and E7016 electrodes are low-hydrogen low-carbon steel electrodes. E7015 electrodes are used with reverse-polarity direct current, and E7016 electrodes are used with alternating current and reverse-polarity direct current. These electrodes are applicable to the welding of hardenable carbon steels that are subject to underbead cracking due to the presence of hydrogen; they can be used without preheating of the metal to be welded or with preheating to a lower temperature than would be necessary with other than low-hydrogen electrodes. However, if E7015 or E7016 electrodes are used without preheating, the notch toughness of the weld will generally be lower than if preheating is employed. The E7015 or E7016 electrodes are also used in the welding of high-sulfur steels; electrodes that are not of the low-hydrogen type are likely to deposit porous weld metal.

With E7015 and E7016 electrodes, the arc, which is moderately penetrating, should be kept as short as possible; the slag is moderately difficult to remove; and the bead shape is slightly convex.

E7018 electrodes are low-hydrogen, iron-powder, low-carbon steel electrodes for use with alternating current and reverse-polarity direct current. These electrodes deposit essentially the same composition of weld metal as E7016 electrodes. The electrode covering contains essentially the same low-hydrogen materials as E7016, but the 25 to 45% iron powder gives E7018 electrodes a higher deposition rate. With E7018 electrodes, the arc, which is moderately penetrating, should be kept as short as possible, the slag is moderately difficult to remove, and the bead shape is slightly convex.

E7018 electrodes can be used in any welding position, and thus are preferred for a wide range of applications.

Low-Alloy Steel Electrodes. With suitable precautions, the low-alloy steel electrodes discussed below can be used for welding hardenable carbon steel, as well as for welding the low-alloy steels for which they were originally developed. They have higher strength than the E70*xx* electrodes.

E8016-C1 and E8018-C1 electrodes are low-alloy, low-hydrogen electrodes for use with alternating current or reverse-polarity direct current. Weld deposits from these electrodes contain about 2.5% nickel. The electrodes are widely used when low-temperature notch toughness is required.

In joints welded using preheat and interpass temperatures of 200 to 225 F and stress

Table 1. Ranges of Welding Current for Various Sizes of Electrodes Used in Shielded Metal-Arc Welding of Hardenable Carbon Steels(a)

Electrode diameter, in.	Current, amp, for electrode of class: E7015, E7016	E7018	E8016-C1, E8018-C1	E8016-C3	E8018-C3	E10016-D2, E10018-D2
3/32	65 to 110	70 to 100	80 to 120	70 to 90	70 to 95	60 to 100
1/8	100 to 150	115 to 165	100 to 150	100 to 130	110 to 140	80 to 120
5/32	140 to 200	150 to 220	150 to 185	130 to 180	130 to 200	140 to 190
3/16(b)	180 to 255	200 to 275	200 to 250	165 to 230	165 to 290	180 to 250

1/4(b)	300 to 390	315 to 400	300 to 425	290 to 330	320 to 400	300 to 400
5/16(b)	375 to 475	375 to 470	....	....	....	....

(a) Lower sides of current ranges are used for vertical or overhead welding; higher sides of current ranges, for welding in the flat position. (b) Not used in all welding positions.

relief at 1150 F, weld metal is required to have the following minimum properties:

Tensile strength	80,000 psi
Yield strength, 0.2% offset	67,000 psi
Elongation in 2 in.	19%

The required Charpy V-notch impact value (at −75 F) for these joints is 20 ft-lb.

The operating characteristics of these electrodes are similar to those of E7016 electrodes.

E8016-C3 and E8018-C3. E8016-C3 electrodes are low-alloy, low-hydrogen electrodes for use with alternating current and reverse-polarity direct current. The weld deposit contains about 1% nickel. When these electrodes are supplied as iron-powder types, they are designated E8018-C3.

In joints welded and tested in conformance with AWS A5.5-69, using preheat and interpass temperatures of 200 to 250 F and no stress relief, the weld metal is required to have the following minimum properties:

Tensile strength	80,000 psi
Yield strength, 0.2% offset	68-80,000 psi
Elongation in 2 in.	24%

The required Charpy V-notch impact value (at −40 F) for these joints is 20 ft-lb.

The operating characteristics of these electrodes are similar to those of E7016 and E7018 electrodes, respectively.

E10016-D2 and E10018-D2 electrodes are low-alloy, low-hydrogen electrodes for use with alternating current and reverse-polarity direct current. The weld deposit contains about 1.75% manganese and 0.35% molybdenum. The electrodes were designed for welding high-strength steels of high hardenability, but they have been used for welding carbon steels containing 0.30% carbon or more, when high strength of the weld deposit is required.

In joints welded using preheat and interpass temperatures of 200 to 225 F and stress relief at 1150 F, weld metal is required to have the following minimum properties:

Tensile strength	100,000 psi
Yield strength, 0.2% offset	87,000 psi
Elongation in 2 in.	16%

The required Charpy V-notch impact value (at −60 F) for these joints is 20 ft-lb.

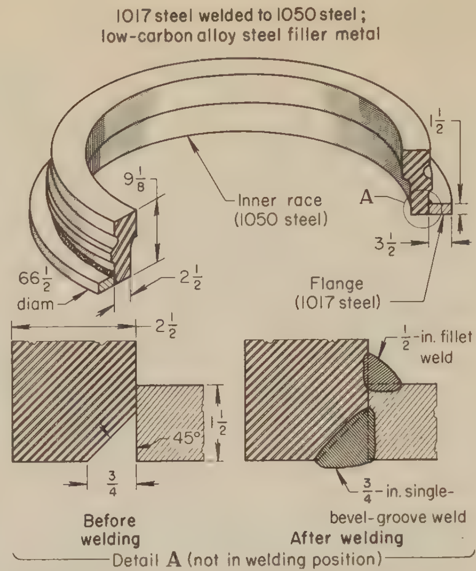
Control of Moisture Content of Electrodes. Because hardenable carbon steels are susceptible to underbead cracking when welded with an arc that contains hydrogen, the moisture content of electrode coverings should be kept at a very low level, which can be done by careful storage and use of electrodes. For information on the care and reconditioning of low-hydrogen electrodes, see "Low-Hydrogen Coverings" on page 7 in the article on Shielded Metal-Arc Welding.

Flux-Cored Arc Welding

For the most part, the process, equipment and techniques discussed in the article on Flux-Cored Arc Welding, pages 24 to 45, apply to the welding of hardenable carbon steel (Example 20 in that article deals with welding of 1045 to 1055 steel).

The procedures for preheating and postheating presented earlier in this article, although generally oriented toward shielded metal-arc welding, apply to a large extent to flux-cored arc welding. However, in welding steels of undetermined weldability, heating procedures must be established with caution. The process should be qualified for the specific application.

Although flux-cored electrode wires are available for welding a wide variety of steels, only low-carbon steel electrode wires have thus far (1971) been covered by specifications. These specifications are discussed in the Appendix to "Flux-Cored Arc Welding", pages 41 to 45 in this volume. Experience and information on the use of the standard electrodes in welding hardenable carbon steels are limited. In the following three examples, electrodes of the E70T-1 classification were used for three different hardenable carbon steel weldments.



Automatic Flux-Cored Arc Welding(a)

Joint types	Corner and butt
Weld types	Fillet and single-bevel groove
Power supply	750-amp rectifier(b)
Electrode holder	Mechanically held, air cooled
Electrode	7/64-in.-diam flux-cored wire(c)
Shielding gas	Carbon dioxide, at 40 cfh
Welding position	Flat
Number of passes:	
Single-bevel-groove weld	Three
Fillet weld	Two
Current (dcrp) and voltage:	
Root pass	550 amp; 28 to 30 v
Filler pass	550 to 600 amp; 32 to 34 v
Welding speed:	
Root pass	25 ipm
Filler pass	13 ipm
Preheat temperature	600 F
Interpass temperature (minimum)	600 F
Postheat	None(d)

(a) Equipment included: an automatic, constant-speed wire feeder; a variable-speed rotating positioner with a universal clamping fixture; a ram-type manipulator for supporting the welding head; and two natural-gas preheating torches on pedestals. (b) Constant-voltage. (c) Composition, 0.06 C, 1.60 Mn, 0.40 Si, 2.30 Ni, 0.40 Mo. (d) Air cooled to room temperature; later the race area only was induction hardened.

Fig. 10. Ball-bearing inner-race assembly that was joined with high-quality welds by the automatic flux-cored arc process (Example 185)

Examples 182, 183 and 184. Flux-Cored Arc Welding vs Shielded Metal-Arc Welding for Three Different Applications (Table 2)

For each of the three applications listed in Table 2, shielded metal-arc welding had been used, and the process was changed to flux-cored arc welding with auxiliary gas shielding, at a substantial saving in welding time, generally from 35 to 50%. Continuous electrode feed, higher deposition rate, and higher travel speed with flux-cored arc welding were mainly responsible for the decreased welding time. No preheating nor postheating was required in these applications.

Details about the base metal, the type of weld, and welding conditions for flux-cored arc welding in the three applications are presented in Table 2.

The example that follows describes an application in which automatic flux-cored arc welding was used to produce welds suitable for service under severe loading and extremes of temperature.

Example 185. Welding Bearing-Race Assemblies by the Automatic Flux-Cored Arc Process (Fig. 10)

Ball-bearing inner-race assemblies 2 to 10 ft in diameter, each consisting of a 1050 steel inner race and a 1017 steel flange, were joined by two circumferential welds, using the automatic flux-cored arc process with auxiliary gas shielding. As indicated in Fig. 10, which shows a typical bearing race, the welds were a ½-in. fillet weld and a ¾-in. single-bevel-groove weld.

Because the bearings were the main supports for mobile cranes and shovels, and were subjected to high loads and extreme weather conditions in service, sound welds with good mechanical properties were essential. The welds were specified to have no underbead cracks or other defects visible under dye-penetrant inspection. With the use of the welding conditions listed in the table with Fig. 10, crack-free welds with no evidence of slag inclusions or porosity were obtained. The weld metal had the following typical tensile properties:

Tensile strength	115,000 psi
Yield strength	102,700 psi
Elongation in 2 in.	20%
Reduction of area	42%

Although all processing conditions contributed to weld soundness, the most important were the use of preheating, the selection of a suitable low-carbon alloy steel electrode wire (see footnote in table with Fig. 10), and the close control that is characteristic of automatic welding.

Submerged-Arc Welding

Submerged-arc welding is used both as a fully automatic and as a semiautomatic process for joining and for surfacing of hardenable carbon steels. The article on Submerged-Arc Welding, which begins on page 46 in this volume, discusses in detail the equipment, electrodes, fluxes, and procedures. Although that article primarily concerns low-carbon steels, most of the information in it is pertinent to the welding of carbon steels with higher carbon content (hardenable grades).

Procedures for preheating and postheating suggested in the earlier part of this article were oriented toward shielded metal-arc welding and do not necessarily apply to the same degree to submerged-arc welding. Preheating and postheating are less likely to be required for submerged-arc welding than for shielded metal-arc welding, for two reasons: (*a*) because of the high heat input and high deposition rate of submerged-arc welding, a larger area is heated, and consequently, the cooling rate is lower and the probability of hardening is lessened; and (*b*) the flux blanket helps to retard cooling. However, in many applications, preheating and postheating are needed in submerged-arc welding of hardenable carbon steels. Each application must be evaluated separately.

The submerged-arc process is ordinarily capable of depositing low-hydrogen weld metal, provided the flux is properly dried and other precautions, including keeping the area surrounding and including the joint free of moisture, oil, grease, paint, scale, or other material that could be a source of hydrogen, are observed. The flux, which

may be hygroscopic, must be kept dry. Proper storage and handling are important. A widely followed practice for maintaining low-hydrogen conditions is to keep the flux in an oven at about 250 F for several hours before it is needed.

The use of preheat, controlled interpass temperature, and postweld stress relieving in joining low-carbon steel arms to a medium-carbon steel shaft is illustrated by the following example.

Example 186. Submerged-Arc Welding of 1015 Steel Arms to a 1038 Steel Shaft (Fig. 11)

The rotor shaft for a motor consisted of four longitudinal arms of 1015 steel joined to a premachined shaft of 1038 steel by two-pass submerged-arc welds.

The arms were beveled by either machining or gas cutting, and were shot blast cleaned before welding. The arms were aligned on the shaft by means of two retaining rings, and the entire assembly was preheated to 400 to 500 F before any welding was done. After preheating, one side of each arm was tack welded to the shaft, as shown in section A-A in Fig. 11, by shielded metal-arc welding with E7016 low-hydrogen electrodes. The shaft was then placed on the turning rolls of a positioner table, and the four arms were checked for alignment. Next, the tack welds were cleaned of slag, and the first passes by submerged-arc welding were made (see position 1 in section B-B in Fig. 11). First-pass weld beads were deposited on side 1 of each of the four arms (the side that had not been tack welded); then the shaft was turned end-for-end, and first-pass beads were deposited on side 2.

With the completion of all first passes, the welding electrode and shaft were repositioned for making the second passes (see position 2 in section B-B in Fig. 11). Second passes were completed on one side of each arm. At this point, the assembly was checked for alignment, so that any distortion could be corrected by changing the sequence of the remaining weld passes. The shaft was then turned end-for-end, and the second passes were made on the other side of the joints.

The placement of weld beads was specified to ensure a smooth transition from the arm to the shaft. The weld surface remained as-deposited, receiving no further finishing except for cleaning and slag removal. (Subsequently, attachments were made to the arms by shielded metal-arc welding with low-hydrogen electrodes.)

During the entire sequence of welding operations, the interpass temperature was held at a minimum of 400 F, and after completion of welding, the assembly was stress relieved at 1175 F for 1 hr per inch of maximum section thickness. The heating rate was 150 F per hour, and the controlled cooling rate was 150 F per hour to 300 F. Additional details of welding conditions are presented in the table with Fig. 11.

Previously, this rotor shaft had been machined from a fluted open-die forging at a cost that was competitive with the cost of the welded assembly. However, because the rotor shafts were produced in a variety of shapes, and with major shaft diameters ranging from 4½ to 10 in., lead times for the forgings gave rise to inventory and handling charges that were considered unnecessary. The change to a weldment eliminated these costs, because the lead time for the components for the welded assembly was less than for the forging. Shafting stock and plate for the arms were readily available, and the arms were gas cut from plate as needed.

Gas Metal-Arc Welding

Gas metal-arc welding is widely used for joining hardenable carbon steels. The article on Gas Metal-Arc Welding, which begins on page 78 in this volume, discusses in detail the advantages, disadvantages, applicability, principles, equipment, shielding gases, design, costs, and safety problems associated with this process. Although the above article is concerned primarily with the welding of low-carbon steel, much of the information is pertinent to the welding of hardenable carbon steels.

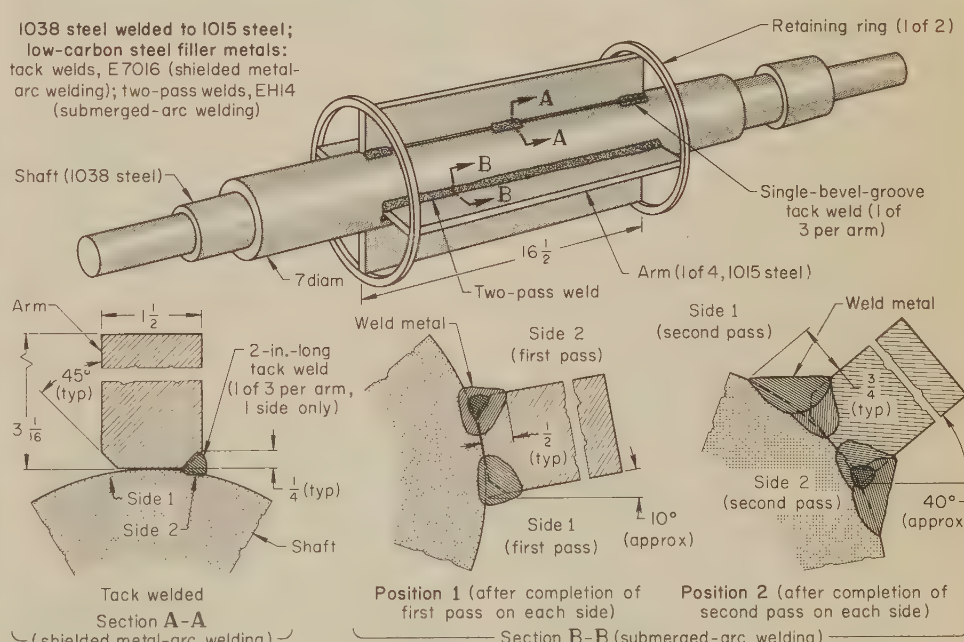
The preheating and postheating practices described earlier in this article for shielded metal-arc welding are frequently applicable to gas metal-arc welding. However, they are not always the same. For example, the depth of penetration can influence preheating practice, and this is likely to differ between the two processes. Furthermore, there may be a difference in requirements for preheating among the different techniques for the gas metal-arc process. In some applications, the need for preheating is eliminated by using argon instead of carbon dioxide as a shielding gas, because of the difference in penetration patterns obtained with the two gases. The mode of metal transfer can also affect the need for preheating — the spray arc penetrates considerably deeper than the short-circuiting arc. Because of the many variables with gas metal-arc welding, it is more important to qualify the procedure for a given application than it is for other arc welding processes.

Because a shielding gas is used instead of a flux, the possibility of introducing hydrogen into the weld metal is minimal, but the usual precautions, including keeping the weld joint free of moisture, oil, grease, paint, scale, or other material that could adversely affect weld quality, should be observed to ensure sound welds. The electrode wire is sometimes a source of hydrogen, particularly if the surface is poor. Laps

Table 2. Operating Conditions for Three Applications of Automatic Flux-Cored Arc Welding of Hardenable Carbon Steels (Examples 182, 183 and 184)

Item	Example 182 (House-trailer axle)	Example 183 (Punch-press gear)	Example 184 (Sinter-pot flange)
Steel welded	1045	1020 and 1045	ASTM A285
Thickness	3/16 to 1/4 in.	...	2 in.
Joint type	Butt	T-joint	Edge
Weld type	...	1/2-in. fillet	(a)
Electrode wire	3/32-in.-diam E70T-1	3/32-in.-diam E70T-1	3/32-in.-diam E70T-1
Shielding-gas (CO_2) flow rate	...	45 cfh	55 cfh
Welding current (dcrp)	300 to 400 amp	600 amp	450 amp
Arc voltage	25 v	32 v	28 to 30 v
Power supply(b)	500 amp	750 amp	500 amp
Travel speed	50 ipm	10 ipm	18 to 24 ipm

(a) Single-bevel-groove weld, 45° by 1 9/32 in. deep, inside; 3/4-in. flat fillet, outside. (b) Constant-voltage motor-generator.

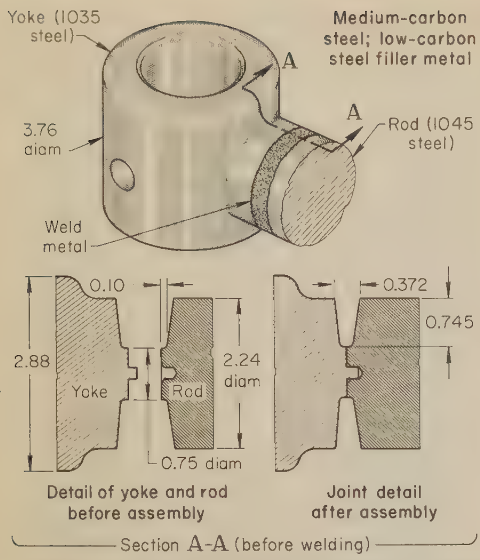


Conditions for Submerged-Arc Welding

Joint type	T
Joint preparation	Machining or gas cutting
Weld type, each side	Single-bevel groove
Electrode wire	5/32-in.-diam EH14(a)
Flux	F72
Welding position	Flat
Voltage	28 to 29 v
Current	540 amp, ac
Number of passes per side	Two
Welding speed, first pass	10 ipm
Welding speed, second pass	7 ipm
Preheat (before tack welding)	400 to 500 F
Interpass temperature (min)	400 F
Postheat	1175 F(b)

(a) Automatic feed. (b) For 1 hr per inch of maximum section thickness. Weldment was heated to 1175 F (and later cooled to 300 F) at 150 F per hour.

Fig. 11. Rotor-shaft assembly in retaining ring for submerged-arc welding, and details of joint design and weld-pass sequence that, together with preheating, maintenance of interpass temperature, and postweld stress relieving, minimized stress concentration (Example 186)



Automatic Gas Metal-Arc Welding

Power supply	300-amp rectifier, with controlled slope, voltage and inductance
Electrode wire	0.045-in.-diam low-carbon steel
Current	Reverse-polarity direct
Arc time	2.56 min
Shielding gas	75% A – 25% CO_2, at 28 cfh
Wire-feed rate	295 ipm
Preheat and postheat	None
Electrode consumption per weld	755 in.
Floor-to-floor time	3.43 min

Fig. 12. Yoke-and-rod assembly, and details of the deep circumferential joint welded by the automatic gas metal-arc process (Example 187)

or folds are likely to contain drawing lubricants.

Welding-grade argon is generally low in hydrogen. A minimum dew-point temperature of −60 F should be specified and certified by the vendor. Sometimes gas suppliers fail to drain and dry cylinders before refilling; this results in dew-point temperatures of −10 to −30 F, which are likely to cause cracking. The moisture content of welding-grade carbon dioxide used for gas metal-arc welding is usually at a dew point of −40 F or less.

An application for gas metal-arc welding of hardenable carbon steel is described in Example 78 in the article on Gas Metal-Arc Welding, and an application where the process was used for surfacing a hardenable carbon steel is described in Example 156 in the article on Hard Facing by Arc Welding.

Automatic Welding. In the three examples that follow, automatic gas metal-arc welding was used because of higher production rate and better quality of welds, and because less operator skill was needed.

Example 187. Automatic Circumferential Welding of a Yoke to a Rod Section (Fig. 12)

The steel yoke-and-rod assembly shown in Fig. 12 required a circumferential weld about ¾ in. deep, with a maximum width of about ⅜ in. at the top of the weld joint. The nature and magnitude of service loading required that the weld begin as close as possible to the center, or core, of the rod, which accounted for the design of the joint (see section A-A in Fig. 12).

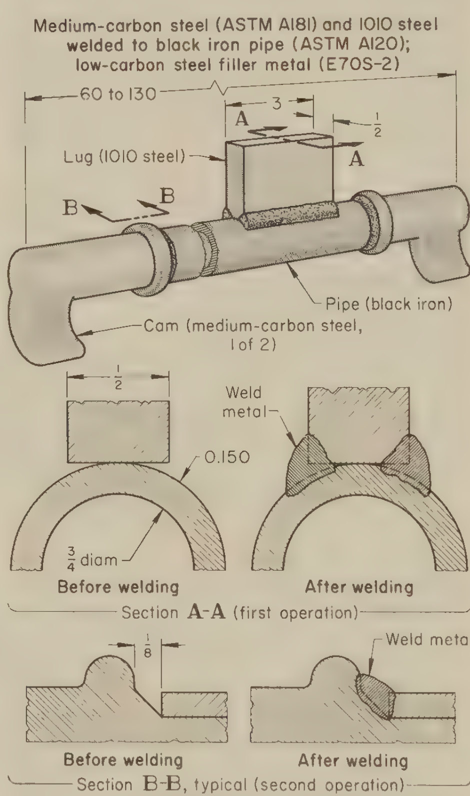
The automatic gas metal-arc process was selected for this application, on the basis of production rate and the ability of automatic welding to produce a narrow weld bead without overfill, so that little subsequent machining would be required. Total investment for the automatic equipment was less than $8000.

Details of the welding operation are given in the table that accompanies Fig. 12. The 1045 steel rod was welded in the cold finished, ground and polished condition. Despite the relatively thick sections (approximately 2¼ in.) and the fact that 1035 and 1045 steels are hardenable, no excessive hardness was obtained in the heat-affected zones. This was attributed to the relatively large amount of weld metal deposited and the use of multiple-pass welding, which functioned with about the same effect as preheating and postheating.

Example 188. Use of Automatic Gas Metal-Arc Welding for Joining Four-Component Door-Lock Assemblies (Fig. 13)

The weldment shown in Fig. 13 — a lock rod for a cargo-trailer door — consisted of two cams forged from medium-carbon steel (ASTM A181, 0.35% max carbon), a rectangular 1010 steel lug, and a length of standard ¾-in. black iron pipe (ASTM A120). Fully automatic gas metal-arc welding was selected for joining these components, for three reasons:

1 The welds were sounder and had better appearance than those made with semiautomatic welding.
2 Almost no distortion occurred when the lug was welded to the pipe.

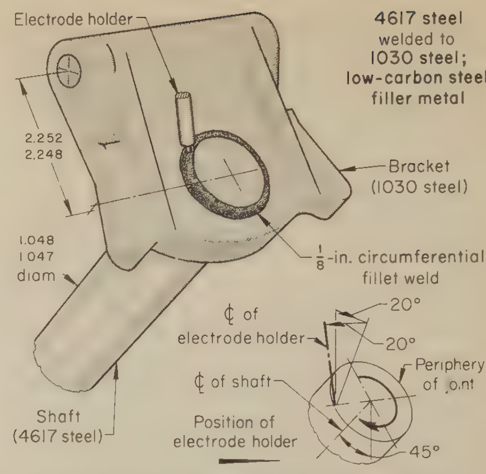


Automatic Gas Metal-Arc Welding

Power supply	Two 200-amp rectifiers(a)
Electrode wire	0.035-in.-diam E70S-2
Electrode holders	Air cooled, machine held
Wire feed	Automatic, constant feed
Current	170 amp, dcrp
Voltage	20 v
Arc type	Short circuiting
Shielding gas	Carbon dioxide, at 20 cfh
Preheat and postheat	None
Welding time, first operation(b)	12 sec
Welding time, second operation(c)	13 sec

(a) Constant-voltage type, with variable slope control. (b) Welds on both sides of lug were deposited simultaneously. (c) Both cams were welded to pipe simultaneously.

Fig. 13. Cargo-trailer door-lock assembly that was joined in two operations by automatic gas metal-arc welding (Example 188)



Semiautomatic Gas Metal-Arc Welding

Joint type	Corner, circumferential
Weld type	Fillet
Power supply	250-amp rectifier
Electrode wire	0.035-in.-diam, copper-coated low-carbon steel
Electrode holder	Mechanically held, air cooled
Current	225 amp, dcsp
Voltage	25 v
Shielding gas	Carbon dioxide, at 5 to 10 psi
Number of passes	One
Wire-feed rate	435 ipm
Welding time, floor-to-floor:	
Original method	1.734 hr per 100 pieces
Improved method	1.470 hr per 100 pieces
Preheat and postheat	None
Rejection rate	Less than 0.1%

Fig. 14. Bracket assembly for which semiautomatic gas metal-arc welding was fully automated to increase production (Example 189)

3 To meet production demand, at least three welders would have been required if semiautomatic welding had been used, whereas only one operator was required for the fully automatic setup.

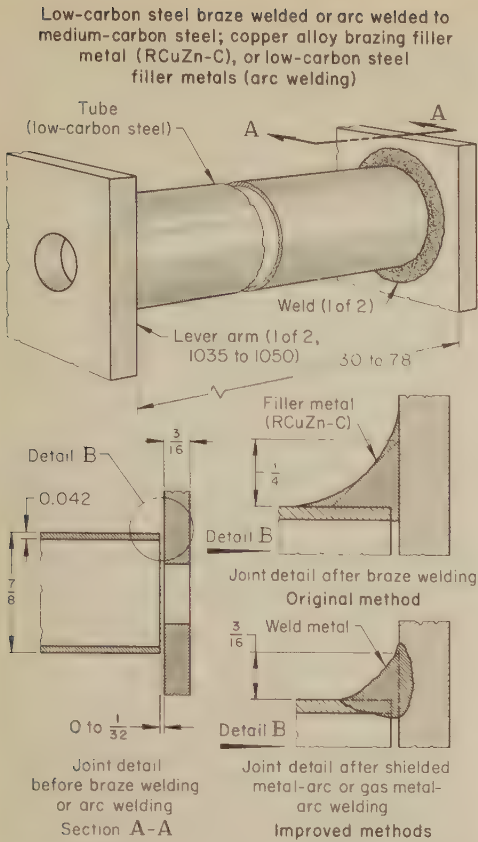
Welding was done in two operations. In the first operation, the rectangular lug was positioned on the pipe and welded to the pipe by means of fillet welds deposited on the two sides of the lug (see section A-A in Fig. 13). For this operation, the pipe and the lug were loaded into a fixturing mechanism, and the two welds were deposited simultaneously.

Welding time was 12 sec, and the production rate, including handling time, was 60 weldments per hour.

In the second operation, the pipe-and-lug weldment, with a cam placed at each end of the pipe, was loaded into the fixturing mechanism (adapted for circumferential welding), the cams were positioned in accurate dimensional relationship with the lug and automatically tack welded, and the assembly was rotated 180° before the initiation of circumferential welding.

Welding the two cams simultaneously (see typical joint detail in section B-B in Fig. 13) required that the assembly be rotated 360° plus a slight overlap. The assembly was then returned to the starting position and was unclamped and unloaded manually. Welding time was 13 sec, and production rate, including handling, was 40 weldments per hour.

Both welding operations were done in a special fixturing device designed to accommodate various types of cams, pipe lengths, and lug positions required to make both right-hand and left-hand assemblies ranging from 60 to 130 in. in over-all length. A full production quantity of parts was first-operation welded (lug to pipe) before the machine was adjusted for the second operation (pipe to cams). Longitudinal speed for the fillet welds was controlled by an air-hydraulic cylinder, and speed for the circumferential welds was controlled by an electronic variable-speed drive. Welding conditions are given in the table that accompanies Fig. 13.



Item	Braze welding(a)	Shielded metal-arc welding(b)	Gas metal-arc welding
Cost per Assembly			
Welding materials	$0.085	$0.014	$0.012
Direct labor	0.105	0.135	0.045
Total	$0.190	$0.149	$0.057

Conditions for Gas Metal-Arc Welding

Power supply	300-amp transformer-rectifier(c)
Electrode wire	0.035-in.-diam low-carbon steel
Electrode holder	Hand held; 150 amp(d)
Wire feed	Push type, continuously variable
Current	75 amp, dcsp
Voltage	25 v
Shielding gas	Carbon dioxide, at 22 psi (cylinders)
Number of passes	One
Wire-feed rate	255 ipm

(a) With an oxyacetylene torch set for a slightly oxidizing flame. Filler metal was RCuZn-C (low-fuming bronze); flux was a liquid proprietary mixture introduced into the flame by a fluxer. (b) With ⅛-in. E6012 electrodes 14 in. long, and direct current from a 300-amp transformer-rectifier. (c) Constant-voltage type, with slope control. (d) Light-duty type.

Fig. 15. Torque-tube assembly for which gas metal-arc welding was the least costly of three joining processes used (Example 190)

Example 189. Change From Semiautomatic to Automatic Operation for Faster Welding With Decreased Welder Skill (Fig. 14)

Increased production demand prompted a change from semiautomatic to automatic gas metal-arc welding for joining the components of the bracket assembly shown in Fig. 14 — a machined 4617 steel shaft and a forged 1030 steel bracket. The change resulted in an increased production rate, and a decrease in welding cost from $4.43 to $3.35 per hundred assemblies. Also, the automatic operation was satisfactorily performed by a less highly skilled operator, and the welded assemblies were more uniform and had a better appearance.

For automatic welding, the press-fitted assembly was held at a 45° angle while being rotated at constant speed. The fixture used was specially designed, and incorporated an air-operated device for positioning and retracting the electrode holder (position of the holder during welding is shown at lower right in Fig. 14). Except for manual loading and unloading, the cycle was fully automatic. Welding conditions are given in the table that accompanies Fig. 14. Weld quality was judged visually.

Gas Metal-Arc Welding vs Other Welding Processes. In the two examples that follow, improvement in weld quality and decreased manufacturing cost resulted from changing to semiautomatic gas metal-arc welding.

Example 190. Change From Braze Welding to Shielded Metal-Arc Welding and Then to Gas Metal-Arc Welding, To Reduce Welding Costs (Fig. 15)

A torque-tube assembly that coordinated the operation of parallel mechanisms of a folding bed consisted of two medium-carbon steel (the grade varied from 1035 to 1050) lever arms, 3⁄16 in. thick, and a 0.042-in.-wall low-carbon steel tube 30 to 78 in. long. The lever arms were joined to the ends of the tube by circumferential fillet welds in T-joints, as shown in Fig. 15.

Originally, the tube assembly was braze welded, but welding cost was high and, despite a low (1%) rejection rate on visual inspection, weld reliability under load was poor. A change to shielded metal-arc welding improved weld reliability, and reduced welding cost by 21.5%. Later, the process was changed to semiautomatic gas metal-arc welding; this resulted in the production of welds with still greater reliability by less-skilled operators, and resulted in a 70% reduction in welding cost compared with that for braze welding, and a 62% reduction compared with that for shielded metal-arc welding. Costs and conditions for the three welding processes are summarized in the table that accompanies Fig. 15.

Although fillet size was different (see Fig. 15), the processing sequence was similar for the three welding methods. The tube, sawed to length, was assembled with the lever arms in a holding fixture, the assembly was welded, and the welds were inspected visually.

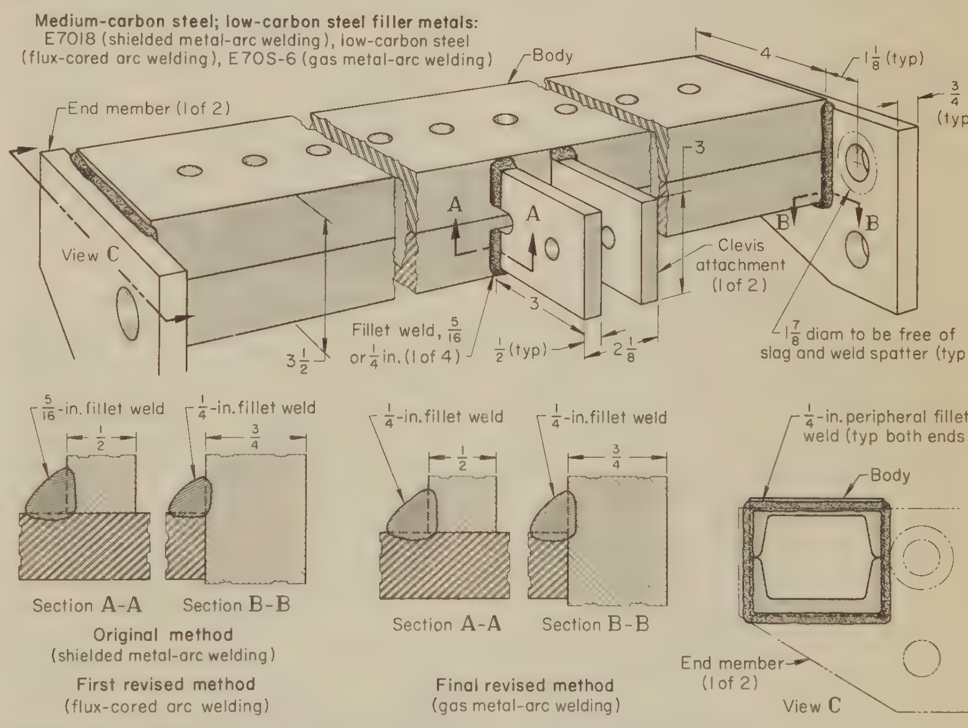
Objectionable hardening did not occur, probably because the fillet size was quite large compared with the wall thickness of the tubing, and so the cooling rate was relatively low.

Example 191. Change From Shielded Metal-Arc and Flux-Cored Arc Welding to the Gas Metal-Arc Process To Eliminate Spatter (Fig. 16)

The medium-carbon (0.45 to 0.55%) steel weldment shown in Fig. 16 is a hitch assembly used as a connector between a tractor and a heavy-duty farm implement. Specifications required that an area 1⅞ in. in diameter on the inside faces of the end members, surrounding two holes for the insertion of hitch pins, be completely free of slag and weld spatter.

Originally, the fillet welds joining the end members and clevis attachments to the body of this assembly were made by the shielded metal-arc process, using E7018 electrodes at 275 amp (dcrp) and 30 volts. Shielded metal-arc welding, though, resulted in excessive slag and weld spatter, whose removal entailed shot blasting, which added to the cost of making the part. Moreover, deposition rate was low.

In an unsuccessful attempt to avoid the difficulty, the process was changed to flux-

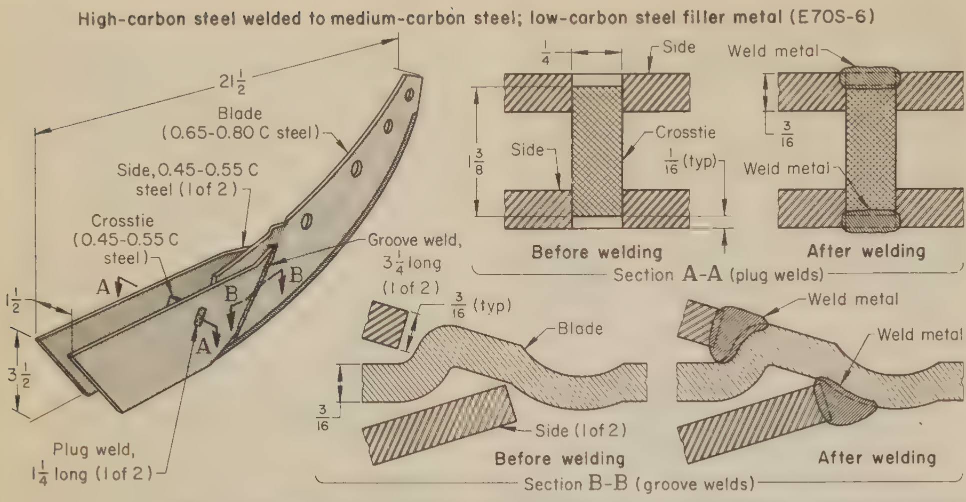


Conditions for Semiautomatic Gas Metal-Arc Welding

Joint type	T	Shielding gas	95% A – 5% O_2, at 30 cfh(b)
Weld type	Fillet	Current	270 amp, dcrp
Welding position	Horizontal	Voltage	28 v
Power supply	300-amp rectifier(a)	Stickout	½ in.
Wire feed	Attached to power supply	Electrode-wire speed	375 ipm
Electrode holder	Hand held, 300 amp	Preheat and postheat	None
Electrode wire	0.045-in.-diam E70S-6	Production rate	50 weldments per 8-hr shift

(a) Constant-voltage type. (b) Supplied from central bulk storage.

Fig. 16. Tractor-hitch weldment for which semiautomatic gas metal-arc welding, under the conditions given in the table, eliminated slag and weld spatter, which had entailed shot blast cleaning after shielded metal-arc and flux-cored arc welding (Example 191)



Conditions for Semiautomatic Gas Metal-Arc Welding

Joint types	Butt and T	Shielding gas	95% A – 5% O_2, at 29 cfh(b)
Weld types	Groove and plug	Current	260 amp, dcrp
Welding position	Flat (15° inclination)	Voltage	29 v
Power supply	300-amp rectifier(a)	Stickout	½ in.
Wire feed	Attached to power supply	Electrode-wire speed	325 ipm
Electrode holder	Hand held, 300 amp	Welding speed	14 ipm(c)
Electrode wire	0.045-in.-diam E70S-6	Preheat and postheat	None

(a) Constant-voltage type. (b) Supplied from bulk storage. (c) Welding speed by the shielded metal-arc process had been 5 to 7 in. per minute.

Fig. 17. Runner for a seed-planter unit, and details of joints for which welding and finishing times were reduced by changing from shielded metal-arc welding to semiautomatic gas metal-arc welding, under the conditions given in the table (Example 192)

cored arc welding, using cored low-carbon steel electrode wire at 375 amp (dcrp) and 29 volts. Although deposition rate was increased over that in shielded metal-arc welding, weld spatter was still excessive enough to entail shot blast cleaning. In addition, fillet legs were unequal, and ingredients in the flux caused green paint that was applied to the completed weldment to turn yellow when dried.

Next, some minor design changes, including slight changes in the side pieces and in the holes in the box section, were made so that welding could be done by the gas metal-arc process. Welding conditions are given in the table with Fig. 16. Quality of the welds was completely satisfactory, and the need for postweld cleaning was eliminated. In addition, there was a saving of 11.175 hr per 100 weldments compared with shielded metal-arc welding. (Annual production was 3850 weldments.)

Before welding, the end members of the hitch assembly were gas cut, and the hitch-pin holes were hot pierced and reamed. The two clevis-attachment members were blanked and pierced in a punch press. The boxlike body had been fabricated as a welded subassembly from two 4-in. structural channels that were pierced before being welded together.

The five components were assembled in a holding fixture, and securely clamped and tack welded. Then the assembly was removed and placed on a worktable for welding. Because the fixture was the same as that employed for shielded metal-arc and flux-cored arc welding, the change to gas metal-arc welding entailed no additional fixturing cost.

To obtain high-quality welds, processing conditions had to be carefully controlled. For consistently sound welds with minimum porosity, the work-metal surfaces had to be free of rust, oil and grease. This was ensured by shot blast cleaning before welding. Heat input had to be controlled, to minimize grain growth and brittleness in the weld metal due to an increase in the carbon content of the weld metal by dilution from the base metal. Welding voltage was maintained within 2 volts, and current was restricted to a maximum rise of 10% above the original value. Stickout was maintained at ½ in., −0, +⅛ in., to control weld-bead shape and to eliminate porosity and spatter. The contact tip was set ⅛ to 3/16 in. inside the nozzle; this retraction afforded optimum control of gas coverage of the weld puddle. To avoid interruption of gas coverage, no fans or drafts were permitted in the welding area.

The size of the fillet welds joining the clevis attachments to the body of the assembly was reduced from 5/16 to ¼ in. for gas metal-arc welding (see Fig. 16). The penetration for the ¼-in. weld beads was greater than for the 5/16-in. beads previously specified, and when a section was cut, polished and etched for examination, the smaller bead, although visually ¼ in. on top, was actually equal to a 5/16-in. fillet when measured through the throat.

The following example illustrates how a change from shielded metal-arc to semiautomatic gas metal-arc welding, for joining a high-carbon steel (0.65 to 0.80% carbon) blade to side frames and crosstie bars made of medium-carbon steel (0.45 to 0.55% carbon), reduced welding, finishing and rework time and produced joints capable of withstanding severe shock and impact in service.

Example 192. Change From Shielded Metal-Arc to Semiautomatic Gas Metal-Arc Welding That Reduced Repair and Finishing Time (Fig. 17)

A runner for a seed-planter unit, shown in Fig. 17, was subjected to severe abrasion during its use in cleaving soil, usually to a depth of 3 to 4 in. In addition, the runner had to sustain the occasional impact that resulted from contact with stones.

Originally, shielded metal-arc welding was used for joining the components of the runner assembly. Despite the use of small (⅛-in.-diam) low-hydrogen electrodes for control of penetration and bead size, 15 to 20% of the weldments required rework, which entailed an excessive amount of grinding, because of melt-through and overwelding. In addition, welding speed was only 5 to 7 in. per minute.

When the process was changed to semiautomatic gas metal-arc welding, under the conditions given in the table with Fig. 17, grinding time was reduced by 75%, rework was decreased to a maximum of 2%, and welding speed was more than doubled. The welds were more uniform in quality than the shielded metal-arc welds, being sound, free of slag and inclusions, and tough enough to withstand field use.

The sides and crosstie were blanked and formed in presses from hot rolled 0.45 to 0.55% carbon steel. The blade was blanked cold from hot rolled 0.65 to 0.80% carbon steel, and hot worked to shape. All components were abrasive blast cleaned before being delivered to the welding department.

After the components had been located over pins and clamped, the assembly was inclined 15° from the flat position for welding. The welder used a slightly oscillating movement to control penetration and bead shape. The end of the nozzle of the electrode holder was held at a distance of about ½ in. from the workpiece; this provided sufficient gas for a porosity-free weld and eliminated excessive spatter. No preheat or postweld heat treatment was used.

Before production was started, three sample weldments were sectioned and etched to check for porosity and cracks. If the samples were satisfactory, the power supply and wire drive were locked and production began. During production, an inspection was made every 30 min, and all defective parts were reworked before production continued.

The change to gas metal-arc welding resulted in a 25% reduction in cost per unit. For every hundred units, welding time was reduced by 2.013 hr and grinding time was reduced by 2.632 hr. With this total saving of 4.645 hr per 100 units, and an annual production of 9000 units, the change to gas metal-arc welding saved 418 hours of production time per year.

Although neither preheating nor postweld heating was used in producing the weldment described in the preceding example (which had one component made of steel containing 0.65 to 0.80% carbon), preheating and postweld heating are ordinarily used. As-welded joints in a steel containing 0.80% carbon should be employed with great caution, because of low notch toughness in the heat-affected zone.

Gas Tungsten-Arc Welding

Gas tungsten-arc welding (discussed in detail in the article that begins on page 113) is less frequently used for joining carbon steel than for high-alloy steels and nonferrous metals.

With gas tungsten-arc welding, as with other welding processes, the use of automatic methods generally is desirable (provided the production volume is great enough to justify the equipment cost), because automatic welding usually increases the uniformity and controllability of weld quality and decreases manufacturing time.

The example that follows describes an application in which a change from manual to automatic gas tungsten-arc welding resulted in improved weld quality and increased production rate.

Example 193. Automatic Gas Tungsten-Arc Welding of Medium-Carbon Steel Tubes to Tube Sheet Overlaid With Low-Carbon Steel (Fig. 18)

Fillet welds joining tubes to tube sheet for use in heat exchangers in feedwater heaters (see Fig. 18) were formerly made by manually rotating a piloted gas tungsten-arc torch centered in the tube hole. Two passes were made around the 3/16-in. tube projection to form a fillet weld, each pass fusing a preplaced filler-wire ring. Although the welds were acceptable, they

lacked uniformity; weld size and contour depended largely on the skill of the operator in rotating the torch at a constant speed for proper fusion of the filler-wire ring. In addition, production rate seldom exceeded 80 welded joints per 8-hr shift.

The substitution of a new procedure, using fully automatic gas tungsten-arc welding equipment under the conditions tabulated with Fig. 18, made it possible to obtain uniformly high-quality welds with good reproducibility. Defects that required rework were few, and production rate increased to an average of 190 welded joints per 8-hr shift.

The automatic equipment included a custom-built gas tungsten-arc welding head that was motor driven to rotate around a water-cooled stationary pilot inserted in the tube hole. Cold filler-metal wire was supplied to the arc from a spool, through a wire-feed drive and an adjustable wire-guide tip, all of which rotated with the welding head. This equipment, together with the slide mounting for horizontal and vertical positioning of the welding head to the tubes, is shown in Fig. 18.

Other equipment features essential to the procedure included: (*a*) an electric gage for accurate positioning of the tip of the tungsten electrode before the first pass was started; (*b*) automatic control of the flow of cooling water for the torch pilot, and of the argon shielding gas; (*c*) an indexing system that automatically retracted the tungsten electrode between passes; (*d*) a 300-amp, constant-current rectifier power supply with high frequency and slope control; and (*e*) an electronic programer with sequence timers, to coordinate the weld cycles for preweld gas (prepurge), arc initiation, weld time per pass, arc decay, postweld gas (postpurge), and cooling-water flow.

The tube sheet had been surfaced with a low-carbon steel overlay of ⅛-in. minimum thickness after machining (see Example 195). The carbon content of the overlay was held to 0.15% maximum, to provide a more ductile heat-affected zone on the tube sheet, since the tube-sheet forging before cladding contained as much as 0.35% carbon.

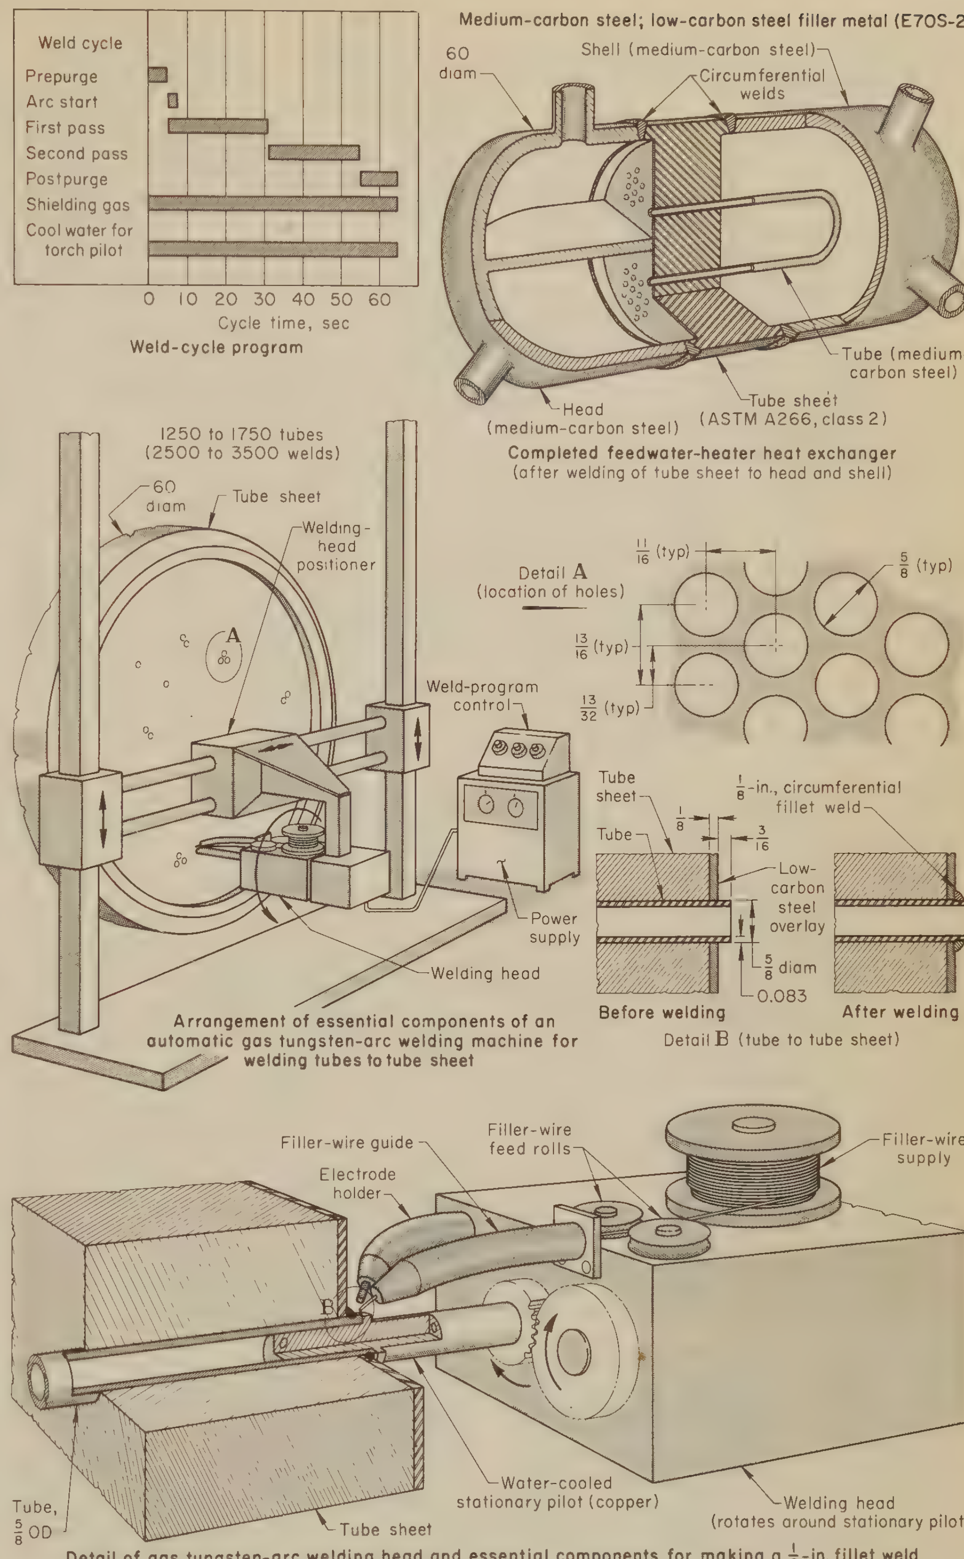
Before assembly, tubes and tube sheet were solvent cleaned, and rigid cleanness was maintained during welding. With tubes in place, the tube sheet was preheated to slightly above room temperature (to 100 F). The welding-head pilot was centered in a tube, and the tungsten electrode and wire-guide tip were properly positioned. Settings for water and gas flow rates, filler-metal feed, rotational speed, welding current, high frequency, and slope control were adjusted for correct values. Finally, the various settings of the timers to control the sequencing of the complete two-pass weld cycle were adjusted on the control panel of the programer, and the weld cycle was initiated by pushbutton. After each weld, the welding head was repositioned for welding the next tube, and the cycle was repeated. The weld-cycle program is shown at the upper left in Fig. 18.

After assembly and welding of the completed tube bundle in the vessel chamber (see view at upper right in Fig. 18), welds were tested hydrostatically, at a pressure of 7300 psi (chamber design pressure was 4500 psi). Welds were also inspected visually for apparent defects and mass-spectrometer Freon tested for leaks.

Surfacing Applications

Although any arc welding process can be used for surfacing by welding, the submerged-arc process, mainly because of the high deposition rate of which it is capable, is generally preferred if the shape of the workpiece is such that submerged-arc welding can be used.

For worn surfaces such as cylindrical bearing journals, restoration by welding to replace the material lost by wear,



Conditions for Automatic Gas Tungsten-Arc Welding

Joint type	Circumferential T	Filler-wire feed	20 ipm
Weld type	Fillet	Shielding gas	Argon, at 15 cfh
Welding position	Horizontal-fixed pipe	Current	140 to 150 amp, dcsp
Preheat temperature	100 F	Voltage	9 to 11 v
Power supply	300-amp rectifier(a)	Arc starting	High frequency
Electrode holder	Orbiting; argon-gas cooled	Number of passes	Two
Electrode	3⁄32-in.-diam EWTh-2	Welding speed	5 ipm
Filler metal	0.030-in.-diam E70S-2 wire	Total time per two-pass weld	1¼ min

(a) Constant-current type, with high-frequency generator, slope control, and sequence timers

The use of the orbital welding setup shown schematically here, in which the welding head was automatically rotated, replaced an earlier procedure employing manual rotation. The change to automatic welding increased reproducibility and more than doubled production rate.

Fig. 19. Setup for submerged-arc surface welding to rebuild worn cylindrical surfaces of a mixer rotor (Example 194)

followed by machining to size, may cost much less than replacement by a new part, as is shown in the next example.

Example 194. Use of an Overlay on Cylindrical Portions of a Shaft To Rebuild Worn Surfaces (Fig. 19)

The cast 1030 steel rotor shown in Fig. 19 was part of a Banbury mixer used in a rubber-production line. This rotor had become severely worn on the cylindrical journal surfaces and on the area of the shaft at which gears were keyed. The rotor was rebuilt by welding and machining for about $2000; a new rotor would have cost $6000.

The worn surfaces were built up by submerged-arc welding, as shown in Fig. 19. The rotor was driven from one end in a horizontal position by a conventional welding positioner, and was held at the opposite end by a roller support. The shaft was turned at a surface speed of 13 in. per minute. The total length of built-up area was 117 in., and total arc time for surfacing the rotor was 15 hr. Additional welding conditions are given in the table with Fig. 19.

Because the rotor was covered with rubber residue and grease, before surfacing it was cleaned by abrasive blasting, after which the worn surfaces were lightly machined (1/16 in. removed) on a lathe, without cutting fluid.

The bead was deposited by an overlap technique. The rotor was turned so that a circumferential weld bead was deposited. At the end of each revolution, the welding head was indexed to make the next bead overlap the last by half a bead width. The rotation of the shaft continued during indexing. The result was an overlay composed of a continuous weld bead with 50% overlap — just as would have been achieved by continuously advancing the bead as the journal turned, but the indexing method did not require an interlock between feed and speed.

After welding, the completed rotor was furnace heated at 1200 F for 4 hr and furnace cooled. The welded areas were then machined and ground to size and the rotor was returned to the mixer.

In the example that follows, a low-carbon steel surface weld was deposited on a tube sheet forged from medium-carbon steel to provide a surface more compatible with the medium-carbon steel tubes to which the forged tube sheet was subsequently welded.

Example 195. Submerged-Arc Surfacing of a Medium-Carbon Steel Forging With Low-Carbon Steel for Later Welding to Medium-Carbon Steel Tubes (Fig. 20)

The tube sheet shown in Fig. 20, forged from ASTM A266, class 2, steel (0.35% max carbon), is typical of those used in feed-water-heater heat exchangers.

Originally, medium-carbon steel tubes were fillet welded directly to bare (unclad) tube sheets, but the welds were hard, and had little ductility, as a result of carbon pickup from the tubes and the tube sheet, and also were porous. The porosity in the welds was attributed to the presence of dissolved gases in the forged tube sheet. The hardness and porosity of the welds often led to cracking and leaks in service. To minimize these problems, a low-carbon steel overlay was deposited on the surface of the tube sheet; the carbon in the overlay did not exceed 0.15%, and the deposit was clean and free of gases that could cause porosity. As a result, subsequent tube-to-tube-sheet welds were sufficiently strong, ductile and nonporous to provide sound, leaktight joints in service. The application of the overlay by multiple-electrode submerged-arc welding is shown in Fig. 20; welding conditions are given in the accompanying table. Qualification of procedure and welders was in accordance with Sections III and IX of the ASME Boiler and Pressure Vessel Code.

After the forged tube sheet had been machined, the center of one of the flat faces was surfaced with linear beads in a 13-to-16-in. square (see operation 1 in Fig. 20). Then, the square was machined so as to obtain a circle of overlay 12 to 15 in. in diameter (see operation 2 in Fig. 20). Outside this circle, the overlay was extended to the rim of the tube sheet by the deposition of overlapping beads in a circular pattern. The circular weld beads, consisting of a single layer nominally 1/4 in. thick, were overlapped 40 to 50% (see operation 3 in Fig. 20).

To develop the desired tracking for deposition of the circular beads, the welding head was mounted on a carriage with vertical and horizontal adjustments. It was fed across the surface of the tube sheet from the central overlay disk to the rim area while the work was rotated at a rate adjusted to produce the necessary overlap (see the welding setup in the upper part of Fig. 20). After welding, slag removal, and a stress-relieving heat treatment, the tube sheet was machined to provide an overlay thickness of 1/8 in. minimum (see operation 4 in Fig. 20).

After machining of the overlay, the tube sheet was ultrasonically inspected, and repaired if necessary. The overlay was required to have 100% bond with the tube sheet, and to be completely free of cracks. Some random slag inclusions or incomplete fusion between beads, if no more than 1/4 in. long, were considered acceptable.

The tube sheet then was drilled and vapor degreased, and the tubes were inserted for welding (see Example 193 for a description of that operation). The amount of rework required for correcting defective tube welds was minimal when tube sheets were surface welded with the low-carbon steel overlay. Over a period of four years, approximately 150,000 tube welds were made using clad tube sheets, and no leaks occurred in service.

Examples in Other Articles

In addition to the 15 examples of practice in this article, there are 36 examples in other articles in this volume that deal with arc welding of hardenable carbon steels. Table 3 directs the reader to those 36 examples, and identifies the steels and welding processes used in the applications they describe.

Carbon content, manganese content, and content of residual alloying elements determine the hardenability (and influence the susceptibility to weld cracking) of carbon steel. Cooling rate determines how much hardening will be attained in the weld area. Sec-

tion thickness has a marked effect on cooling rate. In arc welding, the heat is dissipated rapidly in thin sections, so that susceptibility to cracking is low. In thicker sections, the mass of metal (unless preheating was used) serves effectively as a quench, thus producing martensite.

All other conditions being equal, the welding process used has a significant effect on whether a given steel hardens from welding. Of all the arc welding processes, electrogas welding provides the slowest cooling rate (and least hardening). Because of its high heat input and the blanketing effect of the flux, submerged-arc welding ranks next. Faster cooling rates are obtained in the other arc welding processes.

Twelve of the examples listed in Table 3 deal with AISI-SAE steels that are generally accepted as hardenable carbon steels; the others deal with steels bearing ASTM designations. For most of these ASTM steels, carbon and manganese contents are specified as maximums. For instance, 0.3% max carbon is specified for ASTM A27 steel castings (Example 50), thus allowing considerable latitude in hardenability.

ASTM steel A36 (Examples 64 and 77) is specified for a variety of product forms. Although the carbon content is specified as 0.26% max, in some product forms the manganese content can be as high as 1.20%. Thus, under some conditions A36 has moderate hardenability.

ASTM steel A53 (Examples 50, 52 and 53) is specified for welded and seamless pipe. For some grades, the carbon content may be as high as 0.30% and the manganese as high as 1.20%.

Steel SA-106 (Example 128) is related to ASTM A106. Depending on the grade within the general specification, the carbon content may be as high as 0.35% and the manganese as high as 1.06%.

Steel covered by ASTM A234 (Example 53) is exclusively for fittings, and the composition and hardenability are essentially the same as those of A285 (see second-next paragraph).

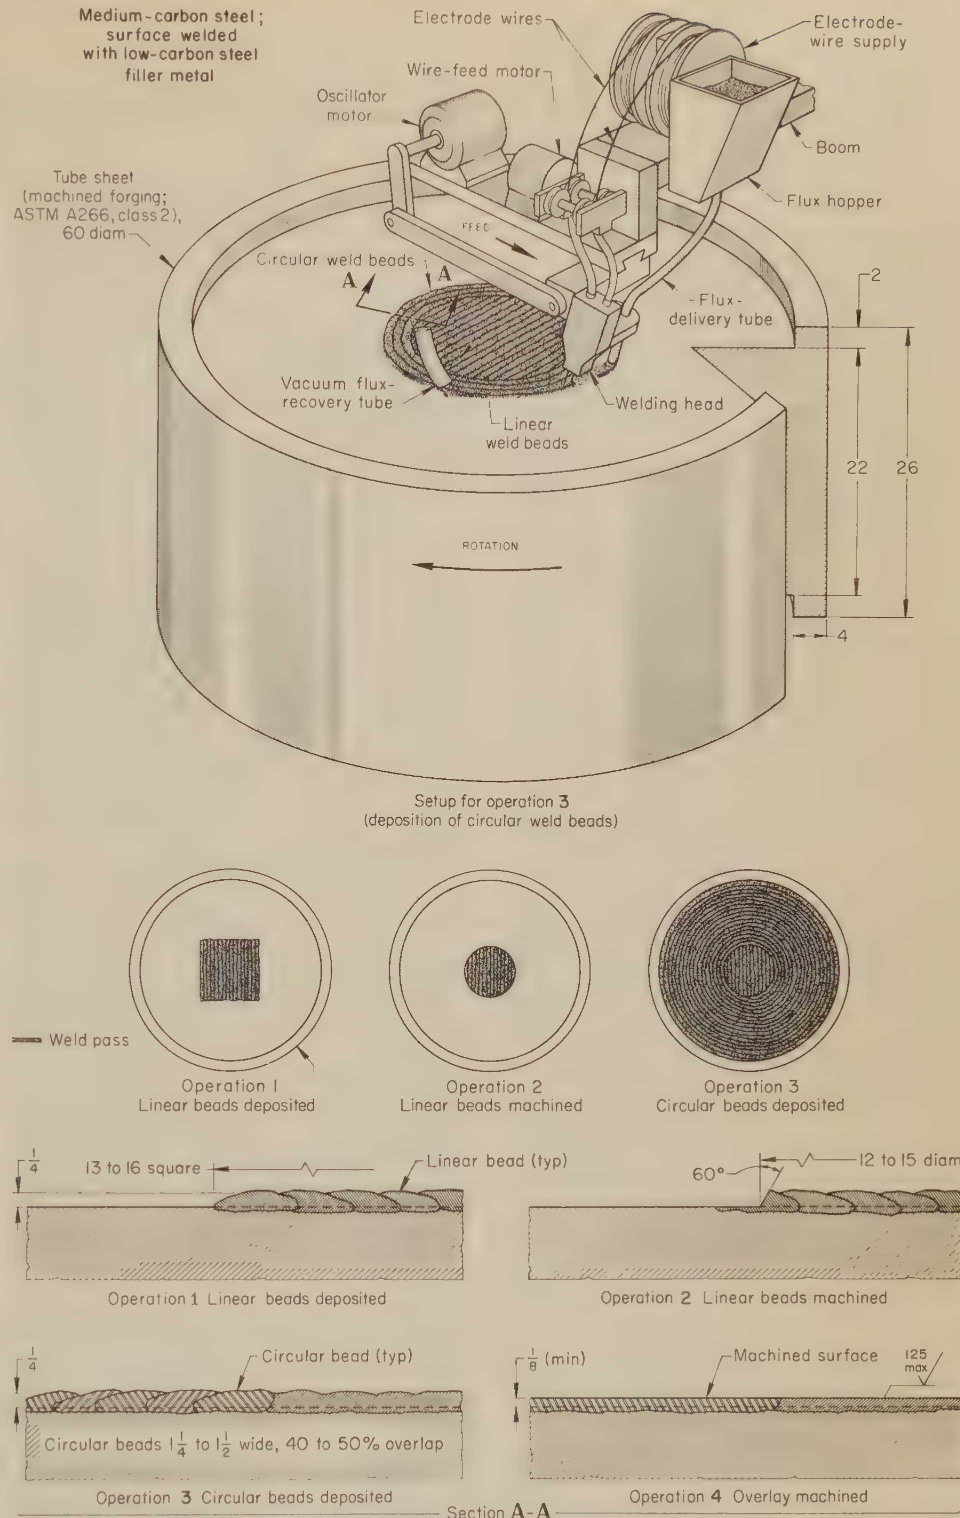
Carbon steel forgings made to ASTM A235 (Example 62) require maximum carbon content of 0.35% if they are to be welded. Thus, a broad range of hardenability is permitted.

ASTM A285 (Examples 5, 24, 25, 56, 70 and 91) covers carbon steel plates having maximum carbon and manganese contents of 0.28 and 0.90%, respectively. Thus considerable hardening can occur in welding.

ASTM A515, represented by 11 of the examples in Table 3, covers steel plate for boilers and pressure vessels. Carbon and manganese contents can be as high as 0.31 and 0.90%, respectively; thus, A515 may have greater hardening capability than A285.

Steel A516 (Example 5) is similar in composition to A515, except A516 has maximum carbon and manganese contents of 0.27 and 1.20%, respectively.

Heat treated steel plates covered by ASTM A537 (Example 5) have established ranges for manganese and silicon of 0.65 to 1.40% Mn and 0.13 to 0.55% Si. Maximum carbon content for A537 is specified at 0.24%. If both carbon and manganese are near the allowable maximums, A537 is capable of developing considerable hardness in welding.



Multiple-Electrode Submerged-Arc Surface Welding, With Oscillation(a)

Weld type	Surfacing	Stickout	2 in.
Surface preparation	Machine to 125-micro-in. finish, and solvent clean	Welding position	Flat(d)
Power supply	Rectifier or motor-generator(b)	Current each electrode	550 to 600 amp, dcsp
Wire feed	Automatic, variable speed(c)	Voltage	37 to 39 v
Electrode wire	5/32-in.-diam low-carbon steel (0.03% carbon max)	Welding speed	7 to 8 ipm
		Deposition rate	20 to 25 lb per hour
		Preheat temperature	350 F, min(e)
Flux	Bonded, neutral	Postheat (stress relieving)	1150 F, 1 hr

(a) Two electrodes; spacing, 1/4 in. Oscillation width, 1 in.; speed, 40 to 45 strokes per minute. (b) Rated at 750 amp; drooping voltage characteristic. (c) With twin feed rolls and wire straighteners on a common shaft. (d) Workpiece was rotated on a positioner for deposition of circular weld beads, as shown. (e) While being rotated, workpiece was preheated locally, with large portable torches; temperature was determined by use of crayon indicators.

Arc Welding of Alloy Steels

*By the ASM Committee on Welding of Hardenable Steel**

ACCEPTABLE RESULTS in the welding of alloy steels are related directly to the metallurgical structures that are produced in the weld metal and in the heat-affected zone of the base metal during and after welding. These structures are governed by the thermal cycles that occur during welding.

Hardness. As in the welding of hardenable carbon steel (see the preceding article in this volume), martensite is the metallurgical constituent of principal concern in the welding of alloy steel. The hardness of martensite depends on its carbon content, as shown in Fig. 1 on page 187 in the article on Arc Welding of Hardenable Carbon Steels. Excessive hardness, and accompanying brittleness, is a major cause of weld cracking.

Carbon and low-alloy steels that have the same carbon content will have the same maximum hardness when cooled rapidly enough to achieve maximum martensite in the microstructure. In Fig. 1(a) below, the maximum hardness is shown at the 1⁄16-in. end-quench distance for five alloy steels that have the same nominal carbon content of 0.40% (maximum of the specification range is 0.44% for each steel). Despite the major differences in alloy content and hardenability among these five steels, each steel has the same maximum hardness, Rockwell C 60. The two steels in Fig. 1(a) that have slightly lower maximum carbon contents (4037H and 1038H) have slightly lower maximum hardnesses, as shown.

Ten 41*xx*H steels are compared in Fig. 1(b). Each of these steels has essentially the same alloy content (nominally 1% Cr and 0.20% Mo, with 0.80% Mn; there are slight variations through the series), but the steels range in maximum carbon content from 0.23% for 4118H to 0.65% for 4161H. As shown in Fig. 1(b), in this series of ten chromium-molybdenum steels, the maximum hardness (at the 1⁄16-in. end-quench distance) increases from Rockwell C 48 to 65 as maximum carbon content increases from 0.23 to 0.65%.

In the welding of high-strength low-alloy steels that contain not more than 0.25% carbon (see page 207), welding procedures are deliberately chosen so that martensitic structures are obtained. These steels are intended to be welded in the quenched-and-tempered condition. The low-carbon martensite formed during postweld cooling has desirable strength, and the as-welded joints have adequate toughness. However, as carbon content is increased, the higher-carbon martensites that are formed are harder and less ductile in the untempered condition, and are a major contributor to the cold cracking of welds.

Higher hardenability is the one characteristic that differentiates alloy steels as a class from plain carbon steels, and is the principal complication in welding. With higher hardenability, martensite forms at lower cooling rates.

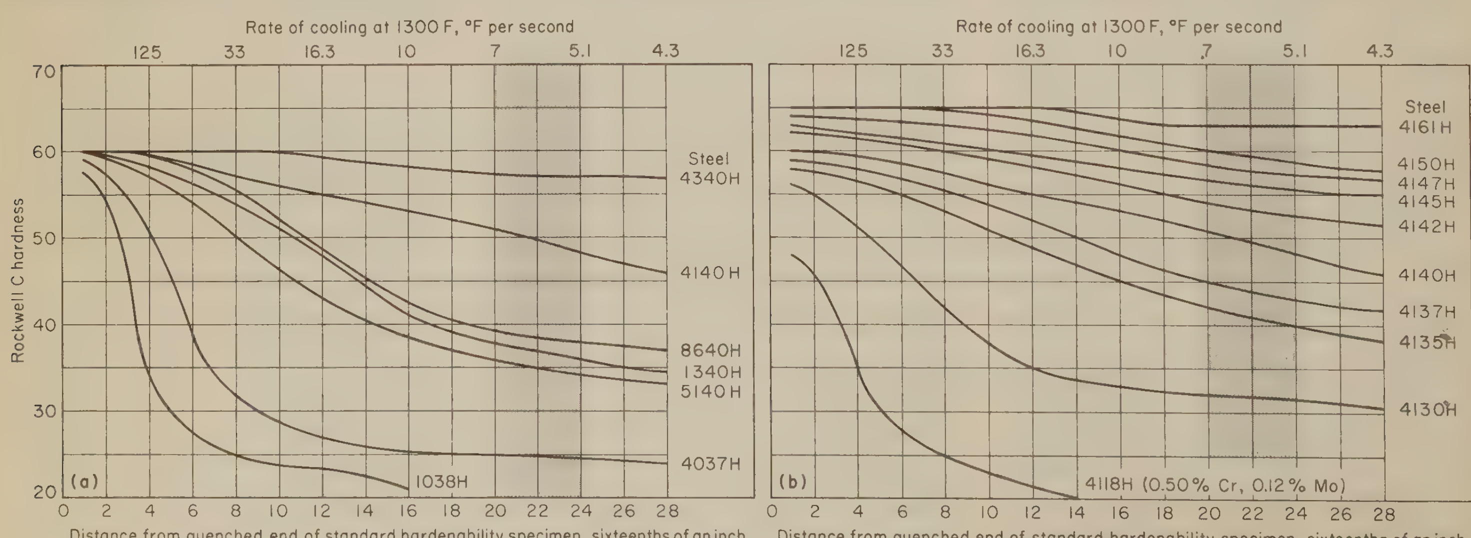
As the alloy content or the carbon content of steel is increased, the hardenability is increased. Figure 1(a) shows the maximum hardenability of 1038H carbon steel and six widely used alloy steels of 0.40% nominal carbon content. The maximum hardenability of carbon steel 1038H (bottom curve) is low; that is, hardness decreases rapidly as cooling rate (top scale) decreases. As various amounts and combinations of alloying elements (Cr, Ni, Mo, Mn) are added to steel containing 0.40% carbon, the maximum hardenability increases to that shown for 4340H. Figure 1(b) shows the large effect of increasing carbon content on maximum hardenability in 41*xx*H steel. The effect on hardenability of increasing carbon from 0.23% (the maximum in 4118H) to 0.65% (the maximum in 4161H) in these alloy steels is somewhat greater than the effect, shown in Fig. 1(a), of increasing total alloy content (Mn, Cr, Mo, Ni) from 1% (maximum in 1038H) to 4.15% (maximum in 4340H).

Hardenability curves such as those shown in Fig. 1 are used primarily for selecting steels for structural members of different thicknesses and in designing appropriate quenching procedures for achieving various cooling rates (see scale across the top of Fig. 1) at various depths below the steel surface in heat treatment. The application of hardenability curves to the welding of alloy steel is largely qualitative, because cooling rates at various locations within the weld metal and the heat-affected zone of the base metal are seldom known with the accuracy that is available for cooling rates in steel sections during quenching in water, oil or air.

In general, the weldability of steel decreases as its hardenability increases, because higher hardenability promotes the formation of martensite under conditions that make cold cracking of the martensitic steel more probable.

In welding, it is seldom possible to achieve cooling rates slower than 5 or 6 °F per second. This cooling rate corresponds to positions of 20 to 24 sixteenths of an inch from the quenched end of the standard end-quench hardenability specimen (see shaded areas of Fig. 1a and 1b). Thus, if the hardness corresponding to this cooling rate

*For a list of the members of this welding committee, see page 187. Most of the 33 examples of practice that are presented in this article were contributed by members of other Metals Handbook welding committees.



(a) Effect of various amounts and combinations of alloying elements in steel with a nominal carbon content of 0.40%, compared with carbon steel 1038H. (b) Effect of carbon content in 41*xx*H alloy steel (nominal 1% Cr and 0.2% Mo, except for 4118H). All data from 1970 SAE Handbook.

Fig. 1. Maximum hardenability of alloy steels and 1038H carbon steel. See text for discussion.

(end-quench distance) for a particular steel is too high to be acceptable in the heat-affected zone of a weldment, the weldment, or at least the zone of excessive hardness, must receive a tempering treatment after welding.

Carbon Equivalent. Several formulas have been developed to assist in evaluating the weldability of alloy steels. These formulas reduce the significant composition variables to a single number, known as the carbon equivalent. One such formula is as follows:

$$\text{Carbon equivalent} = \%C + \frac{\%Mn}{6} + \frac{\%Ni}{15} + \frac{\%Cr}{5} + \frac{\%Mo}{4} + \frac{\%V}{5}$$

Steels having carbon equivalents by this formula of less than 0.40% usually require no preheating or postheating. Steels with carbon equivalents between 0.40 and 0.60% usually require preheating, and steels with carbon equivalents greater than 0.60% may require both preheating and postheating. Because the carbon equivalent is calculated from the base-metal composition and includes no other variables, it is only an approximate measure of weldability or susceptibility to weld cracking. Other factors that contribute to weld cracking must be considered simultaneously, in relation to a specific application.

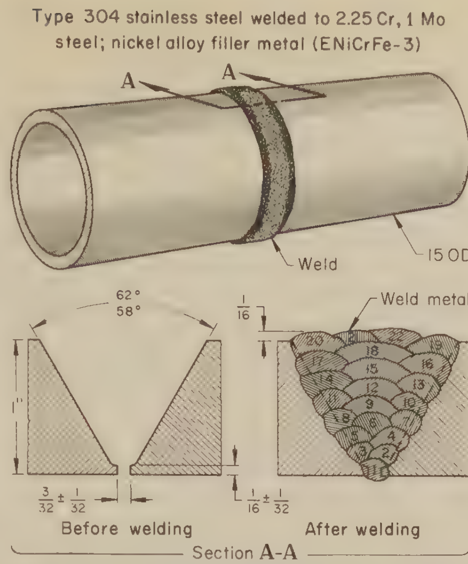
Filler Metal. Filler metals of almost any desired alloy steel composition can be obtained. However, the composition of the deposited weld metal is likely to be quite different from that of the filler metal before welding, depending on how effectively the alloying elements are transferred across the arc. In welding with consumable electrodes, transfer is often less than 75% complete, especially for elements that have high affinity for oxygen. The extent of change in filler-metal composition depends to some extent on the shielding gas used. There is generally less change in composition with argon shielding than with carbon dioxide.

When arc welding with nonconsumable-electrode processes (gas tungsten-arc or plasma-arc welding), there is less change in filler-metal composition, because the filler metal is fed directly into the weld puddle. Often, the filler metal selected to weld an alloy steel differs considerably in composition from that of the base metal, particularly when the base metal is of high hardenability and the objective is to obtain a weld metal of lower hardenability that is less likely to crack.

High sulfur or phosphorus content (from the base metal, the filler metal, or external sources) can cause hot cracking in the welding of alloy steels. The effects of these elements vary with the amounts of other elements present, principally with the carbon and manganese contents. Some advocate a maximum content of sulfur plus phosphorus of 0.025%. In at least one application, a combined sulfur and phosphorus content of 0.020% has been recommended to prevent base-metal cracking in highly restrained joints of 4340 steel. To a considerable extent, the adverse effects of high sulfur can be offset by increasing the manganese content in either the base metal or the filler metal. Resulfurized alloy steels are not recommended for arc welding, but they can be welded (see Example 221, page 230).

In shielded metal-arc welding, the composition of the electrode covering can influence the weldability of high-sulfur steels. Low-hydrogen electrodes E7015 and E7016 have been used for welding resulfurized alloy steels (0.13% max sulfur). Resulfurized alloy steels with high manganese contents are preferred for welding because manganese forms a stable, higher-melting sulfide that counteracts susceptibility to hot cracking caused by sulfur.

Besides base-metal composition, preheating and postheating, the selection of filler-metal composition can be influenced by the coefficient of expansion of the base metal, carbon depletion in the heat-affected zone, and the deposition characteristics of the filler metal. The influence of some of these factors on the selection of filler metal is illustrated in the following example, which describes the use of a nickel alloy filler metal in shielded metal-arc welding of low-alloy steel to stainless steel, without the incidence of cracking or porosity in the weld.



Conditions for Shielded Metal-Arc Welding

Joint type	Butt
Weld type	Single-U groove
Welding position	Horizontal rolled
Number of passes	22
Preheat and interpass temperature	500 F(a)
Postheat	1350 F(b)
Electrode wire	1/8 and 5/32-in.-diam ENiCrFe-3(c)
Power supply	300-amp motor-generator
Current (dcrp) and voltage:	
Tack welding, and pass 1	60 amp, 21 v
Passes 2 and 3	90 amp, 23 v
Passes 4 to 22	120 amp, 24 v

(a) Only the ferritic low-alloy steel side. Heating was by induction. (b) Heated at 1350 F for 1 hr by induction and cooled to 300 F in still air. (c) 1/8-in.-diam electrode wire for passes 1 to 3, and 5/32-in.-diam wire for passes 4 to 22.

Fig. 2. Assembly of a low-alloy steel pipe and a stainless steel pipe that was joined with crack-free welds by use of a nickel alloy filler metal (Example 196)

Example 196. Nickel Alloy Filler Metal for Crack-Free Welding (Fig. 2)

The selection of a filler metal was an important factor in welding a 2¼Cr-1Mo steel pipe (ASTM A387, grade D) to a type 304 stainless steel pipe. This pipe assembly was a component of a steam pipeline that had to withstand cyclic heating and cooling between 1050 F and room temperature. Details of the joint between the 15-in.-OD by 1-in.-wall pipes before and after welding, in 22 passes, by the shielded metal-arc process are shown in Fig. 2. A nickel alloy flux-covered electrode (ENiCrFe-3) was selected in preference to an austenitic stainless steel electrode, for three reasons:

1. The coefficient of thermal expansion (8.5 micro-in. per inch per °F) of weld metal from the ENiCrFe-3 electrode is close to that of the ferritic 2¼Cr-1Mo steel. Thus, during cyclic temperature service, the major differential expansion stresses developed primarily at the stronger interface between the stainless steel pipe and the weld metal, rather than at the weaker interface between the ferritic steel pipe and the weld metal — the location at which such expansion stresses would have developed if a stainless steel electrode had been used.
2. Carbon depletion in the ferritic steel was less when the nickel alloy weld metal was used than when a stainless steel weld metal was used. Therefore, the heat-affected zone of the ferritic steel was not weakened by loss of carbon.
3. The excellent deposition characteristics of the nickel alloy electrode produced a sound, porosity-free weld that was not subject to weld-metal cracking.

The pipe ends were machined to the joint configuration shown in Fig. 2 and wiped clean with a solvent; then the pipes were mounted horizontally on turning rolls for welding. Low-frequency induction heating was used to provide a 500 F preheat for the ferritic pipe. This temperature was maintained, by automatic control, throughout the welding operation.

The joint was tack welded at 6-in. intervals, using a 1/8-in.-diam electrode and the same current and voltage settings as for the first pass (see table of welding conditions with Fig. 2). The edges of the tack welds were thinned by grinding before the root pass, which was carefully deposited to obtain a smooth inside root surface. Each weld bead was deslagged and visually inspected before the next bead was deposited. Immediately after welding, the weld was postheated, by induction heating, to 1350 F for 1 hr and air cooled.

Welds made with the ENiCrFe-3 electrode met bend-test and tension-test requirements of Section IX of the ASME Boiler and Pressure Vessel Code, and also passed visual, dye-penetrant, radiographic and metallographic inspection. Fractures produced in transverse tension tests at room and elevated temperatures were in the base metal away from the heat-affected zones. The welds had markedly better resistance to cracking during thermal cycling than did similar joints welded with type 347 stainless steel electrodes.

Stress-Causing Factors. Local cracking or fissuring in the deposited weld metal or the heat-affected zone occurs either because the strength or the ductility of the steel locally is not sufficient under the conditions of welding to sustain the localized stresses without fracturing. Under conditions of extreme stress, complete failure of the joint may occur during or shortly after welding. However, it is also possible that stresses of lesser magnitude, insufficient to cause instantaneous failure, will generate minute cracks in the weld zone that will enlarge and spread gradually, causing the welded structure to fail in subsequent service.

By far the most significant sources of stress during welding are the thermal gradients, which may generate stresses that exceed the yield strength, especially considering that the yield strength is lower at elevated temperatures than it is at room temperature.

In practice, the stresses are accommodated by movement in the parts of the assembly being welded. This movement may consist of plastic or elastic deformation of the parts, or gross movement of the parts. Thus, conditions that prevent movement of the parts increase the probability of cracking. Therefore, it follows that the thicker and more massive the plates or parts being welded, the more rigid the design; and the higher the hold-down or fixturing loads, the greater is the probability of cracking.

The root pass in massive weldments is especially susceptible to cracking, because the relatively small cross section of weld metal is not strong enough to force the movement of the large mass of base metal.

Restraint in a welded joint is usually imposed by component design, although fixtures that hold the assembly for welding can also contribute. The susceptibility to cracking caused by restraint increases as the hardenability of the base metal or filler metal increases. Thus, cracking caused by restraint is closely related to preheating, postheating, and interpass temperature. The following example describes an application in which fatigue-crack failures in service were traced to rigidity in weldment design and excessive restraint during welding.

Example 197. Prevention of Fatigue Cracks in Welds by Redesigning Weldment for Less Rigidity (Fig. 3)

An upper fifth wheel for a highway semitrailer, when designed as shown at left in Fig. 3, proved unsatisfactory in service because fatigue cracks developed in the welds, made by the semiautomatic gas metal-arc method, at the joints between the longitudinal and cross-member channels. Under a 35,000-lb vertical load on the fifth wheel, the vertical displacement of these joints was ⅜ in. relative to the ends of the cross members. Closer control of weld quality at the junction did not eliminate the cracking, nor did the addition of gussets between the two longitudinal channels and the front cross member. Although deflection under load could have been reduced by increasing the section thicknesses, this was undesirable because of the weight penalty.

The assembly was redesigned to omit the welds that were subject to failure. As shown at right in Fig. 3, a gap was left between the longitudinal and cross-member channels, thereby eliminating the point of overlapping welds and the need for welding in a corner. The bottom plate was made in two pieces, and the longitudinal channels were capped off with an angle. In the improved design, the only attachment between the front and rear sections was a transverse square-groove butt weld that joined the front plate, angle, and rear bottom plate. The groove weld and the gap permitted rotational movement between the longitudinal and cross-member channels.

To verify the simplified design, the entire upper fifth wheel assembly was fatigue tested under a cyclic load of 0 to 35,000 lb at a rate of 19 cycles per minute. The revised assembly design was accepted after withstanding 500,000 cycles without failure. Strain-gage measurements of the stress developed in the metal adjacent to the transverse groove weld by a 35,000-lb load showed it to be 24,000 psi max. This was well within the 43,000-psi fatigue-strength limit (rotating-beam method) generally ascribed to high-strength structural steels of 50,000-psi minimum yield strength.

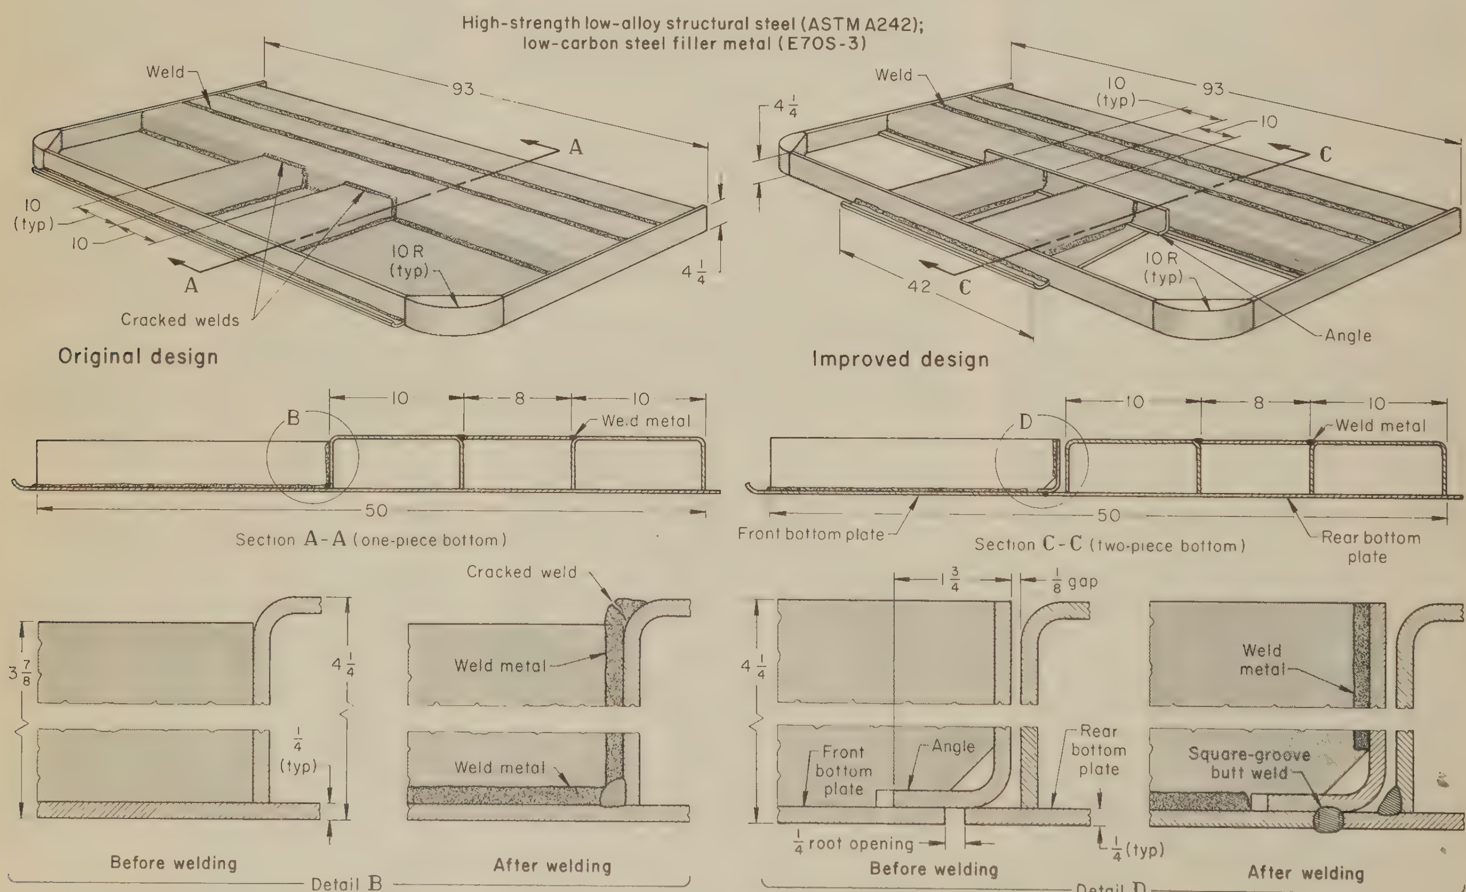
Welding conditions are given in the table with Fig. 3.

Pickup, Dilution and Recovery*

Pickup is the increase in any alloying element in a weld deposit caused by melting and incorporating some of the base metal during welding. Pickup usually occurs when the filler metal is of lower alloy content than the base metal. For example, if a 3% nickel steel is welded with a nickel-free filler metal, the mixture of base metal and filler metal that forms the weld puddle will contain some nickel, perhaps 1%. In a multiple-pass weld, any bead or layer that is directly on the base metal picks up the greatest amount of alloying elements from that metal.

The extent to which the base metal melts controls alloy pickup in the weld metal. This varies somewhat with the

*This section was adapted from pages 435 to 439 in Chapter 15, Welding Alloy Steels, of Volume 2 of "Welding Metallurgy", by George E. Linnert (American Welding Society, 1967).



Conditions for Gas Metal-Arc Welding	
Joint type	Butt and T
Weld type	Square groove and fillet
Welding position	Flat and horizontal
Number of passes	One
Preheat and postheat	None
Fixtures	All components pneumatically clamped in a fixture before welding
Shielding gas	Argon, at 40 cfh
Electrode wire	0.045-in.-diam E70S-3
Electrode holder	Hand held, air cooled
Wire feed	Automatic constant-feed type
Wire-feed rate	300 in. per minute
Power supply	500-amp motor-generator
Current	300 amp, dcrp
Voltage	26 v
Travel speed	12 in. per minute

Fig. 3. Semitrailer upper fifth wheel on which a design change provided less rigid construction, preventing weld failures (Example 197)

different arc welding processes. In many applications of welding alloy steel, the pickup of alloying elements by the weld metal is anticipated, and is utilized to impart certain properties, such as strength, to the weld metal. This practice requires production testing to establish a procedure that will provide the desired pickup.

Dilution is the reduction in alloy content of a weld deposit by virtue of base-metal melting and the incorporation into the weld puddle of melted base metal of alloy content lower than that of the filler metal. Dilution is commonly expressed as the percentage of base metal that has entered the weld metal. If the chemical compositions of the filler metal and the base metal are known, then, by knowing the percentage dilution, the weld metal composition can be calculated. Dilution, or its converse, alloy pickup, can markedly change the composition of weld metal.

The mixing of base metal and filler metal is the most important factor governing the composition of the weld. The extent of the mixing is expressed as the percentage of the entire cross-sectional area of the weld metal, as revealed by a macrosection, that falls within the outlines of the base metal before welding. To measure this percentage, a section is cut through the weld perpendicular to both the direction of welding and the surface of the plates. The cut section is given a rough polish with abrasive paper and is etched to reveal the boundary of the metal that has been melted during welding.

Sections through welds of several types are shown in Fig. 4. The percentage of the entire cross section of weld metal falling within the initial outlines of base metal, called the dilution percentage, is:

$$\% \text{ dilution} = \frac{B + D}{A + B + C + D} \times 100$$

The dilution percentage is high for welds in sheet or thin plate (see lower right view in Fig. 4), for which little filler metal is required. If no filler metal is added, an "autogenous" weld results; dilution is 100%, and the weld composition is essentially the same as that of the base metal (see the "100% dilution" square-groove butt weld in Fig. 4). For bevel-groove welds in thicker plate (upper left view in Fig. 4), the dilution may be as low as 20%. Penetration also has a marked effect on the amount of dilution that takes place (see the fillet welds in Fig. 4).

Depositing the same filler metal under identical conditions of current and speed will result in more dilution when welding on sheet or thin plate than when welding on thick plate, because of the difference in penetration (see lower right pair in Fig. 4). The melting temperature of the base metal also affects dilution. For example, a low-carbon steel electrode will exhibit greater depth of penetration on cast iron (melting point, 2100 to 2200 F) than on steel (melting point, 2750 F) under the same conditions of deposition. Thus, dilution will be greater with cast iron as the base metal.

At one time it was considered generally desirable that the weld metal should have, as nearly as possible, the same composition as the base metal. This is no longer considered a general rule. There are many applications where the filler and base metals differ greatly in composition (see Examples 196 and 210).

Table 1. Solubility of Oxygen, Nitrogen and Hydrogen in Iron

Gas	Solubility (weight %) of gas in: Liquid iron at melting point	Solid iron at melting point	Gamma iron at 1670 F (910 C)	Alpha iron at: 1670 F (910 C)	Alpha iron at: Room temperature
Oxygen ..	0.16	0	...	...	0
Nitrogen .	0.040	0.015	0.020	0.010	0.0001
Hydrogen .	0.0025	0.0006	0.0004	0.0003	0.00005

Recovery is the ratio of the alloy content of the weld deposit to the alloy content of the filler metal or auxiliary material, such as electrode coverings, and is expressed as a percentage:

$$\% \text{ recovery} = \frac{\% \text{ of alloying elements in deposit}}{\% \text{ of alloying elements in filler metal}} \times 100$$

The deposit from a bare consumable electrode containing 0.50% carbon may contain no more than 0.05% carbon (that is, the recovery may be as low as 10%), but if the consumable electrode is covered with flux, the carbon recovery may rise to nearly 100%, depending on the protection afforded by the covering.

Nickel is recovered almost completely when a nickel-containing steel filler metal is used, because nickel has a high boiling point and less affinity than iron for oxygen, nitrogen and other gases that may be present in the welding atmosphere. Copper is also recovered almost completely, for the same reasons. Silicon, though, often is oxidized almost completely from a bare electrode; its recovery can be improved by shielding. Chromium is oxidized to some degree, but to a considerably lesser extent than silicon.

The alloying elements used in steel can be ranked according to extent of oxidation during transfer across the arc, starting with those that have low recovery (are oxidized easily) and ending with those that are recovered almost completely. The order is as follows: aluminum, titanium, silicon, columbium, manganese, vanadium, chromium, tungsten, molybdenum, copper and nickel.

The efficiency of transfer of alloying elements in an electrode, or in a flux covering or core, ordinarily is anticipated by the manufacturer, and compensating amounts are added to offset losses. However, some loss of alloying elements occurs from the molten weld puddle, which includes base-metal alloying elements.

Low recovery of an alloying element may result from the low boiling point (high vapor pressure) of the element, or from its transfer to the slag when slag is present.

Gases

The effect of gases, especially that of hydrogen, on the quality of welds in alloy steels is of major significance. Relatively small amounts of hydrogen in martensite are sufficient to cause underbead cracking. Although both the base metal and the filler metal are potential sources of hydrogen, more significant amounts of the gas are likely to derive from moisture or from flux coverings on electrodes that are not low-hydrogen types. Hydrogen may be introduced from moisture in the surrounding atmosphere or in the shielding gas, from improperly cleaned components, or from improper care of covered electrodes or the fluxes used in flux coverings.

Because of decreasing solubility, the hydrogen in molten metal is rejected as the metal solidifies. For this reason, the hydrogen in weld metal is also a major cause of porosity.

Oxygen, nitrogen, argon, helium, carbon dioxide and carbon monoxide are other gases encountered in welding. Of these, helium and argon are insoluble in steel. Oxygen and nitrogen, as well as hydrogen, are more soluble in molten steel than in solid steel, as shown in Table 1. During freezing, the oxygen dissolved in molten steel may react with carbon from the steel and form bubbles of carbon monoxide, which may be trapped in the solid steel. Similarly, nitrogen coming out of solution may be trapped in the solid steel. Or iron nitride may be formed as a precipitate. In general, however, harm that can result from the other gases listed above is of little significance compared with the damage to the weld area than can be caused by hydrogen.

Welding Process Variables

Consideration of welding process variables necessarily begins with the thermal cycle associated with welding.

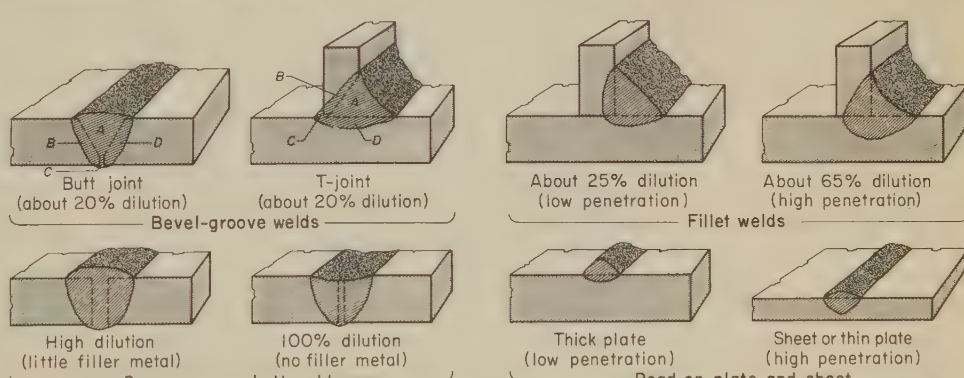


Fig. 4. Effect of filler-metal addition and penetration on weld-metal dilution. See text for dilution-percentage formula, and discussion.

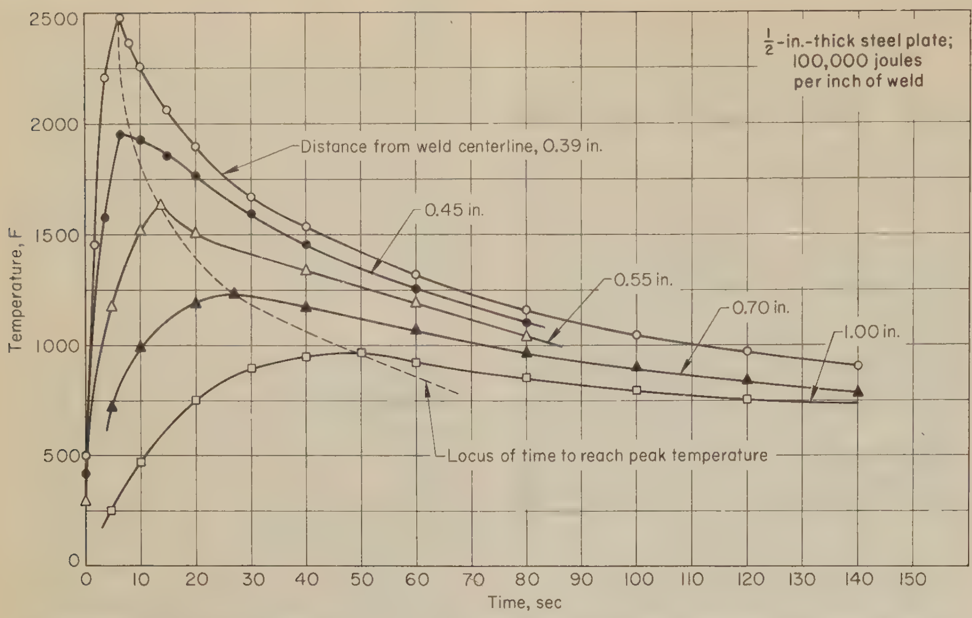


Data are for arc welds made in ½-in.-thick steel plate at room temperature, using a heat input of 100,000 joules per inch of weld. (SOURCE: AWS Welding Handbook, 6th Ed., Section 1)

Fig. 5. Thermal cycles as a function of distance from weld centerline

Several variables affect temperature distribution and metallurgical changes in the vicinity of a weld, notably the heat input of the arc, the initial temperature or preheat temperature of the workpiece, weld design, and the thermal conductivity of the base metal. The heat input provided by the arc is expressed in joules (watt-seconds) per lineal inch of weld and is defined as:

$$H = \frac{E \times I \times 60}{S}$$

where H is heat input (in joules per inch), E is arc voltage (in volts), I is arc current (in amperes), and S is arc travel speed (inches per minute).

Heat input calculated by this formula is an approximation, because heat losses are large. However, it is useful for comparison. Some welding specifications limit heat input, especially for the welding of quenched and tempered alloy steel. Heat input is also related to other welding conditions for the steel. For instance, allowable arc heat input usually varies directly with increasing section thickness and inversely with increasing preheat temperature.

Weld thermal cycles as a function of distance from the weld centerline are shown in Fig. 5. The data presented in Fig. 5 are typical of all arc welds; the following conclusions can be drawn:

1 The peak temperature encountered decreases rapidly with increasing distance from the weld centerline.
2 The time required to reach peak temperature increases with increasing distance from the weld centerline.
3 Rates of both heating and cooling decrease with increasing distance from the weld centerline.

Similar data showing the effects of heat input and preheat are shown in Fig. 6. These data show that decreasing either the heat input or the preheat temperature results in steeper distribution of peak temperatures in the heat-affected zone. Data presented in Table 2 relate heat input and preheat temperature to time of exposure above 2000 F (to the peak temperature, 2490 F) and to cooling rate at 1200 F, which is about 100 F below the lower transformation (Ac_1) temperature. Metal in the weld zone encountering peak temperatures within this range will undergo significant changes in microstructure and mechanical properties. From the data in Table 2 it can be seen that:

1 For a given preheat temperature, increasing the heat input increases the time of exposure to temperatures above 2000 F and decreases the cooling rate at 1200 F.
2 For a given heat input, increasing the preheat temperature decreases the cooling rate at 1200 F but does not significantly influence the time of exposure to temperatures above 2000 F.

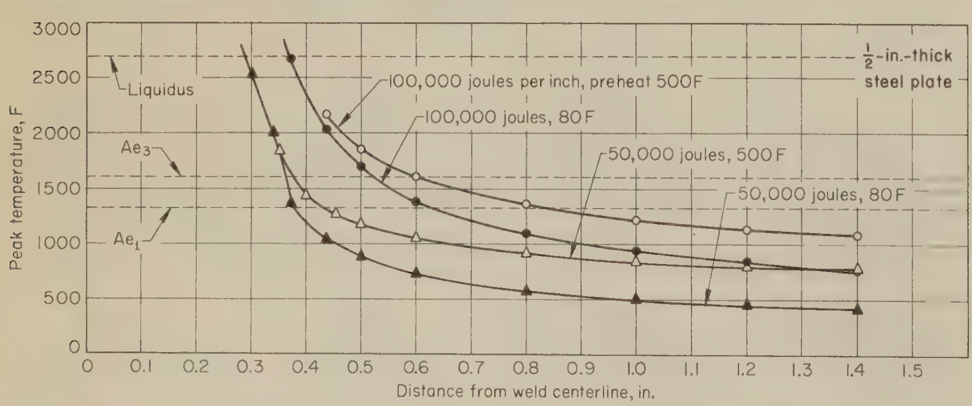
Preheating. Data in Table 2 show the significance of heat input, and of preheating, on the weld thermal cycle and, by implication, on the possibility of martensite formation. This suggests that, as an ideal precaution, all hardenable steels should be preheated to retard the cooling rate after welding. When preheating is used, section thickness, width of root face, and choice of filler metal are less critical.

Control of cooling rate (or postheating) after welding also influences the microstructure and susceptibility to cracking. With control of cooling rate (or with postheating), desired conditions are achieved by: (*a*) preventing formation of martensite by keeping the temperature of the heat-affected zone above the M_s temperature until transformation (to other products) is complete, or (*b*) decreasing the hardness of martensite by postweld tempering, if it has been allowed to form.

Multiple-pass welding may sometimes eliminate the need for preheating or postheating that would be required if the weld were made in a single pass. In multiple-pass welding, each pass serves (to some degree) as a preheat for subsequent passes and as a postheat for previous passes. Each application must be considered individually. In multiple-pass welding, the root pass is especially vulnerable to cracking when preheating is not used, particularly if the joint is highly restrained.

When preheating is not used, the usual practice is to deposit a heavy bead for the root pass. This not only imparts more heat to the joint, which results in slower cooling of the bead, but also provides greater strength and resistance to cracking of the weld metal used for the root pass.

In the example that follows, centerline cracking was eliminated without the use of preheating by changing to multiple-pass welding. In some applications, even though single-pass welds are used, if welds are close together, a similar preheating and postheating effect is obtained (see Example 216).



Data are for ½-in.-thick steel plate welded at room temperature by the manual shielded metal-arc process. (SOURCE: AWS Welding Handbook, 6th Ed., Section 1)

Fig. 6. Effect of heat input (joules per inch of weld) and preheat temperature on distribution of peak temperatures

Example 198. Change From Single-Pass to Multiple-Pass Welding To Prevent Cracking (Fig. 7)

Frames for rough-terrain trucks were fabricated from channel sections formed from ¾-in.-thick 5145 steel. Braces of ⅝-in.-thick 1018 steel were welded in each corner to stiffen the weldment, as shown in Fig. 7.

When the joints were shielded metal-arc welded in a single pass without preheat, using 3⁄16-in.-diam E7018 electrodes, at least half the welds developed cracks (Fig. 7), usually before the joints cooled.

The causes of cracking were found to be:

1 The small size of the weld deposit, and shrinkage stresses from rapid heat dissipation and cooling
2 Lack of penetration to the root of the joint
3 High restraint because of the stiffness of the members, and of the fixture holding the assembly during flat-position welding

4 High hardenability of the deposit as a result of carbon pickup from the 5145 steel base metal, which produced a hardness greater than Rockwell C 50.

Restraint and carbon pickup could not be avoided, and preheating in a furnace was not practical because of the large size of the assembly. Preheating with a torch prevented cracking in the single-pass welds, but this procedure was slow and difficult.

The problem was solved by:

1 Making each weld with three passes, to speed up welding and reduce rate of heat input and dissipation
2 Using a 5/32-in.-diam, instead of a 3/16-in.-diam, electrode for the first pass, to achieve full joint penetration (note Improved method in Fig. 7).

A conventional welding positioner was used, so that all welds could be made in the flat position. The braces were clamped to the frame corners, to avoid the need for tack welding, and all welding was done by the shielded metal-arc process, using E7018 electrodes.

The three passes were made in quick succession so that the beads could not cool appreciably between passes. Slag was quickly removed from the first bead and then the second pass was made, with a 3/16 or 7/32-in.-diam electrode. Slag was quickly removed from the second bead and the third pass was made, using an electrode of the same size as for the second pass.

The heat pattern of multiple-pass welding increased the ductility of the weld metal and heat-affected zone and reduced the hardness to Rockwell C 30 to 35.

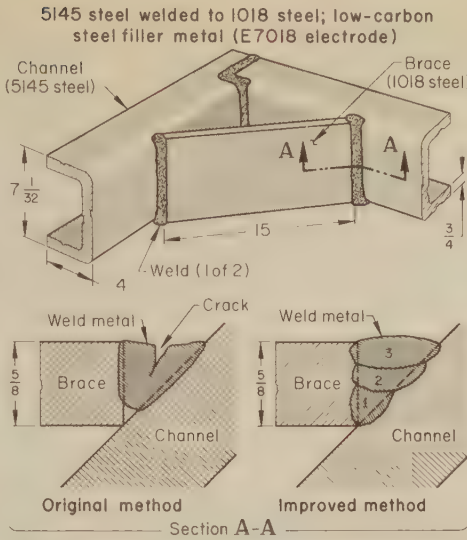


Fig. 7. Corner of a heavy-duty truck frame, showing brace that was shielded metal-arc welded without preheating. Change from single-pass to three-pass welds eliminated cracking. (Example 198)

Work-Metal Thickness. In general, the work-metal thickness influences the need for preheating. Alloy steels having relatively high hardenability often can be successfully welded without preheating when the section thickness does not exceed about ¼ in. As section thickness increases, rapid cooling by mass effect becomes more pronounced and the need for preheating increases. Concurrently, the need for higher preheating temperatures increases as section thickness increases. In the welding of thin sections when no preheat is used, even though heat dissipation is uniform and susceptibility to cracking is minimal, some hard microconstituents are likely to form. Thus, for serviceability, the weldment should usually be postheated to temper any martensite present.

On the other hand, when sections thicker than about 3 in. have been thoroughly preheated, the cooling rate after welding is so slow, because of the mass effect, that the need for postheating is minimal. For a base metal of low hardenability, postheating of heavy sections may be unnecessary.

Root Dimensions. In butt welding, the widths of the root face and of the root opening affect susceptibility to cracking, mainly because they influence the amount of welding done in the root pass. If an insufficient amount of weld metal is deposited in the root pass, the bead will lack strength, so that unless the interpass temperature is carefully maintained, cracking in the root-pass bead is likely. Angles between components being welded also influence susceptibility to weld cracking, because these angles govern the amount of weld deposit and therefore the heat input.

Shielding Gas. Regardless of the shielding gas used, its purity is more important when welding alloy steel than when welding plain carbon steel of low carbon content. A shielding gas that is made up predominantly of argon is less likely to cause cracking than is one containing predominantly carbon dioxide. The reason is that carbon dioxide permits greater heat input; consequently, penetration is deeper (see Fig. 6 on page 85 in this volume).

High-Strength Plate and Structural Steels (As-Rolled or Normalized)

Most steels of this group are known as high-strength low-alloy steels and are used extensively in construction, pressure-vessel and transportation applications. They are sold on the basis of minimum mechanical properties, primarily minimum yield strength, which is from 40,000 to 65,000 psi for the group (see Table 3).

The various producers of most of these steels have adopted different chemical compositions for steels that provide nearly identical properties. There is considerable variation in the number of alloying elements and the total alloy content. For most of the steels, total alloy content is less than 2%. The carbon content is low, usually in the range of 0.10 to 0.26%, although a carbon content as high as 0.33% is used in a few of the steels.

Weldability of these steels, a primary requirement, is somewhat less than that of carbon steels of the same carbon content. Weldability decreases as yield strength increases. However, for all practical purposes, welding of these steels is the same as welding of carbon steels that have the same carbon equivalent. As is true for other steels, weldability decreases as the thickness of the base metal increases.

Table 2. Effects of Heat Input and Preheat Temperature on Time of Exposure to Temperature Above 2000 F and on Cooling Rate at 1200 F(a)

Heat input, joules per inch	Preheat temperature, F	Time above 2000 F, to peak temperature of 2490 F, sec	Cooling rate at 1200 F, °F per sec
100,000	80	16.5	8
	500	17	2.5
50,000	80	5	25
	500	5	8

(a) Data are for heat-affected zones in ½-in.-thick steel plate arc welded using covered electrodes. (Source: same as for Fig. 5)

ASTM specifications group these structural steels according to minimum yield strength without regard to chemical composition of steels having the same mechanical properties. Table 3 lists the ASTM specifications that cover the majority of the steels, together with the minimum yield strength for each category; compositions are given in Table 4. Tables 3 and 4 cover several hundred proprietary steels.

Welding Processes. Steels covered by specifications listed in Tables 3 and 4 can be welded by any of the arc welding processes. Shielded metal-arc welding is used most often, mainly because of the nature (and very often the location) of the joints to be welded. When conditions permit, flux-cored arc, gas metal-arc, and submerged-arc welding may be used, to realize the advantages that are obtained from these processes in welding other steels. Submerged-arc welding (which can be employed only when the welding position is favorable) often proves more economical than other arc processes. Gas tungsten-arc and plasma-arc welding are seldom used for this class of steels. These processes are seldom competitive when applied to fabrication of very large structures, such as those for which these steels are generally used. Electroslag and electrogas welding have been used to a limited extent.

Filler Metals (Electrodes). Selection of a filler metal is of major importance in the welding of any alloy steel, but it becomes more critical as the hardenability of the base metal increases.

The strength of the weld metal deposited in the joint is the primary concern in most applications in which an alloy steel is required. Generally, therefore, filler metals must be selected that will provide the required joint efficiency, which in some cases may be less than 100%. The second major factor in selecting a filler metal is susceptibility to cracking. If the weldment is such that optimum preheating and postweld heat treatment practices can be employed, the selection of a filler metal is less critical than if welding conditions do not permit optimum (or any) preheating and postweld heat treatment.

Filler metals for arc welding of alloy steels can be classified into three general groups: (*a*) mild steels, often used when joint strength requirements are not stringent, or for joining alloy steel to mild steel; (*b*) alloy steels, used when joint strength must equal or approach that of the base metal; and (*c*) high-alloy (stainless steel or nickel-base) filler metals for special applications such as welding dissimilar steels.

Carbon content of the filler metal should never be higher than that of the base metal, because it would unnecessarily increase susceptibility to cracking. More often, the carbon content of the filler metal is lower than that of the base metal. A sufficiently close match of strength between base metal and weld metal can usually be achieved when the carbon content of the weld metal is no more than half that of the base metal.

Electrodes most commonly used for shielded metal-arc welding of high-strength plate and structural steels are listed in Table 5; low-hydrogen electrodes are recommended for all grades. Although the high-strength steels are occasionally welded with conventional electrodes, the danger of causing underbead and toe cracking is far greater with such electrodes than with low-hydrogen electrodes. The best practice for preventing such cracks, which are often difficult to detect, is to use low-hydrogen electrodes. Most regulatory codes require the use of low-hydrogen electrodes. Table 5 also shows that electrodes of higher strength and alloy content can be used as the yield strength of the steel (shown in Table 3) increases.

The moisture content of flux-covered electrodes used for welding alloy steels is an extremely critical factor in achieving sound welds. Table 6 gives the permissible maximum moisture contents for the various grades when packed in hermetically sealed containers. If these sealed containers are damaged or if for any reason there is a possibility that the electrodes have picked up moisture (see Fig. 10, and discussion on care of electrodes, on page 212), the electrodes may be restored for use by rebaking. The supplier of the electrodes should be requested to furnish proper conditions for storage and handling of electrodes, as well as times and temperatures for rebaking electrodes, so that at no time will the moisture content exceed the proper level for the electrode classification.

It is equally important to maintain low-hydrogen conditions in submerged-arc, flux-cored arc, and gas metal-arc welding, and to keep all other sources of hydrogen to required minimums. (For additional information on hydrogen, see page 212.)

Electrode wires for flux-cored arc welding of alloy steels have not been standardized. In applications permitting the use of carbon steel filler metal, alloy steels have been welded with electrodes such as E70T-1 or E70T-2, which have been standardized for the welding of carbon steels. Welds made with these filler metals in alloy steel may have lower strength than the base metal and therefore may not be acceptable for some applications.

Table 7 gives five typical compositions and as-welded mechanical properties for all-weld-metal samples from flux-cored electrodes.

Table 8. AWS Classifications and Composition Limits for Mild Steel Electrodes for Submerged-Arc Welding (AWS 5.17)

AWS classification	Composition, %(a): C	Mn	Si
Carbon Steel (Low-Mn) Electrodes			
EL8	0.10 max	0.30-0.55	0.05 max
EL8K	0.10 max	0.30-0.55	0.10-0.20
EL12	0.07-0.15	0.35-0.60	0.05 max
Carbon Steel (Medium-Mn) Electrodes			
EM5K(b)	0.06 max	0.90-1.40	0.40-0.70
EM12	0.07-0.15	0.85-1.25	0.05 max
EM12K	0.07-0.15	0.85-1.25	0.15-0.35
EM13K	0.07-0.19	0.90-1.40	0.45-0.70
EM15K	0.12-0.20	0.85-1.25	0.15-0.35
2% Mn Steel Electrode			
EH14	0.10-0.18	1.75-2.25	0.05 max

(a) Electrodes of all classes also contain maximums of 0.035 S, 0.03 P, 0.15 Cu (independent of coating), 0.50 total other elements. (b) Also contains 0.05 to 0.15 Ti, 0.02 to 0.12 Zr, 0.05 to 0.15 Al — exclusive of the 0.50% content of "total other elements".

Flux-cored electrodes for depositing alloy steel weld metal are usually made by using a low-carbon steel sheath and adding the alloying elements and flux in powder form to the core. Accordingly, filler metals of special compositions can be produced economically, even in small quantities.

Low-alloy steel electrode wires such as E70T-4 are frequently used in flux-cored arc welding of high-strength structural steels, particularly the grades having yield strength up to about 50,000 psi. Electrodes such as those identified as No. 1 and 3 in Table 7, or electrodes yielding weld metal with similar composition and properties, are commonly used for welding steels of yield strength from 50,000 to 65,000 psi.

Electrode wires for gas metal-arc welding have not been standardized for alloy steels. Carbon steel electrodes such as E70S-3 are often used for welding steels having yield strength of not more than 50,000 psi, such as ASTM A242. For steels of yield strength somewhat above 50,000 psi, E70S-1B and E70S-GB electrodes have proved suitable. Structural steels of the highest yield strength (65,000 psi) can be welded with solid electrode wires having compositions similar to those of the flux-cored electrode wires No. 1 and 3 in Table 7. These, and various similar compositions, are available as proprietary compositions.

Electrode wires of the medium-manganese type, such as EM5K or EM13K (see Table 8), have proved successful for submerged-arc welding of high-strength structural steels.

Preheating. Most welding of high-strength plate and structural steels in thicknesses less than ¾ in. is done without preheating. In many applications, because of location and other welding conditions, preheating is not practical. The need for preheating, and the preheating temperatures used, depend mainly on the thickness and yield strength of the steel being welded, the type of electrode used, and required impact properties. The suggested preheating practice presented in Table 9 considers the first three of these factors and shows the advantages of using low-hydrogen electrodes. No preheating above 70 F is required for plate thickness up to 1½ in. and yield strength up to 50,000 psi when low-hydrogen electrodes are used.

The practice suggested in Table 9 generally assumes that, at the time of welding, the base metal is at least near room temperature (not colder than 50 F). If the temperature of the base metal is less than 50 F, preheating (warming) to within the range of 70 to 100 F is recommended. This is usually done with gas torches, and sometimes with strip heaters.

Even though preheating is not intended, good practice includes warming the surfaces of the work (including any joints or crevices where moisture can be entrapped) to drive off moisture, especially in humid atmospheres. Warming slightly with a torch before welding has often prevented weld porosity.

Postweld heat treating of weldments fabricated from high-strength plate and structural steels is required for some code applications, but for many it is not required.

Examples of Practice. Four applications of arc welding of high-strength plate and structural steels are described in Examples 197, 208, 212 and 219 in this article. Table 10 summarizes these examples, identifying the welding processes, base metals, filler metals, and other welding variables.

High-Strength Alloy Steels Containing up to 0.25% Carbon (Quenched and Tempered)*

The steels discussed in this section are the quenched and tempered weldable alloy steels containing not more than 0.25% carbon, and with a total content of alloying elements (not including manganese and silicon) ranging from 0.85% to about 16% (see Table 11). These steels are welded in the quenched and tempered condition and have yield strengths of 50,000 to 180,000 psi, depending on alloy content, section thickness and heat treatment. They have high strength in combination with good ductility. Various combinations of notch toughness, fatigue strength, and corrosion resistance can be developed to meet the requirements of different applications such as structures and pressure vessels for use at atmospheric, cryogenic or elevated temperatures.

*Condensed from W. D. Doty, Welding of Quenched and Tempered Alloy Steels, *Metals Engineering Quarterly*, Feb 1969, p 66-78. Example 199 has been added editorially.

Table 9. Suggested Preheating Temperatures for ASTM High-Strength Plate and Structural Steels (As-Rolled or Normalized)

Steel thickness, in.	Electrode type	Suggested preheating temperature, F, for yield strength, psi, of: 45,000	50,000	55,000	60,000	65,000
Up to ⅜	Conventional	None(a)	None(a)	None(a)	100	150
	Low-hydrogen	None(a)	None(a)	70	70	70
⅜ to ¾	Conventional	None(a)	100	150	200	250
	Low-hydrogen	None(a)	None(a)	70	70	70
¾ to 1½	Conventional	150	150	200	250	...
	Low-hydrogen	None(a)	None(a)	150	150	...
1½ to 2	Conventional	200	250	300	...	...
	Low-hydrogen	150	150	225	...	...
2 to 3	Conventional	300	300	350	...	...
	Low-hydrogen	225	225	300	...	...

(a) None means that the base metal should not be below 50 F. If it is below 50 F, it should be preheated to the range of 70 to 100 F.

Although high-strength alloy steels with up to 0.25% carbon cannot be successfully welded with simple procedures and minimal control, they are less difficult to weld than are the higher-carbon alloy steels such as 4140. The quenched and tempered alloy steels with up to 0.25% carbon were designed to be welded with moderate or no preheat, and to be used in most applications in the as-welded condition. Knowing the correct procedures that should be used for welding these steels, and rigorously following them, are fundamental to welding them successfully.

Composition, Properties and Microstructure. The composition ranges (ladle analysis) for representative high-strength alloy steels are given in Table 11. The mechanical properties of pressure-vessel-quality plates are given in Table 12. The A517 steels referred to in these tables are also produced, in accordance with ASTM A514, as structural-quality plate steels, and some are available as abrasion-resistant steel plate with minimum hardness of 321, 340 or 360 Bhn. The A543 steels, classes 1 and 2, are modifications of HY-80 and HY-100 steels, respectively. Some steels, such as A514 and A517 (grades B, F, and H), A543, HY-130, and A553, are available as heat treated shapes and seamless pipe.

A517 is a multiple-alloy boron-containing steel of 100,000-psi minimum yield strength in the heat treated condition that is now used extensively in construction equipment, bridges, buildings, pressure vessels, storage tanks, penstocks, spiral cases, and ships.

A533, grade B, steel (manganese-molybdenum-nickel steel formerly known as nickel-modified A302) has been used extensively for nuclear pressure vessels of heavy sections. The same steel at a higher strength (class 3) has been used for thin-wall pressure vessels and layered pressure vessels. A542, a 2¼Cr-1Mo steel, has been used for large-diameter hydrocracking pressure vessels that operate at elevated temperature.

The need for tough steels of high yield strength led to the development of HY-80 steel as ASTM A543. Further development resulted in HY-130, a 5Ni-Cr-Mo-V steel, and in HP 9-4-20, a 9Ni-4Co-Cr-Mo-V steel, mostly for hydrospace and aerospace requirements.

Increasing cryogenic applications led to the development of A553, grade A, a 9% Ni steel, for use at temperatures down to −320 F, and of A553, grade B, a steel of somewhat lower nickel content (8% Ni), for use at temperatures down to −275 F.

The mechanical properties given in Table 12 result from heat treatments described in Table 13.

The purpose of quenching and tempering is to produce low-temperature transformation products, such as bainite and tempered martensite, which have excellent strength combined with toughness. For example, although A533, grade B, steel has limited hardenability, the quenched and tempered microstructure in ½-in.-thick plate consists entirely of tempered martensite, which produces a tensile strength of at least 110,000 psi and a Charpy V-notch energy absorption of at least 25 ft-lb at −85 F. In a 7-in.-thick plate, the microstructure consists of ferrite and tempered bainite, and results in a tensile strength of about 90,000 psi and a Charpy V-notch

Table 10. Summary of Welding Processes, Filler Metals, and Preheating and Postheating Practices Used in Examples in This Article

(a) SMAW = shielded metal-arc welding; FCAW = flux-cored arc welding; GMAW = gas metal-arc welding; SAW = submerged-arc welding; GTAW = gas tungsten-arc welding. (b) Interpass temperature, 200 F min. (c) Similar in composition to A517. (d) Modified type 304; 0.14 max C, 4.0 to 4.5 Mn, 19 min Cr, 9 min Ni. (e) Shielded metal-arc for out-of-position welds; both processes used in shop and field welding. (f) Electrode for flux-cored arc welding had a composition of 0.15 C, 0.93 Mn, 0.22 Si, 0.75 Cr, 0.66 Ni, 0.50 Mo; for shielded metal-arc welding, electrodes had composition equivalent to E11018.

(g) Local preheat, in both shop and field. (h) Stress relief used only in shop. (j) Warmed to 70 F with torch if below 32 F. (k) An unclassified flux-cored equivalent of an E7018 flux-covered electrode. (m) As deposited, 0.15 C, 1.60 Mn, 0.55 Si, 0.70 Cr, 0.75 Mo. (n) Held at temperature for 15 min. (p) To temper martensitic structure. (q) Filler metal and flux combination. (r) For 2 hr, followed by normalizing at 1750 F for 1 hr and tempering at 1200 F for 6 hr. (s) Modified 4335. (t) For 1 hr. (u) Tempered at 600 F for 1 hr, then at 1225 to 1275 F for 2 hr.

(v) A 2.25 Cr-1 Mo steel. (w) On ferritic steel side only. (x) Entire joint heated for 1 hr. (y) Only for buttering of A335 (Cr-Mo) steel pipe; no preheat before welding of circumferential joint between the two pipes. (z) In sulfur-free atmosphere (8 hr) to temper Cr-Mo steel end.

(aa) Flux-cored wire equivalent to E9018-B3 in composition. (bb) Held at preheat temperature until placed in furnace for subsequent heat treating. (cc) A213, T11. (dd) By furnace or oxyacetylene torch. (ee) Held in furnace for 2 hr, or if oxyacetylene torch is used, weldment is then buried in lime for 12 hr. (ff) Cast steel roll containing 1.0 C, 0.9 Mn, 0.5 Si, 0.038 S, 0.038 P, 1.0 Cr, 0.5 Ni, 0.5 Mo. (gg) From a low-carbon steel tubular electrode with alloy-flux core; used with neutral flux.

energy absorption (¼-thickness location) of at least 30 ft-lb at 10 F. If the nickel, chromium, and molybdenum contents are high (as in A543 and HY-130 steels), the microstructure is tempered bainite and tempered martensite, even in very thick steel sections, and results in a desirable combination of strength and toughness. Furthermore, the HY-130 and HP 9-4-20 steels display markedly better toughness when residual or impurity elements such as phosphorus, sulfur, nitrogen, oxygen and hydrogen are restricted to the lowest possible levels.

Within carefully chosen limits on thickness, the A517 steels provide high strength and toughness with the least amount of alloying elements. The effect of quenching and tempering on the longitudinal mechanical properties of ½-in.-thick A517, grade F, steel is shown in Fig. 8. In the hot rolled condition the steel has a microstructure of proeutectoid ferrite and high-carbon martensite, which results in a yield strength of only about 80,000 psi and very poor Charpy V-notch energy absorption at −50 F. In comparison, the as-quenched microstructure contains high percentages of martensite and bainite; consequently, the yield and tensile strengths are much higher than those of the same steel in the hot rolled condition. The toughness of the as-quenched plate, although considerably better than that of the hot rolled plate, is greatly increased when the steel is tempered, particularly at temperatures above 1100 F, as shown in Fig. 8. Also, as a result of tempering, the yield and tensile strengths are significantly lowered and the tensile elongation is almost doubled.

Many studies have been made using underbead-cracking tests, fillet-weld and butt-weld restraint-cracking tests, and hot ductility tests to define the composition limits for susceptibility of steels to hot and cold cracking. Hot cracking normally occurs at a high temperature, usually just below the solidus temperature, whereas cold cracking, or delayed cracking, occurs below the M_s temperature.

Many of the quenched and tempered steels in Table 11 are usually produced with a sulfur content of less than 0.025%, and some, such as HY-130 and HP 9-4-20, are produced with a sulfur content not exceeding 0.010%. The manganese-to-sulfur ratio is generally greater than 30 to 1, so that with a carbon content of about 0.20% or less the susceptibility to hot cracking is negligible.

The A533 steel, with a somewhat higher carbon content, has negligible susceptibility to hot cracking because it has a high manganese-to-sulfur ratio, usually about 50 to 1. The A543 steel, with a low manganese content, is susceptible to cracking when the carbon content is at the maximum unless sulfur content is extremely low.

Susceptibility to cold cracking under conditions of high restraint decreases with increased M_s temperature. This effect has been attributed to the self-tempering of the martensite that forms at high temperatures within the martensite transformation range. Furthermore, cold cracking is directly proportional to the hydrogen content in the welding atmosphere.

All of the steels in Table 11 have negligible susceptibility to cold crack-

(a) The minimum required value for Charpy V-notch impact energy is subject to agreement between the steel producer and the user; the values shown here for the various steels are typical required minimums. (b) For ½-in.-thick steel. (c) Tentative.

ing, provided that suitable care is taken to limit the amount of hydrogen in the welding atmosphere.

Another feature of the steel compositions listed in Table 11 is the frequent use of molybdenum to increase resistance to tempering as well as to provide greater hardenability. Molybdenum, like the strong carbide-forming elements such as titanium, vanadium and zirconium, serves two functions: to retard softening of the steel during tempering at high temperature for increased toughness and ductility, and to provide that portion of the heat-affected zone just below the lower transformation temperature with needed resistance to excessive softening. The retarded softening of A517, grade F, steel at tempering temperatures above 900 F is illustrated in Fig. 8 by the decreased slope of the strength curves between 900 and 1100 F. Thus, in a quenched and tempered steel with adequate resistance to softening, 100% joint efficiency at the desired high strength can be readily obtained if uncommonly high heat inputs in welding are avoided. Furthermore, the resistance to tempering contributes to more uniform bendability in welded joints subjected to forming operations after welding.

Steels having excellent toughness in the unaffected base metal may have inadequate toughness in the heat-affected zone. To ensure that this does not occur, much care has been given to the composition limits and recommended welding procedures for several of the quenched and tempered alloy steels in Table 11.

The development of good notch toughness in the heat-affected zone of quenched and tempered alloy steels depends on the rapid dissipation of welding heat to permit the formation of martensite and bainite on cooling. With increasing section thickness of the steel as a plate, structural section, or forging, a higher hardenability is required to secure the desired hardened structure throughout the section. Sections 1 in. thick and greater, however, produce much higher cooling rates in the heat-affected zone during welding than do ¼-in. or ½-in. sections. Therefore, thicker sections require compositions of higher hardenability principally so that heat treatment will provide the required mechanical properties before welding, whereas thinner sections require compositions of adequate hardenability both to provide the required mechanical properties before welding and to maintain the desired properties after welding.

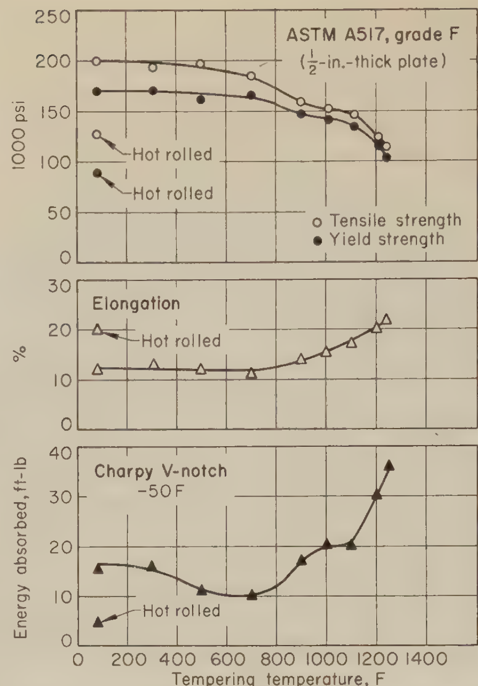

Fig. 8. Effect of quenching and tempering on the mechanical properties of ½-in.-thick ASTM A517, grade F, steel in the longitudinal direction

A microstructure produced by rapid cooling so as to have a high percentage of low-temperature transformation products (martensite and bainite) responds favorably to tempering above 1000 F, whereas the structure that results from slow cooling is only moderately improved by tempering. The structure will be comprised of upper bainite and high-carbon martensite and will have poor impact properties. These same principles apply to the microstructure produced in the heat-affected zone of a weldment.

Results of fatigue tests on butt-welded and fillet-welded joints in the weldable quenched and tempered alloy steels have shown no special sensitivity of the heat-affected zone or weld metal to fatigue failure, provided that the steel has adequate resistance to softening in the heat-affected zone, as previously discussed, and that the weld metal has adequate tensile strength. However, because fatigue-crack initiation is associated with geometric discontinuities and stress raisers, the effect of cutting and welding on fatigue must be carefully considered in relation to shape and soundness.

Location and Design of Joint. To obtain maximum advantage from the weldable quenched and tempered alloy steels, it is necessary that the increase in the yield strength of the steels be accompanied by refinements in design, workmanship and inspection. Even more thought must be given to joint design and location than with steels of which the properties are less dependent on heat treatment. A design that incorporates abrupt changes in section in a region of high stress cannot be tolerated, particularly if the steel has a yield strength of 80,000 psi or higher. Locating welds incorrectly can cause or contribute to abrupt changes in section. The welds must be located at sites where there is sufficient access for the welder and where proper examination can be made by the inspector. For these reasons, butt welds are preferable to fillet welds.

Suitable joint preparation can usually be achieved by gas or arc cutting without preheating, although some codes require preheating. For all the steels in Table 11, the steel temperature should be not lower than 50 F during cutting, but when cutting A533 and A543 steels the preheat temperature recommended for welding (see Table 15) is suggested.

Arc cutting is often preferred for steels such as A553 and HP 9-4-20. All slag or loose scale from cutting should be removed by light grinding. Prior to welding, joint surfaces should be dried, and cleaned to remove organic and hygroscopic materials. Backing bars, when required, should be made continuous, by butt welding, so as to avoid notches, which can be sites for the start of transverse cracking of weld metal. Preferably, backing bars are removed after welding in applications entailing fatigue loading. If fatigue loading is involved, the root must be inspected or back welded.

Butt joints should be welded so as to avoid creating severe stress raisers at the root. Stress raisers at this location, like those at the toe of butt or fillet welds with excessive weld reinforcement or inadequate fairing into the adjacent plates, are of greater concern when the steel has high yield strength.

Selection of the Welding Process. Shielded metal-arc, submerged-arc, flux-cored arc and gas metal-arc welding are most commonly used for joining the quenched and tempered alloy steels of carbon content up to 0.25%. These four processes can be used effectively for welding steels having yield strength up to approximately 150,000 psi. Gas tungsten-arc or electron beam welding must be used for steels of yield strength over 150,000 psi, including the HP 9-4-20 steel.

Weld cooling rates for the arc welding processes are usually so high that the mechanical properties of the heat-affected zone in the high-strength quenched and tempered steels approach those of the steel in the quench-hardened condition. Thus, postweld heat treatment, such as quenching

Table 13. Heat Treatments for Representative High-Strength Alloy Steels (Quenched and Tempered)

Steel	Treatment	Microstructure
A533, gr B	Water quenched from 1550 F (min) and tempered at 1100 F (min)	Tempered bainite and tempered martensite (thin plates); ferrite and tempered bainite (thick plates)
A517	Water quenched from 1650 F (min) and tempered at 1150 F (min)	Tempered bainite and tempered martensite
A542	Water quenched from about 1750 F and tempered at 1050 F (min)	Tempered bainite and tempered martensite
A543	Water quenched from 1650 F (min) and tempered at 1100 F (min)	Tempered bainite and tempered martensite
HY-130	Water quenched from 1475 to 1525 F and tempered at 1000 F (min)	Tempered bainite and tempered martensite
HP 9-4-20	Normalized from 1675 F, water quenched from 1550 F and tempered at 1000 F	Tempered martensite
Mod A203, gr D	Water quenched from about 1600 F and tempered at about 1100 F	Proeutectoid ferrite and fine pearlite
A553	Water quenched from 1450 to 1500 F and tempered at 1050 to 1125 F	Ferrite and austenite

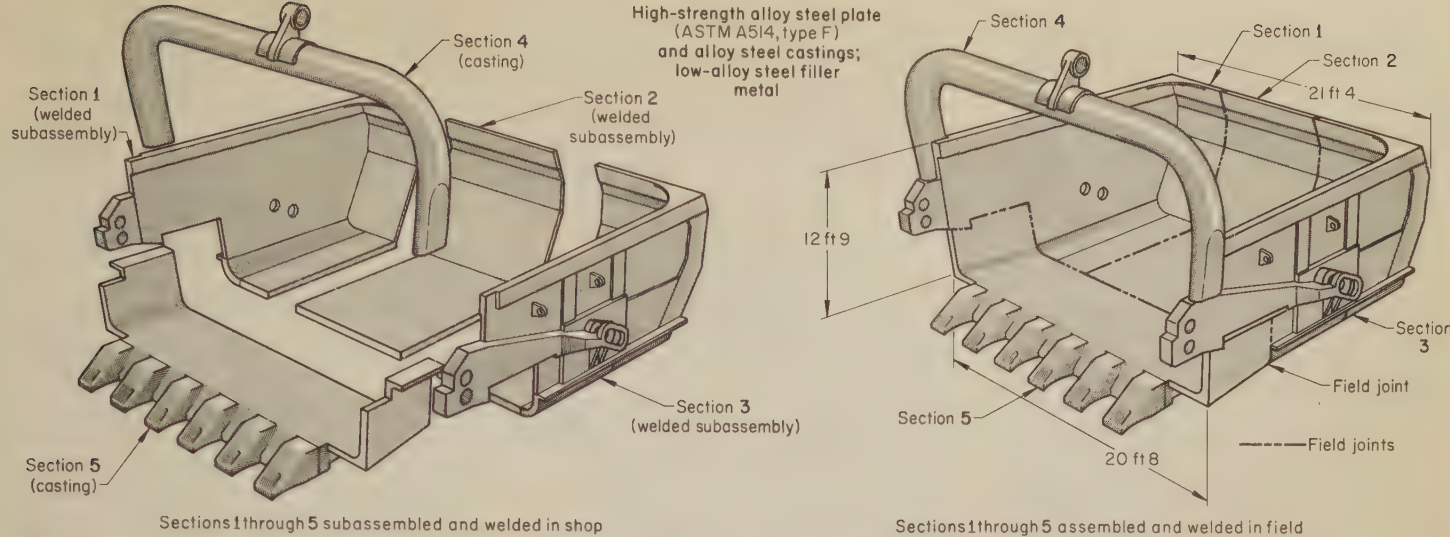

Fig. 9. Dragline bucket that, because of size and weight (158 tons), was produced as five shop-welded subassemblies that were shipped to location for field assembly and final welding. In both shop and field welding, flux-cored arc process was used for flat and horizontal positions, and shielded metal-arc for out-of-position, short, or difficult-access welds. (Example 199)

and tempering, is unnecessary unless stress corrosion is a factor. Electroslag welding, which subjects the base metal to prolonged heating and consequently slower cooling rates, generally requires quenching and tempering of these steels after welding.

Welding of structures in the field often requires welding conditions similar to those used in the shop. To minimize the problem of duplicating shop practice in the field, large sections are often fabricated in the shop and transported to the field for final assembly by welding. The example that follows describes an application in which both flux-cored arc and shielded metal-arc welding were used for joining subassemblies of 158-ton dragline buckets.

Example 199. Flux-Cored Arc Welding and Shielded Metal-Arc Welding for Assembly of 158-Ton Dragline Buckets (Fig. 9)

Because two dragline buckets, each weighing 158 tons and having a capacity of 220 cu yd, were too large to ship in one piece to the site of use, they were shop fabricated in five sections, as shown at the left in Fig. 9. Field welding of the assembled sections presented the problem of duplicating the favorable shop welding conditions.

The plate material, which was a high-strength alloy steel equivalent to ASTM A514, type F, was quenched and tempered to a tensile strength of 105,000 to 135,000 psi. Castings were of a proprietary alloy steel that had a tensile strength of 120,000 to 130,000 psi. The thickness range of the metal was from 1½ to 6 in., and the average thickness of the steel plate was about 2 in.

Groove and fillet welds were used for the various butt, corner, lap and T-joints. Welding these joints and steels required careful control of preheat and weld heat input to avoid cracking. Shop operations were as follows:

1. Plate edges were prepared by gas cutting square edges, and single and double bevels of 30° and 45°, as required.
2. Each section was assembled and tack welded.
3. The joints that were to be shop welded were preheated to 400 F by propane torches. Heat was maintained until all shop welding was completed.
4. All joints except the field joints between the five sections shown in Fig. 9 were welded using both flux-cored arc welding and shielded metal-arc welding. Flux-cored arc welding was used for welds that could be made in the flat and horizontal positions; shielded metal-arc welding, for out-of-position welds, for welds of short length, and for those that were difficult to reach. For flux-cored arc, 3/32-in.-diam electrodes were used; with larger-diameter electrode wires, welds cracked, probably because of the higher heat input and dilution effects.
   The flux-cored electrode yielded a deposit of 0.15 C, 0.93 Mn, 0.22 Si, 0.66 Ni, 0.75 Cr and 0.50 Mo. Flux-cored arc welding was done at 400 to 500 amp (dcrp) and 30 to 32 volts, using carbon dioxide (−45 F dew point, from bulk storage) at a flow rate of 30 to 35 cu ft per hour, for shielding. The electrode holder was a 600-amp water-cooled type; a 750-amp constant-voltage transformer-rectifier was used.
   Shielded metal-arc welding was done with E11018 electrodes, 5/32 and 3/16 in. in diameter, at 150 to 225 amp (dcrp) and at 20 to 30 volts.
5. To minimize distortion, long welds were made using a block sequence, in which full-size welds were deposited in the middle and at the ends of the joint and then weld beads were back-stepped to the blocks. Weld penetration was as near 100% as possible without back gouging the root bead.
6. After shop welding, the sections were stress relieved at 1115 F, furnace cooled and shipped to the site.

For field welding, the five sections were set up and cribbed in such a manner that all joints were accessible to permit welding in all positions. Because the welding had to be done in cold weather, a shelter was provided to help maintain a uniform temperature during welding. Heating was accomplished by the use of electric resistance strip heaters and large (2500 Btu) electric space heaters. Heating was maintained at all times until the job was completed, even on weekends when work stopped.

Field welding was done by the flux-cored arc and shielded metal-arc processes, under essentially the same conditions as those used in shop welding. On long welds, the block sequence described in item 5 above was used. All weld runs were completed before the next weld was started. The body plate was welded first, by joining sections 1, 2 and 3. Section 5, the lip section, was then welded to the body plate. The arch, section 4, was welded last.

Selection and Care of Electrodes. Suitable filler metals for shielded metal-arc, submerged-arc, and gas metal-arc welding of the quenched and tempered alloy steels are described in Table 14. A joint efficiency of 100% can be obtained with most steels.

The covered electrodes listed in Table 14 for joining A533, A517, A542

Table 14. Filler Metals for Joining Representative High-Strength Alloy Steels (Quenched and Tempered) by Three Welding Processes

Steel	Filler metal (and suitable flux and shielding gas, as applicable): Shielded metal-arc welding	Submerged-arc welding	Gas metal-arc welding(a)
A533, gr B, cl 1 & 2	E9018-D1	Mn-Mo wire and neutral flux	Mn-Mo wire and argon-O_2 gas

Mod A203, gr D	(e)	(e)	(e)
A553, gr A & B	68Ni-15Cr-3Ti-9Fe	65Ni-27Mo wire and neutral flux	70Ni-15Cr-3Ti-9Fe wire; helium-argon gas

(a) Consumable-electrode gas metal-arc process, except as noted for HP 9-4-20 steel, which was welded by the gas tungsten-arc process. (b) Lower-strength low-hydrogen electrodes (depending on design stress) may also be suitable. (c) A higher-strength electrode, such as E12018-G (Mn-Ni-Cr-Mo), may be necessary for thin plates of A517, grades A, B, C, D and J, steels. (d) Suitable filler metal – flux combination being developed. (e) At present, same as for A553 steel, but more economical filler metals are being developed.

and A543 steels are those commonly used, but similar low-hydrogen electrodes such as Exx15 or Exx16, with a different covering, are also suitable. Regardless of the strength of the heat treated steels listed in Table 14, electrodes that deposit weld metal having a lower strength than that of the steel are often adequate, as is true of fillet welds in longitudinal shear; in fact, lower-strength weld metal is often desirable to prevent cracking in highly restrained fillet welds.

When a carbon steel electrode and alloy-flux combination is used for submerged-arc welding, rather than an alloy steel electrode and neutral-flux combination, the welding conditions must be closely controlled, to prevent a wide variation in weld-metal composition and consequent wide variation in the cracking susceptibility and mechanical properties of the deposited metal. For example, a fabricator of components for a long-span bridge encountered cracking in submerged-arc butt welds made with a normally satisfactory combination of a carbon steel electrode wire and an alloy flux. The cracking was traced to variations in chemical composition of the weld metal, caused by fluctuations in arc voltage. Cracking was eliminated by controlling the voltage to ±1 volt, and by ensuring adequate supervision.

Hydrogen must be kept to a tolerable amount. The sources of hydrogen are:

1. Organic materials, chemically bonded water, and absorbed water in the electrode covering or welding flux
2. Hydrogen in the filler metal or in contaminants on the surface of the electrode wire, or moisture in the shielding gas or flux
3. Moisture on the steel surface at the location of welding.

In the welding of quenched and tempered alloy steels by the three metal-arc processes, hydrogen is kept to a tolerable amount in shielded metal-arc welding by using properly dried low-hydrogen electrodes; in submerged-arc welding, by using clean, dry flux and clean low-hydrogen electrode wire; and in gas metal-arc welding, by using moisture-free shielding gas and clean low-hydrogen electrode wire. For each of these processes, the steel must be dry at the location of welding. Warming with a torch is often used to ensure dry surfaces.

The low-hydrogen characteristic of covered electrodes must not be taken for granted. Normally, low-hydrogen alloy steel covered electrodes are packaged in sealed containers and the moisture content of the covering is as shown in Table 6. The coverings on special E14018 electrodes have a moisture content not greater than 0.1%. However, experience has shown that such limits on moisture content are not always sufficiently restrictive. For example, the E9015-B3 electrodes listed in Table 14 for joining A542 steels are suitable for these steels *only* if the moisture content of the covering is *less* than 0.2%, rather than the normal 0.4%. If electrodes of a lower strength class than that suggested for any particular steel in Table 14 are used, they should be baked to reduce the moisture content of the covering to that of the higher-strength electrode suggested in Table 14. For example, if E7018 electrodes, normally supplied with a maximum moisture limit of 0.6%, are to be used for welding A517 steel, the moisture content of the electrode covering should be reduced to less than 0.2%. (It should be noted that the feasibility of, and procedure for, baking depend on the composition of the electrode coating; baking should not be done without the advice of the electrode manufacturer.)

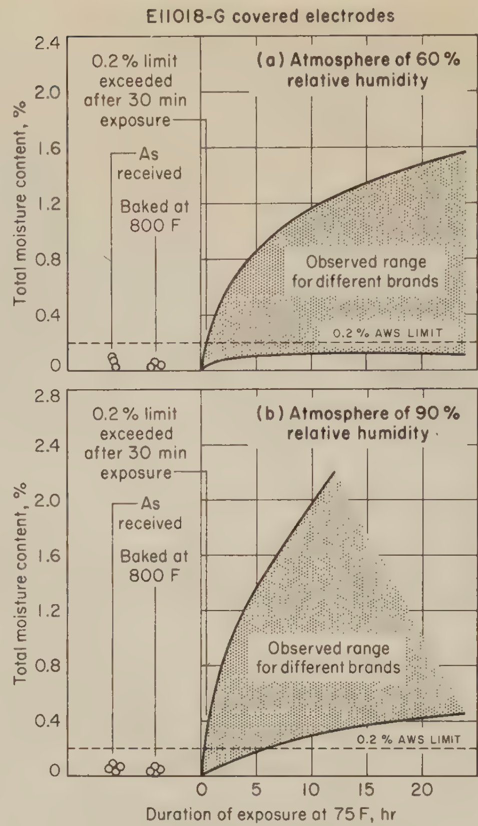

Fig. 10. Moisture content of covering on E11018-G electrodes as a function of time of exposure to atmosphere of moderate (60%) and high (90%) relative humidity

The importance of care in the storage of low-hydrogen electrodes is illustrated in Fig. 10(a) and (b), which show the effect on the moisture content of the covering on E11018-G electrodes of exposure for up to 24 hr at 75 F to atmospheres of 60% and 90% relative humidity. At both humidity levels, the permissible moisture content of 0.2% is exceeded by some of the electrodes after 30 minutes of exposure, and at 90% humidity the increase in moisture content with time of exposure is markedly accelerated.

To satisfy these rigid moisture requirements, electrodes should not be exposed to the atmosphere for more than ½ hr. Electrodes that have been exposed for longer periods must be redried before use. Failure to observe this practice is a common cause for underbead cracking in quenched and tempered alloy steel welds.

For the bare-wire electrodes used in submerged-arc, flux-cored arc or gas metal-arc welding, low hydrogen content is as important as for the covered electrodes used in shielded metal-arc welding. The total hydrogen content of bare-wire electrodes, including the hydrogen from contaminants on the wire surface, should not exceed 5 parts per million (ppm) for electrodes used to weld A517, A542 and A543 steels, and should not exceed 3 ppm for electrodes used to weld HY-130 steel. For example, transverse weld-metal cracks were noted in submerged-arc butt welds joining the flange of girders being fabricated from A517, grade F, steel for a bridge. The cracking was traced to hydrogen-producing contaminants on the surface of the bare-wire electrode used to make the welds. Cracking did not occur in similar joints made with electrode wire containing less than 5 ppm of hydrogen.

Preheating. The minimum preheat and interpass temperatures for satisfactory shielded metal-arc welds in quenched and tempered alloy steels increase with plate thickness, as shown in Table 15. Preheating is required to prevent weld-metal cracking in restrained welds, and temperature above the minimums shown in Table 15 may be required for highly restrained welds. The use of a preheating temperature of less than 100 F requires that any moisture on the plate or introduced to the arc atmosphere by the electrode or welding flux be kept to a minimum — by driving it off by mild heating, if necessary.

The maximum preheat and interpass temperatures should, in general, not exceed the minimum values given in Table 15 by more than 150 F. Otherwise, the upper limit on welding-heat input, as subsequently discussed, is very restrictive. For some grades the maximum preheat and interpass temperatures are more restrictive than for others. Thus, maximum preheat and interpass temperatures for various thicknesses of HY-130 steel plate are:

Table 15. Suggested Minimum Preheat and Interpass Temperatures When Shielded Metal-Arc Welding Representative High-Strength Alloy Steels (Quenched and Tempered)

Plate thickness, in.	Minimum preheat and interpass temperatures for welding with low-hydrogen electrodes, F: A533, B	A517	A542	A543	HY-130	Mod A203, D	A553
To ½, incl	50	50	150	100	75	50	50
Over ½ to ⅝, incl	100	50	200	125	75	50	50
Over ⅝ to ¾, incl	100	50	200	125	125	50	50
Over ¾ to ⅞, incl	100	50	200	150	125	50	50
Over ⅞ to 1, incl	100	50	200	150	200	50	50
Over 1 to 1⅜, incl	200	150	250	200	200	150	150
Over 1⅜ to 2, incl	200	150	250	200	225	150	150
Over 2	300	200	300	200	225	200	200

The minimum temperatures shown are suitable also for gas metal-arc welding and for submerged-arc welding with a neutral flux.

A preheat temperature above the minimum may be required for highly restrained welds. No welding should be done when ambient temperature is below 0 F. Steel that is at an initial temperature below 100 F may require preheating to remove moisture from its surface.

Maximum preheat and interpass temperatures should not exceed the minimums shown here by more than 150 F.

Plate ⅝ in. thick or less	150 F
Over ⅝ to ⅞ in., incl	200
Over ⅞ to 1⅜ in., incl	275
Over 1⅜ in. thick	300

The preheat and interpass temperatures suggested in Table 15 for shielded metal-arc welding are also suitable for gas metal-arc welding and for submerged-arc welding with a neutral flux. For submerged-arc welding with an alloy flux, somewhat higher temperatures are required to prevent weld-metal cracking, as shown by the preheat and interpass temperatures recommended for A517 steels in Table 16.

Heat Input and Welding Techniques. The minimum cooling rate required to produce the desired microstructures with adequate mechanical properties varies with the particular steel being welded. A cooling rate that is sufficiently high for one steel may be too low for another steel; or, expressed in terms of welding heat input, a heat input that is usable for one steel at a specific thickness and preheat may be too high for another steel under similar conditions.

Table 17 provides examples of suggested heat-input limits for some of the quenched and tempered alloy steels listed in Table 11. The limits for A533, grade B, steel in Table 17 were developed for pressure-vessel applications of class 3 steel at service temperatures down to −85 F, whereas the limits for A517, grades B, F and H, steels were developed for applications at more nearly normal service temperatures.

The heat-input limits discussed above, which were established to ensure adequate mechanical properties in the heat-affected zone, also serve to discourage the deposition of large weld beads, produced with large-diameter electrodes and high heat input, and having characteristically poor notch toughness. In welding quenched and tempered alloy steels it is good practice, whenever possible, to deposit many small beads, because this technique improves the notch toughness of the weld metal by the grain-refining and tempering action of successive passes. Such a practice is especially necessary if the welded steel is to endure severe plastic deformation, as obtains, for example, in the Navy multiple-shot explosion-bulge test performed on butt-welded specimens.

Because heat input determines the solidification characteristics and transformation structures (and consequently the properties) of the weld metal, heat input is especially important in the welding of steels of minimum yield strength greater than 100,000 psi. In Table 18, specific values of heat input are suggested for welding of HY-130 steel. Such specific conditions ensure that the heat-affected zone and the weld metal meet high strength and toughness requirements.

Stringer-bead technique, rather than weave-bead technique, is preferred in the welding of quenched and tempered alloy steels, because the heat input per inch of forward travel of the arc is lower, distortion of the joint during welding is less, and notch toughness is better in both the weld metal and the base metal. The partial weaving and uphill motion that is unavoidable when welding in the vertical position should be kept to a minimum. Air carbon-arc gouging, at a controlled heat input, followed by cleanup of the cut surface by grinding, is the preferred method for metal removal to facilitate the making of a sound weld at the root of a joint in quenched and tempered alloy steels of yield strength up to about 150,000 psi. Machining and grinding only are used for metal removal at the root of a joint in HP 9-4-20 steel.

Postweld Heat Treatment. Of the quenched and tempered alloy steels in Table 11, only A533 and A542 are usually given a postweld stress-relief heat treatment. However, these two steels have been used almost exclusively in thicknesses greater than 2 in.

Table 16. Suggested Minimum Preheat and Interpass Temperatures for ASTM A517, Grades B, F and H, Steels (a)

Plate thickness, in.	Min preheat, interpass temp, F: Shielded metal-arc or gas metal-arc	Submerged-arc: Alloy or carbon steel filler metal, neutral flux	Submerged-arc: Carbon steel filler metal, alloy flux
Up to ½, incl	50 (b)	50 (b)	50 (b)
Over ½ to 1, incl	50 (b)	50 (b)	200
Over 1 to 2, incl	150	150	300
Over 2	200	200	400

(a) Preheat temperatures above the minimums shown may be required for highly restrained welds. Maximum preheat and interpass temperatures should not exceed the minimums shown here by more than 150 F. (b) Welding of plate that is at any initial temperature below 100 F will require extreme care to minimize the formation of moisture on the steel being welded.

$$\text{Kj/in. of weld} = \frac{\text{Amperes} \times \text{volts} \times 60}{\text{Speed, in. per min} \times 1000}$$

Heat-input limits for temperatures and plate thicknesses included, but not shown, in this table may be obtained by interpolation; 25% higher heat inputs are allowable for fillet welds.

Table 18. Suggested Welding Heat Input in Kilojoules per Inch for Joints in HY-130 Steel

Plate thickness, in.	Shielded metal-arc	Gas metal-arc
⅜ to ⅝, incl	40	35
Over ⅝ to ⅞, incl	45	40
Over ⅞ to 1⅜, incl	45	45
Over 1⅜ to 4, incl	50	50

Stress relieving is necessary for some applications in which the steel: (*a*) has inadequate notch toughness after cold forming or welding; (*b*) must retain extremely close dimensional stability during close-tolerance machining after cold forming or welding; (*c*) has high residual stresses, from cold forming or welding, that might increase susceptibility to stress corrosion. However, the need for such postweld heat treatment should be thoroughly established for each steel and application, not only because many modern steels for welded construction are designed to be used in the as-welded condition, but also because the properties of the welded steel or the weld metal joining the steel may be adversely affected by a postweld stress-relief heat treatment if stress-relieving temperature exceeds the tempering temperature. If a weldment must be stress relieved, the temperature should not exceed that used for tempering the steel. Stress-relief heat treatment at a temperature at least 50 F lower than the tempering temperature is desirable, to avoid the possibility of overtempering.

The alloying elements that contribute most significantly to the attainment of high strength and notch toughness in quenched and tempered alloy steels are usually those that have an adverse effect when such weldments are heat treated after welding.

Postweld heat treatment in the temperature range of 950 to 1200 F may impair the toughness of the weld metal and of the heat-affected zone. The extent of impairment depends on composition, heat treatment temperature, and time at temperature, and for some steels, is greater with slow cooling, as in stress relieving. Furthermore, when welds in high-strength alloy steel are given a postweld heat treatment above about 950 F, intergranular cracking may occur in the grain-coarsened region of the heat-affected zone, usually in the early stage of the stress-relief treatment. Chromium, molybdenum and vanadium contribute to this crack susceptibility. In A517, A542 and A543 steels, such stress-rupture cracking at the toes of welds has been prevented by properly contouring the welds to minimize points of abrupt change and stress concentration, by light peening at the toes of the welds, by buttering the toes of a fillet weld, or by depositing weld metal having elevated-temperature strength significantly lower than that of the heat-affected zone of the steel during the stress-relief treatment.

Suitable and serviceable welded joints in quenched and tempered steels can be ensured only by the use of welding procedures that have been prepared and tested to prove that they can consistently provide sound welds possessing the required service properties. The usual procedure-qualification tests (as in the AWS Code for Welding in Building Construction, or the ASME Boiler and Pressure Vessel Code) are generally sufficient for the majority of applications.

Examples of Practice. Four applications of arc welding of quenched and

tempered high-strength alloy steels are described in Examples 199, 211, 218 and 220 in this article. A summary of these examples, which identifies the welding processes, base metals and filler metals, and preheating and postheating practice, is presented in Table 10.

AISI-SAE Alloy Bar Steels

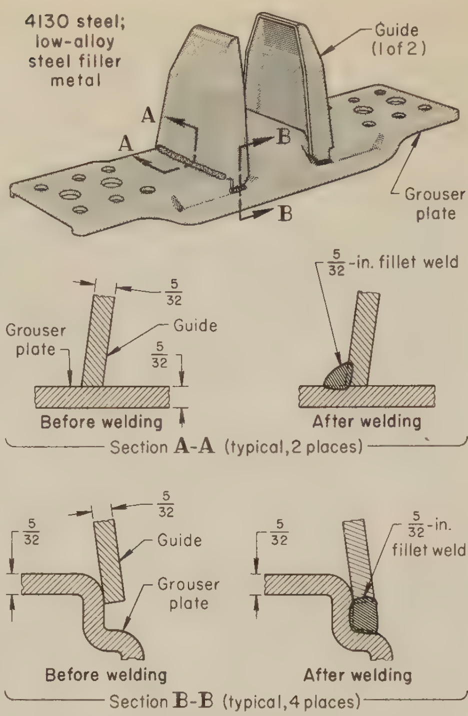
The steels dealt with in this section are the widely used hot rolled and cold finished bar steels, ranging in carbon content from 0.09 to 0.64% and in alloy content (excluding manganese and silicon) from zero (the 13*xx* series) to approximately 4.0% (the 48*xx* series). These steels are capable of developing maximum as-quenched hardness from approximately Rockwell C 36 to 65. The hardenability ranges from only slightly higher than that of plain carbon steels to that characterized by steels such as 4140H and 4340H (see Fig. 1). The weldability of these steels generally decreases as hardenability increases.

Table 19 lists 18 representative AISI alloy steels within the range of 0.18 to 0.53% carbon content. Alloy steels containing more than 0.53% carbon are seldom welded. Table 19 includes the alloy steels that are most frequently selected for weldments, with 4130 being the most widely used, because it combines high strength in the heat treated condition with acceptable weldability. The suitability of 4130 for many welding applications is indicated by the fact that it was used for at least one of the components of the weldments described in five of the 13 examples in this article that discuss the welding of alloy bar steels. Steels 4140 and 4340 are also used extensively for weldments, but are more difficult to weld without cracking than 4130 steel is.

Filler Metals (Electrodes). Table 19 lists covered electrodes commonly used for producing high-strength welds in 18 alloy steels by shielded metal-arc welding. In Table 19, E7018 (or E7018-A1, carbon-molybdenum) is shown as the choice for six steels. This electrode, a low-hydrogen, iron-powder type, provides an as-welded joint having minimum tensile strength of 70,000 psi. The minimum tensile strength, in thousands of pounds per square inch, of deposited weld metal is denoted by the first two of four, or the first three of five, digits in each electrode designation. For single-pass welds, the strength specified for the deposited weld metal usually increases as the carbon content of the base metal increases.

All of the electrodes listed in Table 19 are of the low-hydrogen type. Low-hydrogen electrodes are almost always recommended for welding alloy steels, to help prevent cracking.

Unless a joint of maximum strength is required, a lower-strength filler metal can often be used and the susceptibility to cracking thereby decreased. For instance, the electrode shown in Table 19 as commonly used for welding 4130 steel is E10016-D2, but if a lower as-welded strength is acceptable, E7018-A1 can be used. In Examples 198 and 208, E7018 was used in welding 4140 and 5145, but in both of these applications the alloy steels were welded to lower-strength steels.



Conditions for Flux-Cored Arc Welding

Joint types	T, corner
Weld type	Fillet
Welding position	Flat
Number of passes	One
Preheat	None
Postweld heat treatment	Quench and temper to Rockwell C 35 to 40
Fixture	Special, for 45° tilting
Shielding gas	Carbon dioxide, at 35 to 40 cfh
Electrode wire	5/64-in. diam(a)
Electrode holder	500 amp
Power supply	500-amp constant-voltage rectifier
Current	250 to 300 amp, dcrp
Voltage	23 to 26 v

(a) Specially formulated to produce a deposit with a composition of 0.15 C, 1.50 to 1.70 Mn, 0.50 to 0.60 Si, 0.60 to 0.80 Cr, 0.60 to 0.90 Mo.

Fig. 11. Military-tank weldment for which flux-cored electrode wire of special composition was used to meet strength requirements (Example 200)

Flux-cored electrodes are selected largely on the basis of the mechanical properties of the deposited weld metal. Because susceptibility to cracking increases as strength increases, the lower-strength filler metals should be used if the lower strength is acceptable. This kind of substitution is illustrated by Example 213, in which a lower-strength filler metal, similar to the low-hydrogen E7018, was used for joining 8620 to A36. In this application, a weld deposit with a minimum tensile strength of 70,000 psi (corresponding to the tensile strength of A36) was sufficient. For joining 4130 to 4130 in the application described in Example 200, a weld of acceptable strength was made with an electrode wire that resulted in an as-welded composition of 0.15 C, 1.60 Mn, 0.55 Si, 0.70 Cr and 0.75 Mo.

Table 19. Covered Electrodes Commonly Used for Shielded Metal-Arc Welding of Alloy Bar Steels

Steel	Electrode	Steel	Electrode
1330	E7018	4320	E7018-A1
1340	E10016-D2	4340	E12018-M
4023	E7018-A1	4620	E8016-C1
4028	E7018-A1	4640	E12018-M
4047	E10016-D2	5120	E8016-B2
4118	E7018-A1	5145	E9016-B3
4130	E10016-D2	8620	E7018-A1
4140	E12018-M	8630	E11018-M
4150	E12018-M	8640	E12018-M

Electrode wires designated as electrodes 1, 2 and 3 in Table 7 are used for welding the alloy bar steels. The one selected depends on strength requirements. Electrode No. 3 in Table 7 has been used for welding the higher-carbon steels such as 4140, 4340 and 8640 in applications where high weld strength was a requirement.

The mechanical properties of weld deposits given in Table 7 are for metal in the as-welded condition, before postheating; postweld stress relieving can result in yield and tensile strengths below the values shown, although it will frequently increase the ductility.

One advantage of the flux-cored arc process for welding alloy steels is that cored electrode wires of special composition are more readily obtained than are solid wires of special composition, as described in the following example.

Example 200. Use of Flux-Cored Wire of Special Composition To Meet Mechanical-Property Requirements in Welding 4130 Steel (Fig. 11)

In order to use the flux-cored arc welding process to achieve needed production rates, a special composition of flux-cored wire was produced to meet the mechanical properties specified for the weldment shown in Fig. 11. The weldment, part of a military tank, consisted of two guides mounted saddle-fashion on, and fillet welded to, a grouser plate.

The flux-cored electrode wire could be obtained more quickly and economically than a solid wire of special composition for gas metal-arc welding. The flux-cored wire, which was supplied in 50-lb coils, was formulated to deposit weld metal having the composition given in the table with Fig. 11. Smooth weld beads were obtained, the welds were sound, with satisfactory strength, ductility and toughness, and weld spatter was minimal.

As shown in Fig. 11, each guide required two fillet welds, which were made by the automatic method, after the assembly had been tack welded. A special fixture was used to tilt the assembly at 45° to permit welding the backs of the guides in the flat position — first one guide, then the other. The fixture was then rotated to deposit the short welds at the feet of the guides. Weld starts and stops were controlled by limit switches. After welding, the assembly was quenched and tempered to a hardness of Rockwell C 35 to 40.

Additional welding details are given in the table that accompanies Fig. 11.

Like those for flux-cored arc welding, alloy steel electrode wires for gas metal-arc welding have not been standardized. When only moderate strength is required, low-carbon steel electrodes are used (see Examples 214 and 217). When strength requirements are higher, alloy steel electrode wires that provide weld metal to match or nearly match the alloy composition of the base metal are most commonly used (Example 215). High-quality electrode wires of virtually any composition are obtainable for gas metal-arc welding. The carbon content of the electrode wire should generally be lower than that of the base metal, to minimize the formation of hard, brittle transformation products that may cause cracking. For instance, in welding 4130 steel, an electrode containing no more than about 0.20% carbon should be used. If the completed weldment is to be heat

treated (for example, quenched and tempered), a filler metal of similar composition should be used.

Table 8 lists designations and compositions of mild steel electrodes for submerged-arc welding. These electrodes are intended primarily for welding mild steel, but they are also used for alloy steel weldments, as illustrated by Examples 223 and 224. In Example 223, the low-manganese EL12 electrode was used for welding 4130 to 4140; in Example 224, the flux-electrode combination F71-EH14 (high-manganese electrode) was used to weld 4130 to 1025.

Filler metal that matches the base metal in alloy content is usually recommended when a submerged-arc weld of maximum strength is required, but the carbon content of the filler metal should be lower than (often no more than half) that of the base metal, as previously described for the gas metal-arc welding process.

In many applications, alloy steels are welded by the gas tungsten-arc process without filler metal. Selection of filler metal (if used) for gas tungsten-arc welding generally presents fewer problems than for the other arc welding processes. In gas tungsten-arc welding, the filler metal is fed into the weld puddle, not into the arc, which is an advantage because it results in more efficient alloy transfer and thus enables more accurate control over the composition of the weld metal. It is generally recommended that filler metals match the base-metal composition, but higher alloys are selected whenever special properties are needed (in Example 225, Hastelloy W was selected as the filler metal for welding 4340 to 4140 by the gas tungsten-arc process).

Preheating. Suggested preheating and interpass temperatures for 18 alloy bar steels are given in Table 20. These suggested temperatures are based on the use of low-hydrogen electrodes. The preheating temperature increases with the carbon content or hardenability of the steel and with the section thickness. If local preheating is used, the extent of preheating should be fully through the joint and for about 3 in. (or a distance equal to base-metal thickness, whichever is smaller) on either side of the joint.

The preheating temperatures suggested in Table 20 are intended as a guide. They do not take account of the interrelated variables. The interrelation of variables sometimes eliminates or minimizes the need for preheating alloy steels that have relatively low hardenability. The carbon-equivalent formula given on page 200 in this article can be used as a guide.

Alloy steels can be welded successfully without preheating, as is substantiated by the fact that preheating was used in only three of the 13 examples in this article that deal with welding of alloy bar steels (see Table 10). In the applications where no preheating was used, an examination of the example in detail reveals at least one reason for its omission. For instance, in Example 198 the welding technique was modified in order to eliminate cracking and the need for preheating. Often, preheating of the entire weldment is impractical, so that if preheating is needed, it must be done locally. Preheating is costly in all applications.

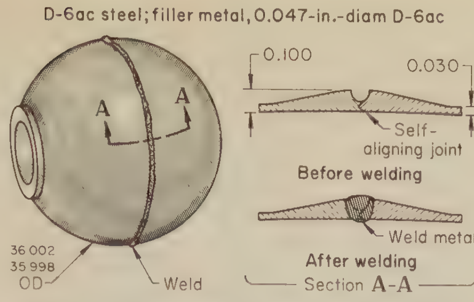


Fig. 12. Rocket-motor case gas tungsten-arc welded from two spun hemispheres that had been quenched and tempered before welding (Example 201)

Postheating. Generally, postheating is specified for the steels in Table 20 that contain more than about 0.35% carbon, although there are many exceptions (see Table 10). One practice for welding these higher-carbon steels is to use a preheating and interpass temperature that is just above the M_s temperature for the particular steel, and then to hold at this temperature for at least 1 hr. The objective is to permit the weld metal to transform from austenite to softer microconstituents, rather than to martensite, and thereby to minimize the possibility of cracking without undue sacrifice in mechanical properties.

Stress relieving is usually required and may be mandatory for weldments of all of the steels listed in Table 20, if the weldment is to be put into service without being quenched and tempered, but if a weldment is to be quenched and tempered, stress relieving can usually be omitted. Dimensional stability and notch toughness usually determine the need for stress relief.

In preferred practice, the heating for stress relieving, or for the austenitizing that precedes quenching, should begin before the weldment cools to a temperature below the interpass temperature. However, this procedure is not always practical, and in some applications the weldment remains at room temperature for an indefinite time before being stress relieved. Drafts of air impinging on the weldment while it is cooling to room temperature should be avoided.

For complete, or almost complete, stress relief, the weldment should be heated to 1100 to 1250 F and held for one hour per inch of maximum base-metal thickness. If heating in this range is impractical, partial stress relief can be attained by heating at a lower temperature (for instance, 900 F) for several hours.

Examples of Practice. Thirteen examples in this article describe applications of arc welding of alloy bar steels; Table 10 identifies the welding processes, base metals and filler metals, and preheating and postheating practice (when such practice was employed).

Table 20. Suggested Preheat and Interpass Temperatures for Various Alloy Bar Steels

8640	350-450	400-500	450-550

High-Strength AMS Alloy Steels Containing 0.30 to 0.50% Carbon

The steels of this group have carbon content in the range of 0.30 to 0.50%, and total content of chromium, nickel, molybdenum and vanadium between approximately 2.0 and 7.0%. These alloy steels have high hardenability and, depending primarily on their carbon content, may be capable of developing high hardness and may prove difficult to weld without cracking.

Representative compositions are given in Table 21. Although some compositions are closely similar to those of the AISI-SAE alloy bar steels (4340, for example), they are always purchased to AMS (Aerospace Material Specifications) requirements, and the principal field of application for these steels is in the aerospace industry. They are sometimes welded in the quenched and tempered condition; generally, however, welding is done before final heat treatment. In nearly all applications, a postweld heat treatment is required.

The next example describes production of a rocket-motor case by welding together two hemispheres of D-6ac steel in the heat treated condition.

Example 201. Welding High-Strength Alloy Steel Rocket-Motor Cases in the Heat Treated Condition (Fig. 12)

Special design and preheat and postheat techniques made it possible to weld D-6ac rocket-motor cases in the quenched and tempered, rather than in the annealed, condition. As shown in Fig. 12, the motor cases consisted of two 36-in.-diam, 0.030-in.-wall spun hemispheres welded at the equator. Heat treated D-6ac was used in this application to provide a minimum yield strength of 200,000 psi. Manufacturing the motor cases by welding before quenching and tempering would have been difficult, if not impossible, because of the need to maintain a ±0.002-in. tolerance on the diameter.

Wall thickness at the joint was increased to 0.100 in. to compensate for expected decrease in strength due to the welding heat. Because a slight mismatch at the joint could cause loss of tolerance and reduce

Table 21. Nominal Compositions of Some High-Strength AMS Alloy Steels Containing 0.30 to 0.50% Carbon

AMS No.	Similar to	C	Mn	Si	Cr	Ni	Mo	V
6302, 6385	17-22A(S)	0.30	0.55	0.65	1.25	...	0.50	0.25

6431	D-6ac	0.47	0.75	0.22	1.05	0.55	1.00	0.11

strength, a self-aligning type of joint was used (see Fig. 12).

To avoid the development of a brittle heat-affected zone, the joint was locally preheated to 650 F, and held at that temperature during welding and for 1 hr thereafter. Then the welded joint only was locally stress relieved at 900 F for 1 hr, using radiant heating equipment. The resulting structure was strong and ductile enough to meet specification requirements.

Equipment consisted of a gas tungsten-arc stationary head with automatic voltage control. The workpiece was rotated beneath the arc on a circumferential fixture supplied with electrically heated hold-down and backup tools made of stainless steel. Welding conditions were generally the same as in Example 227 (see table, Fig. 35).

Welding Processes. Shielded metal-arc and gas metal-arc welding have been used successfully for joining these steels (Example 209 describes an application of shielded metal-arc welding), but gas tungsten-arc welding is generally preferred and more often used, because it provides more precise control. Plasma-arc welding and electron beam welding have also been used successfully (see Table 7 on page 143 in the article on Plasma-Arc Welding for typical conditions for plasma-arc welding of D-6ac steel, and the article on Electron Beam Welding, which begins on page 519).

Susceptibility to Cracking. With the exception of some high-carbon tool steels, these AMS alloy steels, as a group, are the most susceptible of all steels to the various types of weld cracking. Of the steels for which compositions are given in Table 21, AMS 6431 (well-known as D-6ac) is the most susceptible to cracking, because it has the highest carbon content. However, the demand for AMS 6431 for components such as motor cases, missile tanks and other aerospace hardware has resulted in the development of welding techniques that produce acceptable results.

Gas Tungsten-Arc Welding of D-6ac. The welding and heat treating procedures described in the remainder of this section (including Examples 202 and 203) are from the article "Weldability of Low-Alloy Steels Heat Treated After Welding", by D. K. Hanink and N. F. Bratkovich, *Metals Engineering Quarterly*, Feb 1969, p 18-27.

Base Metal and Preweld Heat Treatment. The earliest high-strength rocket-motor cases and missile tanks were fabricated from alloy steels such as 4130 and 4340. Because of low fracture toughness, resulting from attempting to achieve yield strengths above 200,000 psi, these steels proved unsatisfactory. To obtain the required high yield strength, the quenched steels had to be tempered in the range of 500 to 700 F. In addition to the low fracture toughness, these low tempering temperatures did not allow temper straightening of large pressure vessels, which distort during welding and heat treating.

These difficulties led to the development and use of secondary-hardening, low-alloy martensitic steels, such as D-6ac, that can be tempered in the range of 1000 to 1125 F to provide a combination of high yield strength and good fracture toughness.

Steel D-6ac, procured to AMS 6431 (vacuum melted from consumable electrodes), is used for pressure-vessel applications utilizing gas tungsten-arc welding. Most of these pressure vessels are tempered at 1000 F. Large thick-wall vessels, however, require slightly higher tempering temperatures (in the range of 1000 to 1125 F).

Depending on the specific application, the D-6ac steel to be welded was obtained as machined rolled rings or as cylinders spun from premachined forged rings. Heat treatment for original forgings was a normalizing treatment at 1750 F, air cooling, then tempering at 1300 F for 4 hr and air cooling. Stress relieving at 1300 F for 1 hr sometimes followed rough machining. A heat treatment at 1650 F plus a 1300 F temper was used after spinning and before final sizing. The sized cylinders were trimmed and the ends were machined and abrasive blast cleaned for welding.

Filler Metal. Criticality in the choice of filler metal for good fracture toughness in D-6ac weldments was minimized when the base metal was tempered at temperatures higher than 1000 F. Because cracking of weld deposits and low ductility of the welded joints resulted when the filler metal matched the composition of the D-6ac base metal, modified low-alloy filler metal with carbon content somewhat lower than that of the base metal was used. Correct joint preparation and control of heat input in welding were important in maintaining consistent dilution of weld metal by base metal.

For joint thicknesses of about 0.200 in., a low-carbon, 2¼% chromium alloy steel filler metal was used to produce a weld in which considerable base-metal dilution was achieved. For joint thicknesses of about 0.900 in., a higher-carbon, lower-alloy filler metal was used, because there was less dilution in the larger welds. Carbon and alloy contents of the filler metal were adjusted to obtain satisfactory response to heat treatment. The compositions of the two filler metals are given in Table 22.

Welding Procedure. When welding a medium-carbon, low-alloy steel of this type, good results were obtained when preweld and postweld heat treatments were employed to control weld cooling rates so as to produce mixed structures of bainite and tempered martensite in the weld zone and to prevent the formation of primary martensite. Such structures could better withstand subsequent processing and final heat treatment to produce high weld joint efficiency and high notch toughness.

Examples 202 and 203. Procedures for Welding D-6ac Steel 0.200 and 0.900 In. Thick (Tables 23 and 24)

The details of a procedure for girth welding of a 0.200-in.-thick pressure vessel (Example 202) are shown and described in Table 23. The girth welds were made in two passes by automatic gas tungsten-arc welding. To maintain the required preheat and interpass temperatures, resistance heating elements were incorporated in backup supporting ID and OD rings. Appropriate grooves in the backup support rings provided for adequate shielding of the weld joint by inert gas. On completion of the welding operation, induction heating was used for the postweld stress relieving.

The detailed welding procedure for joining 0.900-in.-thick D-6ac steel (Example 203) is given in Table 24. Considerably greater restraint was encountered in the thick-wall pressure vessel, and eight passes were required in welding the double-U joint. The automatic welding machines that were used incorporated a closed-circuit TV system to monitor deposition of the ID weld passes. A combination of local induction heating and furnace heat treatment was essential in postweld stress relief.

The welding, postweld heat treatment, and semifinishing of weld face and root were sequenced to accommodate nondestructive testing. If weld repair was necessary, the procedures were similar to those used for the production operation, but manual gas tungsten-arc welding was used for minor weld repairs.

Final Heat Treatment. Before final heat treatment, the pressure-vessel weldments were thoroughly inspected for soundness and the existence of any

undesirable sharp weld undercut that could be a source from which a quenching crack might start during the hardening operation. The final heat treatment was:

1 **Austenitize.** 1650 F for 1 hr, hot salt quench at 400 F for 10 min, air cool.
2 **First Temper.** 400 F for 1 hr, air cool.
3 **Final Temper.** Thin-wall (0.200-in.) vessels: 1000 F for 4 hr, air cool. Thick-wall (0.900-in.) vessels: 1125 F for 4 hr, air cool.

In the final tempering operation, ring fixtures for rounding and straightening were used to hold dimensions within the required limits. Control samples, selectively positioned on the vessel, were used to measure response to heat treatment and mechanical properties.

The weldment (weld area and adjacent base metal) was thoroughly inspected after final heat treatment, prior to final machining and hydrostatic testing.

Examples of Practice. Table 10 summarizes six examples in this article that describe applications of arc welding of high-strength AMS alloy steels. In addition, Example 205 (next page) describes fabrication of rocket-motor cases from H11 tool steel, a 5% Cr, 1.5% Mo steel widely used in aerospace structural applications (AMS 6437).

Heat-Resisting Alloy Steels

The ten heat-resisting steels of which the nominal compositions are given in Table 25 are typical of the alloy steels used for components of boilers, petroleum-refining equipment, and other products that operate at elevated temperatures up to about 1050 F. They have a total alloy content (chromium, molybdenum and vanadium) in the range of 0.5 to 10%.

The six grades of ASTM A335 steel listed in Table 25 are used for seamless alloy steel pipe. The alloy content of the six steels varies from 0.5 to 10%, and with the exception of grade P1 their carbon content is 0.15% max. They are specified to be in a formable condition as purchased, either fully annealed or, more often, quenched and tempered, or normalized and tempered (they are tempered at about 1250 F).

A193, grade B16, is designed for high-temperature bolting applications. It is available as bars or forgings in various conditions of heat treatment.

AISI 501 and 502 have the same composition except for carbon content. They are available in various product forms and several conditions of heat treatment and are used in a wide variety of elevated-temperature applications such as oil-refinery equipment.

H11 is primarily a hot work tool and die steel but it is also used in structural applications that require high strength at elevated temperature.

Welding Processes. Of the five examples in this article that deal with arc welding of heat-resisting alloy steels (see Table 10 for a directory and summary), two involve the use of shielded metal-arc welding, in two others the process was gas metal-arc welding, and in one the flux-cored arc process was used. In addition to these three arc welding processes, submerged-arc welding also has been used successfully and has the same capabilities and limitations for heat-resisting alloy steels as for other types of alloy steels.

For the pipe and bolt grades, gas tungsten-arc welding is seldom used for making the entire weld, although it is sometimes used for making the root pass in the welding of pipe sections. This can be done with or without filler metal; consumable inserts are often used (see page 128 in Gas Tungsten-Arc Welding). The filler passes are then made by either the shielded metal-arc or the gas metal-arc process.

The gas tungsten-arc process is often used for welding H11, 501 and 502 when close control of the weld composition is required.

The two examples that follow compare alternative welding processes used for welding of heat-resisting alloy steels. The first example illustrates why flux-cored arc welding was preferred to shielded metal-arc welding for repair of alloy steel castings conforming to ASTM A217, grade WC9. The second example describes an application in which welding time was reduced by as much as 87% by a change from the automatic gas tungsten-arc to the automatic gas metal-arc process for welding of H11 steel motor cases.

Example 204. Cost of Repairing Heat-Resisting Alloy Castings by Shielded Metal-Arc vs Flux-Cored Arc Welding (Table 26)

The use of shielded metal-arc welding to repair defects in large heat-resisting alloy steel castings for pressure service was found to be slow and costly for the large volume of work involved. Some of the cavities that had to be filled required 60 lb of weld metal. Of the several available alternative processes, flux-cored arc welding with auxiliary gas (carbon dioxide) shielding was favored.

Welding costs for shielded metal-arc welding were known. Therefore, a cost study was made of the flux-cored arc process for repairing defects in alloy steel castings conforming to ASTM A217, grade WC9 (0.18% C, 2.5% Cr, 1.0% Mo). A typical casting measured 4 by 6 by 8 ft over-all, weighed approximately 14,000 lb and was valued at about $18,000. The welds were made in accordance with the repair requirements of the specification, which applied equally to all welding processes.

Operations such as preparing the defect cavity for welding, preheating, control of interpass temperature, postweld stress relief, qualification details, inspection and testing were the same for both processes. Reference radiographs of ASTM E71, class 3, were used as the acceptance criteria for the control of weld quality. It was possible, therefore, to compare costs strictly on the basis of the welding operation.

Welding conditions for both processes are given in Table 26. Control of preheat and interpass temperatures, and the use of postweld stress relief, were important in helping to minimize cracking and dimensional instability in welding this alloy steel. The flux-cored electrode used for this application was supplied as being equivalent to the E9018-B3 iron-powder, low-hydrogen electrode used for shielded metal-arc welding. Weld deposits having a nominal composition of 0.12% C, 2.5% Cr and 1.0% Mo approximately matched the composition of the base metal (0.18% C, 2.5% Cr, 1.0% Mo). The 90,000-psi minimum tensile strength of the weld metal was considerably higher than the minimum tensile

Table 25. Nominal Compositions of Typical Wrought Heat-Resisting Alloy Steels

Wire-feed rate	20 to 42 in. per minute	Current-regulated feed
Power supply	750-amp transformer	750-amp constant-voltage rectifier
Current	70 to 135 amp, ac(d)	460 to 470 amp, dcrp
Voltage	10 to 14 v(e)	30.4 to 30.6 v
Arc stabilization	High frequency	None
Travel speed	8 to 11 in. per minute (avg)	13 in. per minute (avg)
Welding time:		
Longitudinal welds	132 min (for 9/16-in. thickness)	11 min (for all three thicknesses)
Two circumferential welds	522 min (for 9/16-in. thickness)	76 min (for all three thicknesses)
Total welding time(f)	6.8 to 11.4 hr(g)	1.45 hr (for all three thicknesses)

(a) Depending on base-metal thickness, as shown in illustration; root pass for each thickness was made without filler metal. (b) Except for root passes, which were made without filler metal. (c) No trailing shield was used for gas tungsten-arc welding, and with a ceramic-insulated backing bar, no backing gas was needed; no backing gas was required for gas metal-arc welding. Before welding, electrode holder and joint were purged with shielding gas for 15 to 30 sec, at a flow of 15 cu ft per hour. (d) First pass, 70 amp; second pass, 95 amp; third pass, 110 amp; fourth pass (7/16-in. thickness), 135 amp; fourth and fifth passes (9/16-in. thickness), 135 amp. (e) First pass, 10.5 volts; remaining passes, 10 to 14 volts. (f) Includes one 10-ft longitudinal weld and two 10-ft-diam circumferential welds. (g) For thicknesses of 3/8 to 9/16 in.

Fig. 13. Designs of longitudinal and circumferential joints in 10-ft-diam, 10-ft-long rocket-motor cases for which process was changed from multiple-pass gas tungsten-arc welding to single-pass gas metal-arc welding, effecting a 79 to 87% saving in welding time (Example 205)

strength of the base metal (70,000 psi), established by ASTM A217.

The cost comparison is summarized in Table 26, in terms of cost per pound of weld deposit. Because a pound of weld metal deposited by flux-cored arc welding cost less than half that of weld metal deposited by the shielded metal-arc process, flux-cored arc welding was adopted by the foundry for all possible casting repairs.

Example 205. Change From Gas Tungsten-Arc to Gas Metal-Arc Welding of H11 Steel Rocket-Motor Cases To Reduce Welding Time (Fig. 13)

Automatic gas tungsten-arc welding of H11 steel rocket-motor cases produced high-quality joints, but the process proved too costly because of the long welding time it required. As a result of extensive laboratory tests, a procedure for automatic gas metal-arc welding was developed which reduced welding time by approximately 79% for 3/8-in.-thick plates to 87% for 9/16-in.-thick plates.

The two welding procedures were compared on the basis of welding a longitudinal joint and two circumferential joints of a cylinder 10 ft in diameter and 10 ft long, in three thicknesses: 3/8, 7/16 and 9/16 in. Because H11 steel is air-hardening, precise temperature control during welding was essential.

Joint configurations and welding conditions for the two processes are given in Fig. 13 and the companion table. Automatic equipment and tooling were essentially the same for both processes. Longitudinal welds were made on a conventional seam welder, and girth welds were made in a fixtured positioner.

As shown in Fig. 13, the gas tungsten-arc welds were made in three passes for the 3/8-in. thickness, four passes for the 7/16-in., and five for the 9/16-in. For all three thicknesses, the root pass was made without filler metal. Average total welding time for the three gas tungsten-arc welded joints ranged from 6.8 hr for the 3/8-in. thickness to 11.4 hr for the 9/16-in. thickness.

The gas metal-arc welds in all three thicknesses were deposited in single passes, which enabled three joints to be welded in an average total welding time of 1.45 hr — the time needed to adjust the equipment for welding and to deposit the weld.

As shown in Fig. 13, joints were designed specifically to suit the penetration characteristics of the process used, with the root face of the joint for gas metal-arc welding being the deeper of the two. The greater depth was needed to prevent burn-through by the higher-amperage arc used for the single-pass weld.

An important feature of both welding processes was the use of low-carbon steel backing bars with a ceramic-coated groove against which the weld root surface was deposited to ensure full penetration. The ceramic coating, which prevented welding to the backing bar, covered the 0.060 to 0.065-in.-deep groove, as shown in Fig. 13, and the backing bar eliminated the need for a backing gas to shield the root surface.

Several ceramic materials for the backing bar were investigated, including aluminum oxide, magnesium zirconate, spinel, and zirconia. All but zirconia could be applied by flame spraying without excessive porosity. It was found that a coating thickness of 0.010 to 0.015 in. gave the required protection. The major difficulty was to obtain a uniformly dense coating that would resist burn-through and prevent welding to the backing bar. Because the ceramics were hygroscopic, the density of the coating was important. Moisture pickup by the more porous coatings caused porosity in the root-pass weld bead. Accordingly, the backing bars were heated to 250 F by built-in resistance heaters to dry the surface before welding and prevent moisture pickup. A coating of required density was obtained with plasma-arc-sprayed zirconia; two or more welds could be made before the backing bar had to be recoated.

Variables of the gas metal-arc process that were evaluated included diameter of the electrode wire, electrical requirements (current and voltage), travel speed, and distance from the contact tip to the work. Arc stability was maintained by holding the tip-to-work distance at 5/8 to 3/4 in. Since voltage was constant, arc length was automatically controlled. The arc condition, as well as the appearance of the weld puddle, provided a constant visual check of welding uniformity. Shielding-gas flow at the electrode holder was most efficient at a cup-to-work distance of 1/2 in.

Single-pass welds made with a 1/16-in.-diam electrode did not give complete penetration on the 3/8-in.-thick plate when used near maximum current density. When higher current was used, penetration was achieved, but it also resulted in erratic arc action and irregular weld shape. Satisfactory results were obtained by using 3/32-in.-diam electrodes. However, settings for current and travel speed had to be confined to a relatively narrow range for optimum weld crown height, penetration and shape.

As shown in Fig. 13, joint design for gas metal-arc welding was the same for the 3/8-in. and 7/16-in. thicknesses. Tests on single-pass welds in plates from 1/2 to 3/4 in. thick showed that the electrode could not fill the V and also give complete penetration. Thus, for the 9/16-in.-thick plate, the V was narrowed from 90° (45° bevel) to 76° (38° bevel), but the root-face width remained the same (45 to 50% of base-metal thickness).

Hardness readings taken across sections of the weld (after stress relieving but before tempering) indicated the following typical ranges: base metal, Rockwell C 5.5 to 13.5; heat-affected zone, Rockwell C 37 to 57.5; weld zone, Rockwell C 55 to 56. The difficulty of getting the vessel to the fixture for stress relief after welding without excessive cooling was eliminated by heating the backing bars to 650 F initially and reheating them by resistance whenever, during cooling, the temperature approached 300 F.

Temperature was controlled by thermocouples attached to the weldment in the area of the weld zone. Resistance heating elements were built into the fixturing of the shells and domes for preheating. Domes and shells were removed from the welding fixtures while at preheat temperatures and placed on stress-relieving fixtures, which were also heated by resistance.

Filler metals (electrodes) for welding heat-resisting alloy steels by the shielded metal-arc and gas metal-arc processes are presented in Table 27. Filler metals other than those shown have also produced satisfactory welds. The choice depends largely on specific joint requirements. The filler metals shown in the table will produce welds of 100% joint efficiency. Regardless of composition, all electrodes should be of the low-hydrogen type.

Although flux-cored arc welding is not used extensively for welding heat-resisting alloy steels, it is used at times (see Example 204 and Table 26).

Preheating. Preheating and interpass temperatures for heat-resisting alloy steels are determined by the composition and section thickness of the steel, as shown in Table 28. These temperatures are for average welding conditions, and are minimums. In general, maximum preheat and interpass temperatures should not exceed those listed in Table 28 by more than 150 F.

Preheating is generally preferred practice, and for compliance with specific codes it may be mandatory. Sometimes, however, as in Example 216, the steel can be welded without being preheated, because the welding conditions are more favorable than the average conditions on which the suggested temperatures in Table 28 are based. Conversely, when the conditions are less favorable than average, as with single-pass welds or welds made under severe restraint, preheating temperatures up to 150 F higher than those shown in Table 28 may be required.

Postweld Heat Treating. The need for postweld heat treating varies considerably for the steels listed in Table 25. The low-carbon steels (all grades of ASTM A335, and AISI 502) do not always require postweld heat treating. In most applications, these steels are postweld heat treated to develop specific properties (such as tensile and impact strength) without relation to the prior welding operation. After welding, the weldment should not be allowed to cool appreciably before being heated to the postweld heat treating temperature.

A 501 steel that contains more than 0.18% carbon should not be allowed to cool from the preheating and interpass temperature after welding until the weldment can be stress relieved at 1125 to 1250 F.

The high-temperature bolting steel (ASTM A193, grade B16) has high hardenability (almost as high as 4340) and is extremely susceptible to cracking. Weldments made from this steel should be kept at the preheat temperature during and after welding until they can be heated to the stress-relieving temperature of 1125 to 1250 F.

Among the steels listed in Table 25, H11 is the most susceptible to weld cracking. This steel is air-hardening and is almost certain to crack if allowed to cool in air directly from welding. Best practice for welding H11 is described in Example 205; the weldment is not permitted to cool before the final heat treatment — usually austenitizing, quenching and tempering.

Heat input and welding techniques discussed on page 213 in the section on High-Strength Alloy Steels Containing up to 0.25% Carbon (Quenched and Tempered) generally apply also for welding the heat-resisting alloy steels. It is especially important to use multiple passes and small stringer-type beads and if a weaving technique must be used, the width of weave should not exceed ⅜ in. or 2½ times the diameter of the electrode wire, whichever is less.

Tool Steels

The compositions of tool steels range from that of the plain low-carbon mold steel P1 to that of the high-alloy high speed steels, some of which have a total alloy content that exceeds 25%. It follows that their weldability also varies over a broad range.

Steels such as P1, like other plain low-carbon steels, can be welded without special procedures such as preheating and postheating. However, most tool steels have a high carbon content (some as high as 2.50%) and a relatively high content of alloying elements such as manganese, silicon, chromium, molybdenum, tungsten, vanadium and cobalt. Therefore, most tool steels require the use of carefully controlled preheating and postheating, and in most applications a considerable amount of welder skill is required.

Although tool steels, with a few exceptions such as the low-carbon mold steels, are relatively difficult to weld, many are arc welded for one of the following purposes:

1 Assembly of components into a tool
2 Fabrication of a composite tool by depositing an overlay of tool steel weld metal on specific areas of a carbon steel or a less highly alloyed steel (a shear blade, for example)
3 Rebuilding of worn surfaces and edges
4 Alteration of a tool or die to meet a change in design of the product being manufactured by use of the tool
5 Repair of cracked or otherwise damaged tools (see Examples 206 and 207).

For assembly of components (the first item above), the use of a low-cost steel as part of a tool assembly often permits the construction of tooling that is far more economical than if it were made entirely of tool steel. Moreover, this practice often permits use of a tougher steel to provide a backing for the tool steel portion. Purposes covered by items 2 and 3 in the above list represent most of the welding that is done on tool steels and constitute a special type of welding, described in the article on Hard Facing by Arc Welding, beginning on page 152 in this volume. The welding of tool steel described in the present article deals mainly with the repair of metalworking tools (item 5 in the preceding list).

Conditions for Welding. Tool steels (or tools) are preferably welded in the annealed condition, but often this is impractical as well as costly to the extent that any gain made possible by the use of weld repair would be nullified by the cost of annealing.

Tools and dies in the quenched and tempered condition can often be repaired by welding, but in such a case the preheating and postheating treatments for the base metal must not exceed the original tempering temperature. In some applications, therefore, the microstructure of the base metal, in addition to composition, influences the choice of filler metal.

General Guidelines. Most of the rules that apply to the welding of alloy steels apply also to the welding of tool steels, but as the alloy content or carbon content, or both, increase, the importance of adhering to these rules also increases. The following guidelines apply to the arc welding of all grades of tool steel.

1 Always use the smallest-diameter electrode that will do the job.
2 Prepare the surface by machining or grinding. A crack should be gouged out to a U-shape, never to a V-shape, because sharp angles will promote cracking.
3 Grind or machine away all of the existing cracks, and provide at least 1⁄16 in. of excess weld metal for finish grinding.
4 Make sure that all electrodes and base-metal surfaces are clean and dry before welding. Absolute freedom from oil and grease is essential.
5 Insofar as possible, position the work so that weld beads are laid slightly uphill. This aids joint penetration.
6 Never weld any tool steel that is at room temperature; the recommended preheating temperature must be adhered to.
7 Keep heat input to the minimum; use minimum arc voltage and amperage, and reduce amperage for secondary and finishing passes.

Table 27. Suggested Electrodes for Shielded Metal-Arc and Gas Metal-Arc Welding of Heat-Resisting Alloy Steels

Steel	Shielded metal-arc	Gas metal-arc
ASTM A335, grade P1	E7018-A1	E70S-6
grade P12	E8016-B2	E70S-1B
grade P11	E8016-B2	E70S-1B
grade P22	E9015-B3	2.25% Cr wire
grade P7	E505 or E309	ER502 or ER309
grade P9	E505 or E309	ER502 or ER309
ASTM A193, grade B16	E11018-M	E70S-1B
AISI 501	E502	ER502
AISI 502	E502	ER502
H11 tool steel	....	H11 wire(a)

(a) Carbon content should be no higher than that of the base metal and preferably lower; ER502 electrode wire has been successfully used.

Table 28. Preheat and Interpass Temperatures for Wrought Heat-Resisting Alloy Steels

Steel	Preheat and interpass temperature, F, for section thicknesses, in., of: Up to ⅜	⅜ to ¾	¾ to 1½
ASTM A335, grade P1	None(a)	200	200
grade P12	None(a)	200	250
grade P11	None(a)	200	250
grade P22	200	250	300
grade P7	400	500	550
grade P9	500	600	650
ASTM A193, grade B16	400	500	600
AISI 501	350	450	550
AISI 502	None(a)	300	400
H11 tool steel	350(b)	500(b)	600(b)

(a) Assuming that the base metal is near room temperature. If base metal is colder than 50 F, it should be preheated to at least 70 to 100 F. (b) After welding is completed, the weldment should be held at the interpass temperature until reheating for austenitizing begins.

8 Travel slowly and straight, using narrow stringer beads rather than heavy deposits; avoid weaving.
9 Deslag and wire brush thoroughly between passes.
10 Peen lightly immediately after each bead has been deposited. The weld metal must be peened while it is at 700 F or higher; never peen when the weld metal is cold. Peening helps to relieve shrinkage stresses, minimizes distortion, and improves the mechanical properties of the weld.

Welding Processes. Repair of tools by welding is most often done by shielded metal-arc welding. The principal reasons for the use of this process are flexibility in welding position and location, simple equipment that can be quickly moved about, and the wide variety of filler-metal compositions available as covered electrodes.

The other arc welding processes, though, are not precluded. All of them have been used under certain conditions for the welding of tool steels. For instance, submerged-arc welding is often used for repair welding of large tools such as rolls.

The two examples that follow describe techniques for repair welding. The first example deals with repairing of a cracked die by shielded metal-arc welding, and the second describes how defects in a large roll casting were repaired by submerged-arc welding.

Example 206. Repair Welding of a D2 Tool Steel Die (Fig. 14)

The punch-and-draw die shown in Fig. 14 was made from D2 tool steel and was used for blanking and drawing steel shells from low-carbon steel sheet 0.075 in. thick. Improper operating conditions caused the crack, which propagated completely through the sidewall of the die, as shown in Fig. 14. The cracked sidewall was successfully repaired by shielded metal-arc welding, in spite of the difficulty generally encountered in obtaining sound welds in D2 tool steel. [Because of its composition (1.5% C, 12% Cr, 1% Mo), D2 tool steel is air-hardening. In addition to its extremely high hardenability, the microstructure of the steel is characterized by massive alloy carbides. Both of these conditions contribute to its high susceptibility to weld cracking.]

As shown in Fig. 14, the crack was repaired by a partial-penetration weld, rather than by welding the entire crack. The groove for the weld was cut, by grinding, to less than the full depth and length of the crack. During preheating to 800 ± 100 F, a slight excess of heat was applied to the cracked side with an oxyacetylene torch to open the crack so that any particles lodged in the crack could be removed with a piece of music wire. A temperature-indicating crayon for 800 F was used to check preheat temperature, which was maintained during welding.

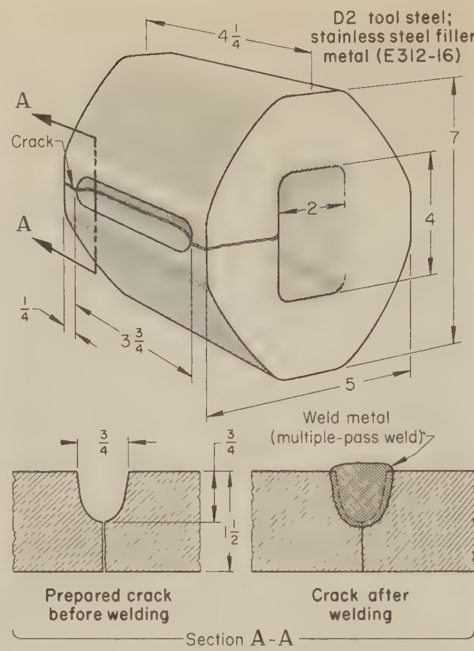
The weld was made with E312-16 stainless steel electrodes. Welding current was kept as low as possible. Short stringer beads, approximately 1 in. long, were deposited with minimum penetration; weaving was carefully avoided. Welding details are given in the table with Fig. 14.

Success of the operation depended greatly on the effective use of peening. Immediately after it was deposited, each weld bead was vigorously peened while it was still hot, using an air-operated or electrically operated gun, with a rounded thin-edge tool equivalent to a dull chisel. Peening the hot weld metal not only helped to produce a more favorable stress pattern (the most common reason for peening a weld), but in this application also helped to prevent a continuous formation of alloy carbides at the grain boundaries.

The crack closed after deposition of each of the first few beads, but reopened after each of the first few peening operations. Peening did not appear to open the crack when the groove was about one-fourth filled, but peening was just as essential from this point on and was done with equal thoroughness for the remaining beads. After welding, the die was allowed to cool slowly to room temperature out of drafts. The die was postheated in a furnace at 800 F and air cooled.

As an alternative, an oxyacetylene torch could be used for both preheating and postheating. When a torch is used, it is important to have a neutral flame with a large tip, and to heat the die slowly and uniformly over the entire surface. When a torch is used for postheating, the die should be buried in lime immediately after welding and postheating, and held there for 12 hr.

Cost savings realized with this repair welding operation were significant. The welding required approximately 8 man-hr and $5 for material, compared with 50 man-hr and $50 for material for a new die. Die repairs by welding in one shop that used techniques similar to those described above were 98% successful.



Conditions for Shielded Metal-Arc Welding

Joint type	Butt
Weld type	Partial-penetration U groove
Welding position	Flat
Preheat	800 ± 100 F
Postheat	800 F(a)
Electrode wire	⅛-in.-diam E312-16
Power supply	300-amp rectifier
Current	150 to 200 amp, dcrp
Hot peening	Required; applied to each bead

(a) For furnace heating, 800 F for 2 hr. For torch heating, after heating to 800 F, bury in lime for 12 hr.

Fig. 14. Punch-and-draw die that cracked in service and was repaired by shielded metal-arc welding (Example 206)

Example 207. Weld Repair of Casting Tears in a High-Carbon Alloy Steel Roll (Fig. 15)

The large cast alloy steel mill roll illustrated in Fig. 15 was produced to the following composition: 1.0 C, 0.9 Mn, 0.5 Si, 0.038 S, 0.038 P, 1.0 Cr, 0.5 Ni and 0.5 Mo. During rough machining of the roll neck to within ⅛ in. of finished size, a number of short discontinuous casting tears or cracks appeared. The cracks were completely removed by cutting a circumferential groove of the size shown in section A-A in Fig. 15; absence of the defects was confirmed by dye-penetrant inspection. The defective area was then repaired by automatic submerged-arc welding.

Previous repair welding experience had shown that local preheating was ineffective because of the heat sink effect of the large mass. Therefore, after machining and degreasing of the groove, the roll casting was heated slowly to 750 F in a furnace over a period of 27 hr (1 hr per inch of body radius). When the casting was removed from the furnace it was completely covered with asbestos cloth, except for the area to be welded, and was positioned in a lathe for rotation in the horizontal position. The lathe was equipped with an automatic stepping carriage on which the submerged-arc welding head was mounted. A gas burner was placed under the roll for use if the interpass temperature dropped below 700 F, but this did not occur and welding was completed without the need for additional heat.

The electrode was selected for good color match and toughness, and to provide a deposit that would be equal in hardness to that of the base metal. A tubular electrode was used, consisting of a low-carbon steel sheath and a core of neutral flux and alloying elements. Typical composition of as-deposited weld metal was 0.10 C, 1.35 Mn, 0.75 Si, 2.0 Cr and 1.0 Mo.

The roll was submerged-arc welded under the conditions tabulated with Fig. 15. These conditions had been shown by earlier tests to provide the most desirable bead shape with maximum deposit thickness and minimum deposit dilution. There was some carbon pickup that caused increased hardness at the bond line, but the condition was acceptable. The weld metal was built up to approximately ¼ in. above the surface of the roll neck (see section A-A in Fig. 15) by stringer beads deposited about ½ in. wide with a buildup of about 3/16 in. A bead overlap of about 40% was obtained by setting the stepping carriage for a 5/16-in. advance after each pass.

After being welded, the roll was placed in a furnace and cooled slowly to 600 F, at which temperature the metal in the weld zone that had been above the austenitizing temperature was transformed to bainite. The roll was then heated to 750 F (the specified tempering temperature) at 15 F per hour and cooled to room temperature in 50 hr.

After heat treatment, the weld buildup was machined flush with the roll-neck surface and dye-penetrant inspected. The deposit was found to be free from cracks and porosity and was therefore checked for hardness, ground to finish dimensions, and polished in a roll grinder.

Selection of Filler Metal (Electrodes). The factors that must be considered in the selection of an electrode for arc welding of tool steel are: (*a*) composition of the base metal, (*b*) heat treated condition of the base metal (annealed or hardened), and (*c*) service requirements of the welded area — that is, whether the weld is located at a critical working surface such as a cutting edge or in an area of high wear. Typical electrode compositions (deposit analyses) are presented in Table 29. The selections listed in this table are based on the assumption that the welded area is a working surface of the tool and, therefore, must have approximately the same hardness, or be capable of achieving the same hardness, as the base metal. Selection of an electrode is often simplified when this requirement does not have to be met.

When welding annealed tools, the composition of the deposited weld metal should approximate that of the base metal, so that the weld and base metal will respond similarly to heat treatment and will develop the same hardness after heat treatment.

Selection of electrodes for welding hardened tools requires more consider-

ation than for welding annealed tools. If the weld metal is to be deposited at a functional area of the tool (such as a cutting edge), it is necessary to select a filler metal that will harden as it cools. Under these conditions, the composition of the deposited weld metal may be entirely different from that of the base metal.

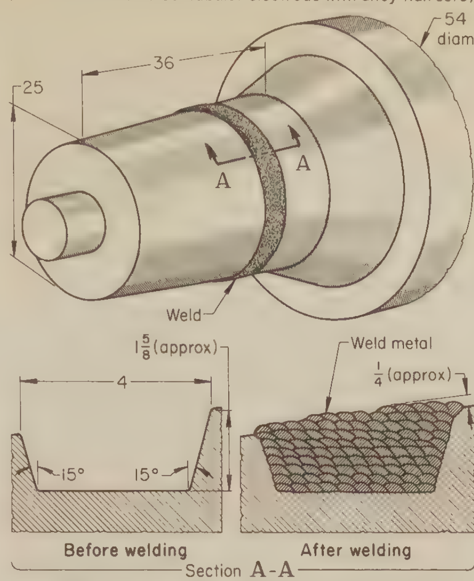
Another technique that is often used in repair welding of hardened tools when the weld will be in a working area is to begin the weld with an electrode that deposits weld metal that hardens only slightly or not at all on cooling — for example, a stainless steel or a low-hydrogen low-alloy steel electrode. A major portion of the weld is made with one of these electrodes, but approximately 3/16 in. of the weld depth is left for completing the weld with an electrode that deposits approximately the same composition as the base metal. This final layer may need to be thicker than 3/16 in., depending on the stresses to which it will be subjected. However, this procedure should not be used if the welded tool will be quenched and tempered, because it will be likely to crack.

When high hardness is not required in the welded area, the most common practice is to make the entire weld with a low-alloy, stainless steel, or nickel-base alloy electrode.

Preheat and Interpass Temperature. Regardless of composition or condition (annealed or hardened), tools should never be welded without preheating. Preheating temperature varies with tool steel composition. Sometimes, a steel of a given composition is preheated at different temperatures depending on whether it is in the annealed or the hardened condition. Preheating temperatures commonly used for various grades of tool steel in both annealed and hardened conditions are given in Table 29; as will be seen from the table, preheating temperatures range from 250 F for the water-hardening tool steels (W grades) to 1200 F for annealed hot work steels (H grades). When a temperature range, as opposed to a specific temperature, is shown (for instance, 250 to 450 F for W1 and W2), the lower temperature of the range is used for thin sections and the higher temperature for thick sections and massive tools. The minimum preheating temperature should always be maintained as the interpass temperature during welding.

Postweld Heat Treating. When welding annealed material, best practice

1% carbon alloy steel; Cr-Mo steel filler metal (from low-carbon steel tubular electrode with alloy-flux core)



Conditions for Submerged-Arc Welding

Weld type	Circumferential single-V groove
Preparation	Machined to remove cracks
Welding position	Flat(a)
Number of passes	About 102 (10 layers)
Preheat	750 F, in a furnace
Postheat	See text
Electrode wire	5/32-in.-diam low-carbon steel(b)
Flux	Neutral, with alloy content
Flux consumption	15 lb per hour
Bead width	½ in., 40% stepover
Power supply	Constant-voltage motor-generator
Current	500 to 550 amp, dcrp
Voltage	25 to 27 v
Electrode stickout	1½ in.
Travel speed	20 in. per minute
Deposition rate	10 lb per hour
Finishing	Machined and ground
Auxiliary equipment	Roll lathe, flux-recirculating system, automatic stepping carriage

(a) Horizontal rolled pipe position. (b) An unclassified low-carbon steel tubular electrode with a core containing flux and alloying elements. Typical weld deposit was 0.10 C, 1.35 Mn, 0.75 Si, 2.0 Cr, 1.0 Mo.

Fig. 15. Large cast alloy steel mill roll that was salvaged by automatic submerged-arc welding (Example 207)

is to allow the weldment to cool to about 150 F, and then to heat it within the appropriate temperature range (see Table 29). When dealing with hardened base metal, the postheating temperature must not exceed the original tempering temperature if the hardness of the tool is to be retained. Common practice is to heat at 25 to 50 F below the original tempering temperature.

Shielded Metal-Arc Welding

Most alloy steels discussed in this article can be successfully joined by shielded metal-arc welding. This process offers the same advantages for welding alloy steels as it does for plain low-carbon steels (see the article on Shielded Metal-Arc Welding, which begins on page 1 in this volume).

Shielded metal-arc welding is more versatile than the other arc welding processes for work to be done in the field or in drafty areas, because less equipment is required and because under adverse conditions the shielding obtained from decomposition of the electrode covering during welding is more dependable than gas shielding.

An important advantage of the shielded metal-arc process for welding alloy steel is that flux-covered electrodes (filler metals) are available in a wide range of standardized compositions (see Tables 5, 19 and 27). Because the slag covering the weld metal retards cooling, it is sometimes an advantage in welding alloy steel.

The major disadvantages of the shielded metal-arc process for welding alloy steels are those encountered in the welding of other metals — namely, the variation in weld quality, and the loss of time that results from frequent interruptions to replace spent electrodes. This loss of time can be greater for alloy steels than for mild steels because alloy steels generally are welded with smaller-diameter electrodes, and thus electrodes have to be replaced more often. Also, the frequent stops make it more difficult to control interpass temperature — a critical factor in some alloy steel applications.

As with all metal-arc welding processes, composition of the weld deposit is more difficult to control than when the deposit has been produced by a process such as gas tungsten-arc welding in which the filler metal is fed directly into the weld puddle without passing through the arc.

The use of low-hydrogen electrodes and close control of moisture content in the electrode covering are essential if the danger of underbead and toe cracking is to be minimized (see preceding sections of this article, especially pages 205 to 207).

Production Examples. Detailed descriptions of practice used in shielded metal-arc welding of several different types of alloy steel are presented in the four examples that follow (see also Examples 196, 198 and 206).

Table 29. Conditions for Arc Welding of Tool Steels

		Annealed base metal						Hardened base metal	
Steel (AISI type)	Type of tool steel electrode(a)	Annealing temperature, F	Preheat and postheat temperature, F	Hardening temperature, F	Quenching medium	Tempering temperature, F	Resulting hardness, Rockwell C	Preheat and postheat temperature, F	Rockwell C hardness(b)

Fig. 17. Gas-turbine compressor wheel that was welded by the shielded metal-arc process because of the adaptability of the process to small quantities (Example 209)

Example 208. Use of a Preheating Furnace Designed To Give Welder Access to Assembly (Fig. 16)

The floodgate-trunnion hub assembly shown in Fig. 16 required preheating and the maintenance of interpass temperatures to produce sound welds. The hub portion was made from an alloy steel forging of 4140 composition meeting the requirements of ASTM A237. The two wings and three webs were made of high-strength structural steel plates conforming to ASTM A441 specification (0.26 C max, 1.30 Mn max, 0.05 P max, 0.063 S max, 0.01 V min, and 0.18 Cu min; 67,000 psi tensile, 46,000 psi yield, and 18% elongation in 8 in.).

Shielded metal-arc welding was selected because it was the most practical process for this assembly, which involved all welding positions and five different joint designs. The joint designs, before and after welding, are shown in Fig. 16. The assembly required a preheat of 400 F and a minimum interpass temperature of 200 F.

The preheat was supplied by a specially constructed furnace that consisted of an insulated box, which measured 7 ft long by 7 ft wide by 3 ft deep, and, under the box, a burner made of 1¼-in. standard pipe drilled to provide ⅛-in.-diam holes for gas ports. The top of the box was removable and two sides could be swung back, to allow the welder access to the joints. Temperature of the assembly was maintained at 200 to 300 F during welding. Welding was discontinued when the temperature dropped to 200 F, at which point the boxlike furnace was closed and the temperature was allowed to recover to 300 F before the box was opened and welding was resumed. The welding sequence was:

1. Tack weld, then weld, the two wings to the center web (detail B in Fig. 16)
2. Weld the wings and center web to the hub (details C and E in Fig. 16)
3. Tack and then weld the two outside webs to the wings (detail D in Fig. 16) and to the hub (detail A).

After being welded, the assembly was allowed to cool slowly in the furnace with the burners shut off. Additional welding details are given in the table that accompanies Fig. 16.

Example 209. Turbine Wheels of High-Strength Alloy Steel Welded by the Shielded Metal-Arc Process (Fig. 17)

Because only six of the assemblies were needed, and because of the simplicity of developing procedures for the process, shielded metal-arc welding was selected for joining a shaft to a compressor wheel for a gas-turbine engine (see Fig. 17).

The wheel and shaft were of 17-22A(S) steel (see Table 21 for composition) in the annealed condition at a maximum hardness of 179 Bhn. The weld groove shown in detail A in Fig. 17 was machined in the wheel and shaft, and the parts were degreased and wiped with acetone before being preheated in a furnace. Initially, the shaft was preheated to 600 F and, because the shaft hole in the wheel was 0.002 in. undersize to give a press fit, the wheel was preheated to 800 F, to produce the additional expansion needed for clearance. The temperature of the assembly was equalized at 600 F after the assembly was placed in a welding positioner. The preheat temperature of 600 F reduced the cooling rate and was close enough to the M_s temperature (630 F) of the steel to prevent the formation of martensite in austenitized areas.

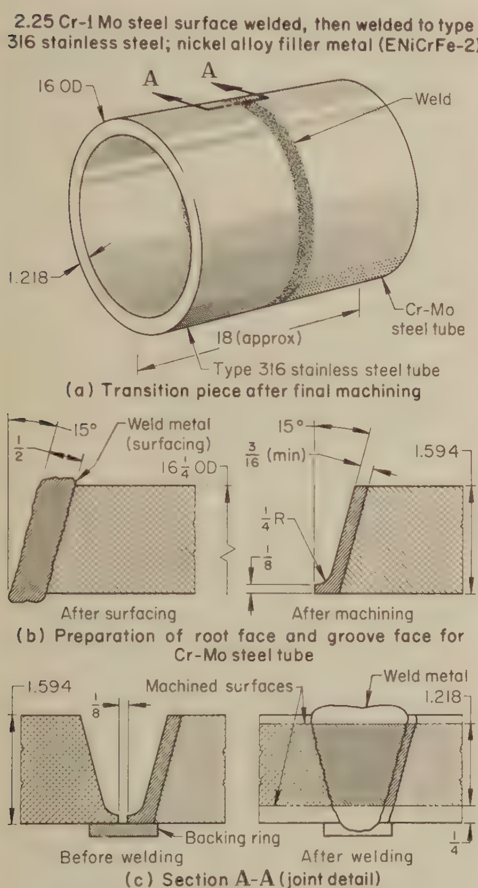
The preheat temperature, which was maintained throughout the welding operation by means of a circular gas burner located beneath the joint, was held in the range of 500 to 700 F, as measured by a surface pyrometer.

The welding sequence, shown in Fig. 17, consisted of six passes — the first two at a current of 120 to 130 amp to deposit stringer beads, and the remaining passes at 170 to 180 amp to fill the joint. Slag was removed after the first pass, and the bead was wire brushed, before the assembly was turned

over in the fixture for the second pass. The current range selected for the first two passes gave 100% penetration of the 0.060-in. root face. The remaining four passes were made at the higher current and with a weave technique to obtain the deposition needed to fill the joint. Immediately after being welded, the assemblies were stress relieved at 1065 F for 2 hr, followed by air cooling, and the welds were then machined flush and inspected by radiographic and magnetic-particle techniques.

Final treatment consisted of normalizing for 1 hr at 1750 F, air cooling, tempering for 6 hr at 1200 F, and air cooling.

The weld metal had the following composition: 0.11 C, 0.36 Mn, 0.62 Si, 0.45 Cr, 0.14 V, 0.64 Mo, 1.68 Ni, 0.007 P and 0.015 S. The weld metal responded favorably to heat treatment, resulting in a hardness of Rockwell C 23 to 26, compared with Rockwell C 27 to 35 for the base metal. Mechanical properties of the weld in the transverse direction (Fig. 17) were comparable to those of the base metal and within specified requirements. Additional welding details are given with Fig. 17.



Conditions for Shielded Metal-Arc Welding

Joint type	Butt
Weld type	Surfacing; single-U groove
Welding position:	
Surfacing	Flat
U-groove weld	Horizontal rolled
Number of passes	Variable(a)
Preheat (for surfacing only)	300 F
Postheat (stress relief)	1275 F for 8 hr(b)
Electrode wire:	
Surfacing	ENiCrFe-2
U-groove welding	3/32, 1/8 and 5/32-in.-diam ENiCrFe-2
Power supply	300-amp rectifier
Current (dcrp) and voltage, U-groove welding:	
3/32-in. wire	50-70 amp, 18-22 v
1/8-in. wire	80-100 amp, 20-25 v
5/32-in. wire	120-140 amp, 20-26 v

(a) As required for filling to dimensions. (b) In furnace with sulfur-free atmosphere.

Fig. 18. Machined shielded metal-arc welded transition piece consisting of a stainless steel tube and an alloy steel tube that was surface welded and machined before being joined to the stainless tube (Example 210)

Example 210. Welding Alloy Steel to Stainless Steel To Produce a Transition Piece (Fig. 18)

The transition piece shown in Fig. 18(a), consisting of thick-wall tubes of type 316 stainless steel and 2¼Cr-1Mo (ASTM A335, grade P22) alloy steel — the same dissimilar metals as were to be welded in a field installation — was shielded metal-arc welded under favorable shop conditions to ensure a sound weld and to prevent carbide precipitation in the stainless steel. The transition piece could then be welded into place in the field, using conventional procedures.

A 15° bevel was machined on one end of the 2¼Cr-1Mo tube, the tube was preheated to 300 F, and the joint surface was "buttered" with a ½-in. thickness of nickel alloy (ENiCrFe-2) filler metal, deposited in successive layers (see "After surfacing" view in Fig. 18b). Each weld layer was carefully cleaned of slag, and liquid-penetrant inspected for defects.

After being built up to full thickness, the surface weld deposit was machined to the shape and dimensions shown in the "After machining" view in Fig. 18(b). The stainless steel tube was machined to the same configuration, and the two tubes were assembled, with a low-carbon steel backing ring as shown in Fig. 18(c), for welding in the horizontal rolled position. The resulting joint was welded without preheat, using the same filler metal (ENiCrFe-2), cleaning method and inspection procedure as were used for surfacing. Additional welding conditions are given in the table that accompanies Fig. 18.

After welding, the assembly received a postweld heat treatment at 1275 F for 8 hr to temper and stress relieve the heat-affected zone of the 2¼Cr-1Mo tube without causing excessive carbon migration. A sulfur-free furnace atmosphere was employed, in order to prevent sulfur embrittlement of the ENiCrFe-2 weld deposit.

The transition piece was machined to size, internally and externally. As shown in Fig. 18(c), the weld metal was removed completely at the root of the joint, where dilution had resulted from the use of a low-carbon steel backing ring. This machining operation also removed any root defects. The final surfaces, which were free of any weld reinforcement, received liquid-penetrant and radiographic inspection.

Transition pieces of this type were used on other dissimilar-metal joints. For joining piping systems of 347 stainless steel to 2¼Cr-1Mo alloy steel, the same procedure, in general, was followed, but in this application the 347 tube was also surface welded, using a 16Cr-8Ni-2Mo filler metal, before the final groove weld was deposited with ENiCrFe-2 filler metal.

Example 211. Welding Alloy Steel Bucket Teeth to an Austenitic Manganese Steel Lip Section (Fig. 19)

As shown in Fig. 19, a casting of austenitic 12% manganese steel constituted the lip section of a bucket used in stacking coal, coke and cinders. The bucket lips were cast with six rectangular platforms, to each of which an alloy steel tooth was to be welded. The low-carbon low-alloy high-strength steel from which the teeth were cast was in the quenched and tempered condition. Welding these dissimilar alloys presented the problem of keeping the austenitic manganese steel relatively cool, to avoid embrittlement, while the base of the alloy steel tooth was preheated, to avoid underbead cracking.

Satisfactory joints were produced by two welding procedures, both employing the shielded metal-arc process and the joint design shown in Fig. 19. A stainless steel filler metal that was capable of absorbing shrinkage stresses without cracking was used in both procedures.

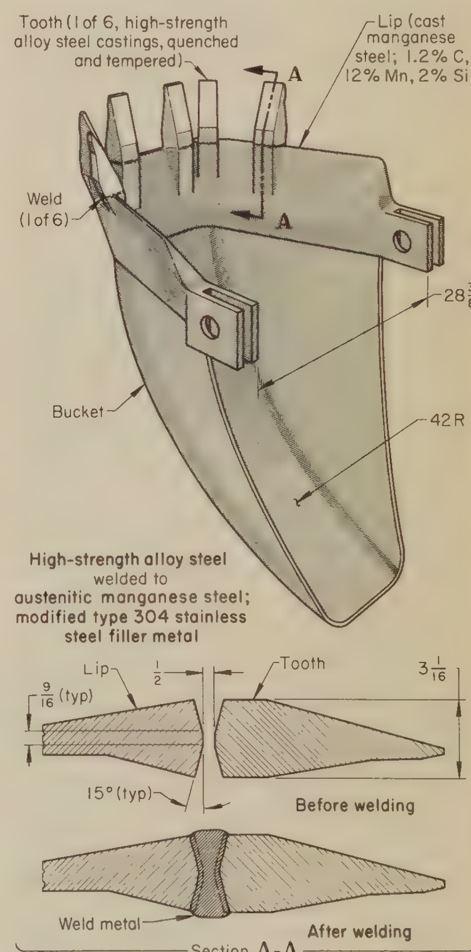
One procedure consisted of separately preheating the teeth to 400 F, applying a surfacing pass, tack welding the teeth in position, and welding without further preheating.

In the other procedure, the teeth were tack welded to the lip and the weld was made with a 400 F preheat that was applied only to the base of the teeth. The preheating was done with a torch.

The composition of the stainless steel covered electrode was: 0.14% max C, 4.0 to 4.5% Mn, 19% min Cr, and 9% min Ni. Mechanical properties of undiluted weld metal from this electrode were: tensile strength, 90,000 psi; yield strength, 67,000 psi; and elongation in 2 in., 44%. Attempts to weld the joints using E309 and E310 electrodes resulted in cracking in the heat-affected zones of the teeth, even though both of these electrodes normally provided a weld deposit as tough and ductile as the electrode used for the successful welds.

Flux-Cored Arc Welding

Flux-cored arc welding can be used to join most of the alloy steels dealt with in this article. This automatic or semiautomatic process is considerably



Conditions for Shielded Metal-Arc Welding

Joint type	Butt
Weld type	Double-V groove
Preheat	400 F (tooth base only)
Postheat	None
Filler metal	Proprietary stainless steel(a)

(a) Electrode composition was: 0.14% max C, 4.0 to 4.5% Mn, 19% min Cr, 9% min Ni.

Fig. 19. Bucket with a lip cast from 12% Mn steel to which six teeth cast from a high-strength alloy steel were joined by shielded metal-arc welding (Example 211)

faster than shielded metal-arc welding, because it utilizes a continuously fed electrode wire (see the article on Flux-Cored Arc Welding, which begins on page 24 in this volume). It is particularly suitable for production applications where high deposition rates are desirable. Because the flux-cored arc process enables welding to proceed with fewer interruptions, control of interpass temperature, which is an important factor in welding alloy steels, is better than when shielded metal-arc welding is used.

Flux-cored arc welding has essentially the same limitations for welding alloy steels as for welding plain low-carbon steels. When an auxiliary gas shield is used, flux-cored arc welding is less satisfactory than shielded metal-arc welding for use in drafty locations. The equipment for both the auxiliary gas-shielded and the self-shielding methods of flux-cored arc welding is more elaborate and less portable (especially for the auxiliary gas-shielded method) than the equipment needed for shielded metal-arc welding.

Electrodes. A major advantage of the flux-cored arc process in the welding of alloy steels is that the cores of tubular electrode wires can be formulated in almost any required composition to suit specific applications (see Example 200). The flux-cored wire consists of the sheath portion, which is always low-carbon steel, and the core, which contains alloying elements and flux, both in powder form. Thus, it is practical to produce small quantities of electrode wire of virtually any special composition that may be needed. Alloy-containing flux-cored electrode wires that meet standard specifications are not available to the same extent as flux-covered electrodes for shielded metal-arc welding. Most of the flux-cored electrode wires for welding alloy steel are marketed as proprietary compositions.

Table 21 on page 42 in the article on Flux-Cored Arc Welding gives compositions and mechanical properties of weld metal from an alloyed basic flux-cored electrode.

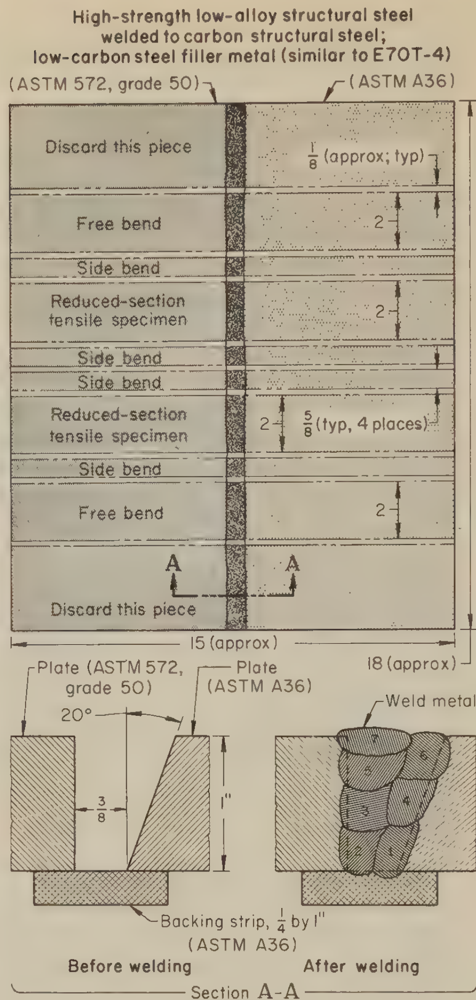
Shielding Gas. Carbon dioxide is used almost exclusively as shielding gas for auxiliary gas-shielded flux-cored arc welding. For alloy steels, the carbon dioxide must be of welding grade (dew point, −40 F or lower). Although welding-grade carbon dioxide is also recommended for welding plain low-carbon steels, the low dew point is of greater importance in welding alloy steels.

Shielding gases composed of 75% argon and 25% carbon dioxide, and of 98% argon and 2% oxygen, have also been successfully used for welding alloy steels, but these gas mixtures cost more than carbon dioxide and, since they usually do not provide any improvement in results, their use is seldom justified.

Self-shielding flux-cored arc welding can be used outdoors or in drafty locations indoors. Whether or not the self-shielding method is acceptable for welding alloy steels depends on weld-quality requirements.

Production Examples. Details of practice that have proved successful for welding of several alloy steels by flux-cored arc welding are presented in Examples 199, 200 and 204, and in the two examples that follow.

Before a flux-cored arc welding procedure is used in production welding, it should be qualified using the same materials as those to be welded in production practice. The first of the two examples that follow gives details of a qualification test for self-shielding flux-cored arc welding. The second of these examples describes a production application of flux-cored arc welding with auxiliary gas shielding.



Conditions for Flux-Cored Arc Welding

Joint type	Butt
Weld type	Single-bevel groove
Welding method	Semiautomatic, self-shielding
Electrode holder	Hand held, air cooled
Electrode wire	0.120-in.-diam(a)
Welding position	Flat
Wire-feed speed	125 in. per minute
Preheat	70 F
Postheat	None
Current	400 to 425 amp, dcrp
Voltage	27 to 28 v
Welding speed:	
Root passes 1 and 2	9 to 10 in. per minute
Subsequent passes	17 to 19 in. per minute

Results of Procedure-Qualification Tests

Tension tests(b):
1 83,000-psi tensile strength, break in base metal
2 80,600-psi tensile strength, break in base metal

Side-bend tests:
1 Defect under ⅛ in. — passed
2 Defect under ⅛ in. — passed
3 Defect under ⅛ in. — passed
4 No defect — passed

Free-bend tests(c):
1 41.8% elongation
2 43.5% elongation

(a) Similar to E70T-4; see text. (b) Reduced-section tensile specimens, 0.958 in. thick by 1.503 to 1.502 in. wide. (c) Not mandatory for qualification.

Fig. 20. Test plate used to qualify a procedure for self-shielding flux-cored arc welding. Table gives principal welding conditions and results of the qualification tests. (Example 212)

Example 212. Qualifying a Procedure for Self-Shielding Flux-Cored Arc Welding of High-Strength Low-Alloy Structural Steel to Carbon Structural Steel (Fig. 20)

To obtain procedure qualification for self-shielding flux-cored arc welding, a fabricator and erector of structural steel followed the rules given in the AWS Code for Welding in Building Construction (D1.0). This fabricator sought a qualified status for code conformance for flux-cored arc welding procedures. (Certain shielded metal-arc and submerged-arc welding procedures, as well as certain types of joints that have had a long record of satisfactory performance, have been granted a prequalified status.) The fabricator depended on submerged-arc welding for the major portion of in-plant production welding, and chiefly on shielded metal-arc welding for welding that was done in the field. Self-shielding flux-cored arc welding was considered to be more economical for some of the field welding. Because neither the flux-cored arc process nor the proposed joint design had a prequalified status, procedure qualification was necessary for the welding to comply with AWS D1.0.

Of the many details specified in the AWS code, the principal requirements of the qualification procedure are: (*a*) to use approved base metals and filler metals; (*b*) to specify the design details of the joint; (*c*) to define the welding process and all welding conditions, such as machine settings, welding position, preheat, speed, techniques, and number of passes used; and (*d*) to perform a prescribed type and number of tests on welded joints, and to meet the acceptance criteria established for the tests. The code also defines the extent of deviations from a welding procedure for which additional qualification tests would be required. Usually, several qualification tests were needed to cover a range of welding conditions. The procedure qualification, which was only one of such tests, is described in the next five paragraphs.

Base Metals. Two approved base metals, ASTM A572, grade 50 (a high-strength low-alloy structural steel with 50,000-psi minimum yield strength), and ASTM A36 (a carbon structural steel with 36,000-psi minimum yield strength), were used to show the capability of the process for welding structural steels. Tensile strength of the joint was expected to equal or surpass the nominal tensile strength of the weaker joint member, which was the A36 steel (58,000 to 80,000-psi tensile strength).

Filler Metal. The flux-cored wire was a proprietary composition for which the mechanical properties of the deposited weld metal were as follows:

Tensile strength	90,000 to 100,000 psi
Yield strength	60,000 to 65,000 psi
Elongation	17 to 20%

This 0.120-in.-diam wire was similar to AWS E70T-4, except that the elongation requirement of the latter is 22%, and the closest wire size in which it is available is ⅛ in. in diameter.

Joint Design. The single-bevel butt joint with backing strip shown in Fig. 20 was designed for economy. The cross-sectional area of this joint was 0.664 sq in. The comparative savings in deposited weld metal for this joint over the prequalified designs for the same type of joint for submerged-arc welding (0.989 sq in.) and shielded metal-arc welding (0.864 sq in.) were about 110 lb per 100 feet of weld (submerged-arc) and 70 lb per 100 feet of weld (shielded metal-arc). In addition, the proposed joint re-

quired only one edge to be beveled, whereas the other processes required both plate edges to be beveled. Access to the smaller groove in flux-cored arc welding was possible because of the small wire diameter and nozzle tip, and the use of a visible wire stickout of 1¼ in.

The procedure was qualified with a 1-in.-thick joint. Qualification for greater thicknesses was obtained by proportionately increasing the number of passes. The backing strip was attached by tack welding.

Welding Conditions and Techniques. Welding was qualified for the flat position, under the welding conditions shown in the table with Fig. 20. Edge preparation was by machining, but gas cutting was permitted. Joint edges were cleaned of oil, grease, excessive amounts of moisture, scale, rust and other foreign material, in accordance with the preweld cleaning requirements. Preheat temperature for the base metals selected was 70 F in the thickness range of ¾ to 1 in. No postheat was required. Welds were deposited using stringer-bead technique, and maintaining the visible stickout at 1¼ in. To obtain adequate penetration with the 0.120-in.-diam electrode, two root beads were used. Five additional passes were needed to fill the joint (Fig. 20). Slag was carefully removed after each pass.

Test Requirements. The length of the test plate (see Fig. 20) was determined by the number of tests required by the code. In this case, two tests for the tensile strength of reduced sections and four side-bend tests were specified. The fabricator chose to add two free-bend tests to determine bend elongation (not to be confused with elongation values obtained in tension tests).

The results of all tests (see table with Fig. 20) met required acceptance criteria.

Example 213. Procedure for Welding Components of a 25-Ton Jackslide (Fig. 21)

The jackslide shown in Fig. 21 weighed 25 tons and was designed to resist the thrust of the main hydraulic jack on a large dragline excavator. One of four such weldments produced, this jackslide consisted of: (*a*) a 44-in.-diam ball-end stanchion forged from a single billet of 8620 steel, (*b*) 3-in. and 5½-in.-thick stiffener plates made of hot rolled ASTM A36 structural steel containing 0.29% carbon max and 0.85 to 1.20% manganese, (*c*) a 5½-in.-thick base plate of A36 steel, and (*d*) end plates and cover plates, also of A36 steel, which boxed in the stiffener ends and formed continuous platforms to the right and left of the main stiffeners. (The cover and end plates have been omitted from Fig. 21.)

The ball-end stanchion had a 10-in.-diam hollow core that extended from the center of the ball to about 3½ in. from the base plate, where the core diameter increased to about 32 in. to produce a 6-in. wall. A single circumferential J-groove weld (not shown in Fig. 21) joined this wall to the base plate.

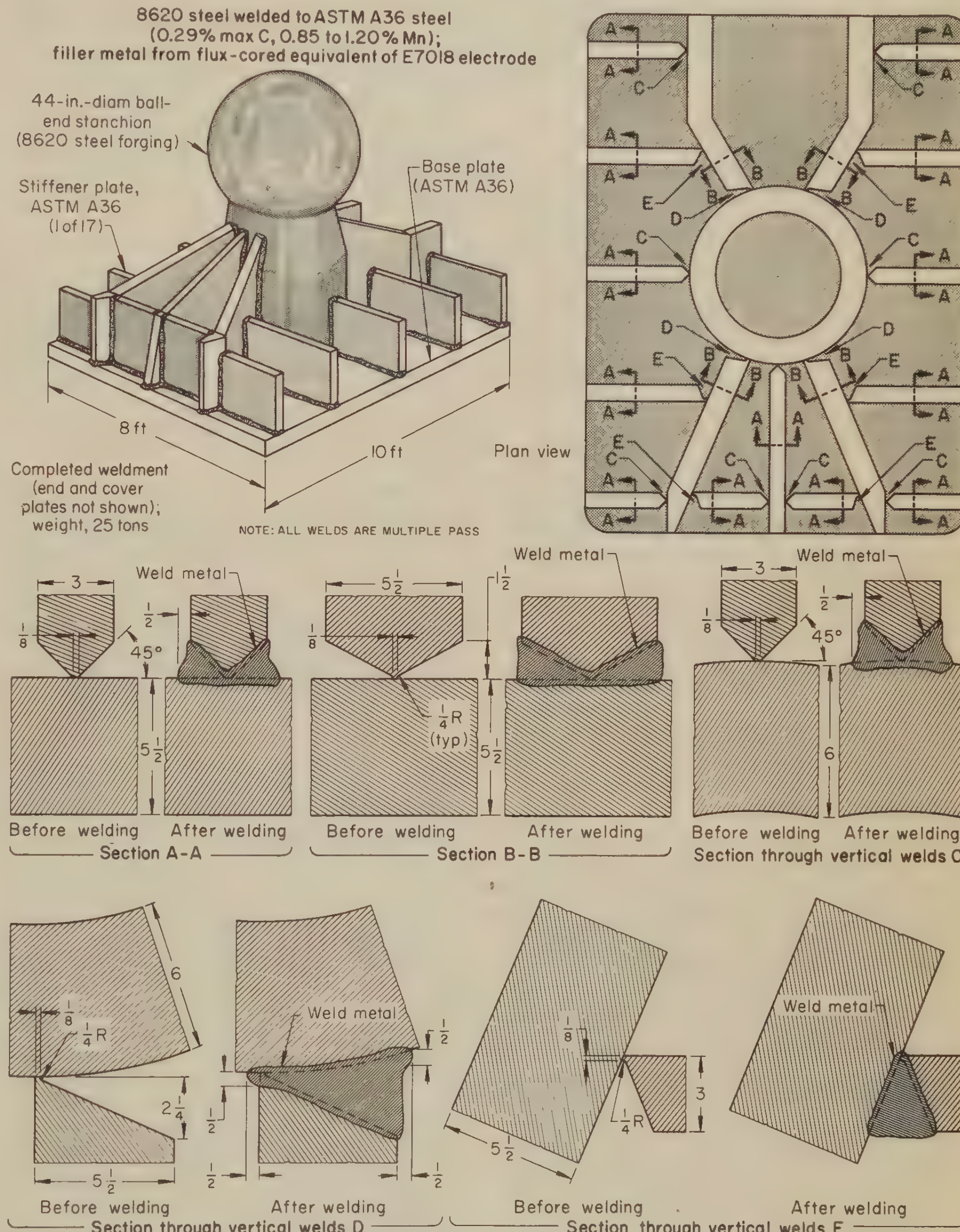
All other joints between components of the assembly were either right-angle or oblique T-joints, and the welds were multiple-pass, full-penetration groove welds. The stems of the T's were either 3 or 5½ in. thick. Edge preparation for the right-angle T-joints in 3-in.-thick material consisted of gas cutting double bevels, each of 45°, on the stem of the T. All other T-joints were prepared by planing single-J or double-J grooves. Typical double-bevel and single-J-groove joints, before and after welding, are shown in Fig. 21.

Welding was done by semiautomatic flux-cored arc welding with carbon dioxide shielding, in the flat and horizontal positions (see table with Fig. 21 for welding conditions). Lifting lugs, 2 in. thick, were full-penetration welded and fitted with clevises for positioning the assembly, which was done by a crane.

The first step was to tack weld the ball-end stanchion to the base plate and heat this assembly to 400 F in a furnace. This joint was then welded without stopping, under continuous heat maintained by torches located under the base plate. Next, all stiffeners were securely tack welded in place, and the assembly was stress relieved by heating in a furnace to 1115 F in 12 hr, holding at temperature for 12 hr, and furnace cooling to 600 F before it was removed and allowed to cool in air. The weld joining the stanchion to the base plate was inspected, and repaired where necessary.

After again preheating to 400 F, all the stiffeners were welded, working two welders per shift, 24 hours a day for 7 days to completion. All surfaces except those being welded were insulated with asbestos blankets. The assembly was again stress relieved, using the same cycle as for the first stress-relief treatment. After the welds were carefully inspected and repaired, the end and cover plates were fitted and welded. The completed weldment was given a third stress-relief treatment, inspected and repaired before machining.

The major hazard in welding the assembly was the danger of weld or underbead cracking, which could be caused by the presence of hydrogen, or caused by shrink-



Conditions for Flux-Cored Arc Welding

Joint type	T
Weld types	Double-bevel, single and double J grooves
Welding positions	Flat, horizontal
Edge preparation	Double-bevel grooves, gas cut; J grooves, planed
Preheat	400 F
Postheat (stress relief)	(a)
Shielding gas	Carbon dioxide(b)
Electrode	$\frac{3}{32}$-in.-diam flux-cored equivalent of E7018 flux-covered electrode
Electrode holder	600 amp, water cooled

Preheat	None		
Postheat (stress relief)	1250 F for 15 min	Current and voltage	90 amp (dcrp); 18 v
Fixture	Assembly jig	Travel speed	4.1 in. per minute

Fig. 22. Brake-frame assembly (one half shown) that was gas metal-arc welded using the short-circuiting mode of metal transfer for close control of deposition (Example 214)

age stress resulting from the number of massive welds made under high restraint. For this reason, the sequence of preheating, fitting, welding and stress relieving was a critical factor.

The initial plan was to preheat, assemble and weld all components except the cover plates. The welds were then to receive a magnetic-particle inspection, be repaired, and the entire assembly stress relieved before the cover plates were added. However, because preheat had to be maintained to the time of stress relief to avoid cracking, it would have been impractical to inspect the welds. Therefore, the weldment received a full stress-relief treatment before each inspection was made.

Gas Metal-Arc Welding

Most of the alloy steels discussed in this article can be welded successfully by the gas metal-arc process. Advantages of this process for the welding of alloy steel are generally the same as for the welding of plain low-carbon steel (see the article on Gas Metal-Arc Welding, which begins on page 78). In some applications, gas metal-arc welding is preferred over other metal-arc processes for alloy steel because of the various modes of metal transfer (spray, globular, short-circuiting, pulsed) that can be obtained and closely controlled.

Two specific advantages of the gas metal-arc process for welding alloy steel are: (*a*) several standardized electrode wires (filler metals) are available (for instance, E70S-1B); and (*b*) extremely small-diameter electrode wire is available. Small-diameter wire helps to deposit a small bead, which is often required in welding alloy steel.

Limitations of gas metal-arc welding compared with shielded metal-arc welding are essentially the same for welding alloy steel as for welding plain low-carbon steel — namely, equipment cost is relatively high, the process is largely restricted to use at nondrafty sites, and equipment is less portable.

Shielding Gas. Factors influencing the selection of shielding gas for welding alloy steel include: base-metal composition, filler-metal composition, mode of metal transfer, welding position, and required quality level. There is no uniformity of practice in regard to gas selection, as is reflected in the eight examples of gas metal-arc welding in this article, in which four different shielding gases (or gas mixtures) were used: carbon dioxide, three examples; 98% argon with 2% oxygen, two; argon, two; and 85% argon with 15% helium, one.

Established practice in a given shop is an important factor in gas selection. For instance, in a shop where most welding is done on low-carbon steel and the available gas is carbon dioxide, every effort will be made to utilize the same shielding gas for welding alloy steel, to avoid installing a separate system. In another shop, where most of the welding is on stainless steel, for which the shielding gas would probably be argon or an argon mixture, the same gas would be utilized for welding of alloy steel. If the amount of welding being done on alloy steel is relatively small, using the available gas will be much more economical than installing a separate system.

Carbon dioxide, because of its low cost, is the most widely used shielding gas for gas metal-arc welding of low-carbon steel, and is also used to a considerable extent for welding of low-alloy steel (see Examples 214, 215 and 217). However, carbon dioxide results in a heat pattern different from that obtained with argon or argon mixtures. Other conditions being the same, greater heat input is obtained with carbon dioxide shielding. This can increase the probability of weld cracking. Sometimes the electrode can be changed to permit carbon dioxide shielding (see Example 215). For welding of low-alloy steel (carbon and alloy content no higher than that of 4130), and when other welding conditions such as section thickness and type of joint are favorable, carbon dioxide is usually suitable as a shielding gas. Since carbon dioxide is an oxidizing gas, the electrode wire must contain greater amounts of deoxidizers such as silicon and aluminum than are required for argon-base shielding gases. In any application, the required weld quality must be considered. For welding of steels having higher hardenability than 4130, carbon dioxide shielding is usually considered unsuitable.

Argon mixtures that include 98% argon and 2% oxygen are extensively used (see Examples 205 and 216) for a variety of different alloy steels. The mixture of 75% argon and 25% carbon dioxide has also been used successfully for welding various alloy steels. Argon-base shielding gases cost more than carbon dioxide, but they provide a more favorable heat input and higher-quality welds.

An all-argon shielding gas is less often used for welding alloy steel, because of weld-bead undercutting, although there are exceptions (see Examples 197 and 219).

Helium costs about 2½ to 10 times as much per cubic foot as argon, depending on the locality and the form and quantity of purchase. An all-helium gas is never used for gas metal-arc welding of alloy steel, and only in relatively few applications is helium used as a component of a shielding-gas mixture. Helium provides a higher heat input than argon, which is sometimes desired. In welding the higher-alloy steels, helium is sometimes mixed with argon (see Example 218, in which a mixture of 85% argon and 15% helium was used for shielding gas in welding of a special tank). Two other mixtures that are sometimes used are: 70% argon and 30% helium (which has the same density as air), and 75% argon and 25% helium.

The mode of metal transfer may influence the choice of shielding gas (see the section on Arc Characteristics on page 79 in the article on Gas Metal-Arc Welding). If it is desired to use the spray-arc mode of transfer, carbon dioxide shielding cannot be used, because a true spray arc does not exist in carbon dioxide. Therefore, argon-base shielding gases are required for the spray-arc mode of transfer (including the pulsed-arc mode). With short-circuiting transfer, either carbon dioxide or an argon-base gas can be used.

Production Examples. The six examples that follow describe techniques that were used for gas metal-arc welding of several alloy steels under various conditions and to meet various requirements (see also Examples 197 and 205).

Example 214. Use of Short-Circuiting Mode of Transfer for Close Control of Deposition in Welding 4130 Steel (Fig. 22)

A brake frame, half of which is shown in Fig. 22, was a welded assembly of two 4130 steel frame pieces (stampings) and sixteen 4130 steel torque bars (extrusions), joined by the gas metal-arc process. Forty mounting holes (20 opposing pairs) had to be held in accurate alignment, and each weld had to be closely controlled for bead

size and shape, weld-metal flow, and joint penetration. It was required that surfaces and edges as designated in Fig. 22 be free from weld metal and that undercutting along two sides of each weld (see detail C in Fig. 22) not exceed 25% of the stamping thickness. Porosity was limited to a maximum of three pinholes in any one continuous weld, with a maximum pinhole diameter of 1/32 in. The close control necessary for compliance with these requirements was achieved with the short-circuiting mode of metal transfer.

The stampings and torque bars were assembled in a welding fixture, with a tension bar (not shown in Fig. 22) tack welded to each frame half to maintain alignment of the mounting holes. The joints were then welded by the semiautomatic gas metal-arc process, under the conditions tabulated with Fig. 22. Each of the 16 joints on one side of the assembly was welded on three sides in the flat position (detail A in Fig. 22). Then the assembly was inverted and the process was repeated on the reverse side.

After welding, the assembly was removed from the fixture and stress relieved at 1250 F for 15 min. On cooling to room temperature, the tension bar was removed, and the tack weld was ground off. Finally, the assembly was shot peened.

Example 215. Selection of Filler Metal To Attain 100% Penetration Without Cracking in Welding 4130 Steel Rings (Fig. 23)

Cargo tie-down rings were fabricated from 4130 steel rods that ranged from 1/2 to 7/8 in. in diameter. Cut to length with a standard rod cutter, the rods were formed into rings 3 to 8 in. in outside diameter and welded, using the semiautomatic gas metal-arc process under the conditions in the table with Fig. 23. Because the rod cutter produced beveled ends, as shown in Fig. 23, no further joint-edge preparation was necessary.

Weld requirements included 100% joint penetration, and freedom from defects detectable by magnetic-particle inspection. No preheating or postweld stress relieving was used, although welded rings were quenched and tempered for strength and toughness.

For economy and speed of production, a three-pass weld sequence was developed, as follows:

1 Penetrate through the root on one side of the ring with the first pass.
2 Turn the ring to the reverse side and, without back grinding, fill this side of the joint in one pass.
3 Reverse the ring to its first position and complete the weld with the third pass (see Fig. 23).

Selection of a suitable combination of electrode wire and shielding gas was difficult. At first, a 4130 steel electrode wire was used with argon, or a mixture of argon and carbon dioxide, as the shielding gas. Full penetration could not be obtained with either of these shielding gases. By changing to a 100% carbon dioxide shielding gas, full penetration was obtained. With all three shielding gases, however, cracks were found after heat treatment. Cracking was prevented without the need for preheating by replacing the 4130 steel electrode wire with a low-carbon, low-alloy wire having the composition shown in the table with Fig. 23. With this electrode wire and carbon dioxide shielding, full penetration was also obtained.

Sample sectioning was used to verify full penetration, and freedom from cracks was ensured by 100% magnetic-particle inspection. Tension tests made after heat treatment of joints welded with the low-carbon, low-alloy electrode wire ensured that joint strength was sufficient.

Example 216. Change From Shielded Metal-Arc to Gas Metal-Arc Welding To Eliminate Cleaning and Reduce Cost (Fig. 24)

Water-wall panels, for later installation adjacent to burner openings in power boilers, were fabricated by welding a series of tubes made of 1.25 Cr, 0.5 Mo steel (ASTM A213, grade T11, 0.15 C max) to fins of the same material. Figure 24 shows a portion of a typical panel assembly, and the joint and weld details. Joint-groove preparation was not required. The 1/8 to 5/32-in. fillet welds produced the desired partial joint penetration.

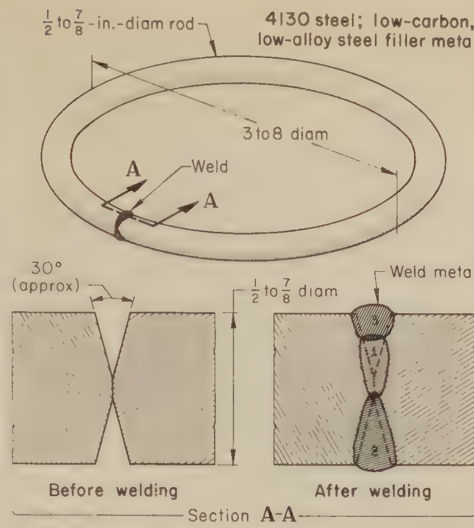
Originally, the panels were welded by the shielded metal-arc process, which produced welds with acceptable properties, but a slag-removal operation was required and the process was considered slow.

Gas metal-arc welding also produced welds of the required quality, and in addition, eliminated the need for removing slag, and more than doubled the welding speed. Welding cost per foot was reduced from $0.825, for shielded metal-arc welding, to $0.225, for gas metal-arc. Welding conditions for both processes, together with a comparison of costs per foot of weld, are presented in the table with Fig. 24.

Often, preheating or postheating, or both, are required when welding this steel. In this application, however, a combination of favorable conditions resulted in the production of sound welds without preheat (only to 60 F if needed) or postheat treatment. One of these conditions was weldment design; because section thicknesses were relatively uniform, and, more important, because the four single-pass welds were close to each other, the entire weldment was heated considerably (up to 500 F) during welding, thus providing the effect of preheating and postheating. A second favorable condition was that the gas metal-arc welding was done with the pulsed-arc mode of metal transfer. This type of welding current was used because it produced spray-type metal transfer at a lower heat input than was obtained by conventional spray-arc transfer. A third favorable condition was that the 98% argon, 2% oxygen shielding gas used in gas metal-arc welding resulted in a heat input that was less likely to cause cracking than the much greater heat input that results from shielding with carbon dioxide.

The tubes were precleaned by belt sanding and the fins were cleaned by shot blasting. Tack welding was used in making the assembly.

The shielded metal-arc process that had been used for this application was, therefore, superseded by the more economical gas metal-arc process. Welds made by both processes were tested in accordance with requirements of the ASME boiler code: two reduced-section tension tests, two root bends, and two face bends.

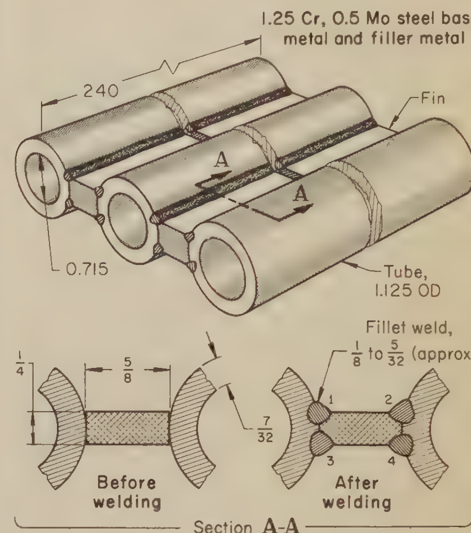


Conditions for Gas Metal-Arc Welding

Joint type	Butt
Weld type	Double-V groove
Welding position	Flat
Number of passes	Three
Preheat or postweld stress relief	None(a)
Shielding gas	Carbon dioxide, at 20 cfh
Electrode wire	0.035-in.-diam low-alloy steel(b)
Electrode holder	Hand held, air cooled
Wire feed	Constant-speed type
Power supply	300-amp constant-voltage rectifier, with slope control
Current	150 amp, dcrp
Voltage	20 v

(a) Welded rings were quenched and tempered for strength. (b) Composition: 0.11 to 0.17 C, 1.75 to 2.10 Mn, 0.65 to 0.85 Si, 0.40 to 0.60 Mo, 0.15 max Ni.

Fig. 23. Tie-down ring, gas metal-arc welded without preheat or postweld stress relief, for which 100% joint penetration without cracking was obtained by use of a low-carbon, low-alloy filler metal and carbon dioxide shielding (Example 215)



Conditions Common to Both Processes

Joint type	T
Weld type	Fillet
Welding position	Flat
Number of passes	One
Preheat	None (except to 60 F, if required)
Postheat treatment	None

Conditions for Shielded Metal-Arc Welding

Electrode	5/32-in.-diam E8018-B2L
Current	170 to 195 amp, dcrp
Voltage	23 v
Welding speed (approx)	12 in. per minute
Deposition efficiency(a)	50%
Operating factor(b)	0.20

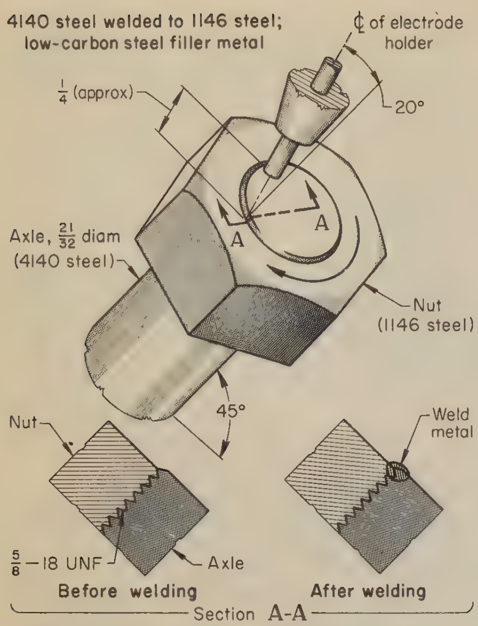
Conditions for Gas Metal-Arc Welding

Power supply	300-amp constant-voltage transformer-rectifier with half-wave rectified pulser
Electrode holder	200 amp, not water cooled
Wire feed	Push type, dial control
Shielding gas	98% argon – 2% oxygen, at 35 cfh
Electrode wire	0.035-in.-diam 1.25 Cr, 0.50 Mo steel
Current	170 amp, dcrp (pulsed)(c)
Voltage	23 v
Welding speed	30 in. per minute
Deposition efficiency(a)	95%
Operating factor(b)	0.40

Item	Shielded metal-arc	Gas metal-arc
Comparison of Costs per Foot of Weld		
Electrode cost	$0.075	$0.052
Gas cost	...	0.023
Manufacturing cost(d)	0.750	0.150
Total(e)	$0.825	$0.225

(a) Weight of weld deposit divided by weight of electrodes consumed. (b) Arc time divided by operator time. (c) Value represents average peak pulse. (d) Labor and overhead. (e) Includes cost of cleaning.

Fig. 24. Portion of a water-wall panel, of heat-resisting steel, that, although successfully welded by both processes without preheating or postheat treatment, cost less to weld by gas metal-arc than by shielded metal-arc (Example 216)



Conditions for Automatic Gas Metal-Arc Welding

Joint type	Circumferential butt
Weld type	Square groove
Number of passes	One
Preheat and postheat	None
Shielding gas	Carbon dioxide(a)
Electrode wire	0.035-in.-diam low-carbon steel
Electrode holder	Machine held, air cooled
Wire-feed rate	264 in. per minute
Power supply	250-amp constant-voltage transformer-rectifier
Current	160 amp, dcrp
Voltage	19 v
Travel speed	16.8 in. per minute
Production rate	115 assemblies per hour(b)

(a) Supplied from cylinder, at 5 to 10 psi. (b) In semiautomatic method, production rate was 59 assemblies per hour.

Fig. 25. Axle assembly for which change from semiautomatic to automatic gas metal-arc welding increased production rate and improved appearance of weld (Example 217)

Example 217. Change From Semiautomatic to Automatic Gas Metal-Arc Welding of Axle Assemblies (Fig. 25)

The rear-wheel axle assembly shown in Fig. 25 was originally welded by the semiautomatic gas metal-arc process at a rate of 59 assemblies per hour. A change to automatic gas metal-arc welding increased production to 115 assemblies per hour; also, less skill was required for the welding operation, and all welds had a more uniform appearance.

The axle was made of 4140 steel, strain hardened to approximately 125,000-psi yield strength. The nut was made of a killed 1146 free-cutting steel. Although this steel is not recommended for welding, the free-cutting additives produced no noticeable detrimental effects.

Before being welded, the axle and nut were degreased and assembled. The assembly was manually loaded in a special chucking fixture, and the axle, at 45° to the horizontal, was rotated clockwise, at 16.8 in. per minute at the joint. Welding was fully automatic, and the electrode holder was held in a retractable air-operated mechanism. The holder was air cooled. No preheating or postheating was needed, and the weld was made in one pass.

Since the purpose of the weld was to fix the nut permanently to the axle, penetration through at least one thread engagement (see Fig. 25) was required. This penetration was obtained by welding under the conditions listed in the table with Fig. 25.

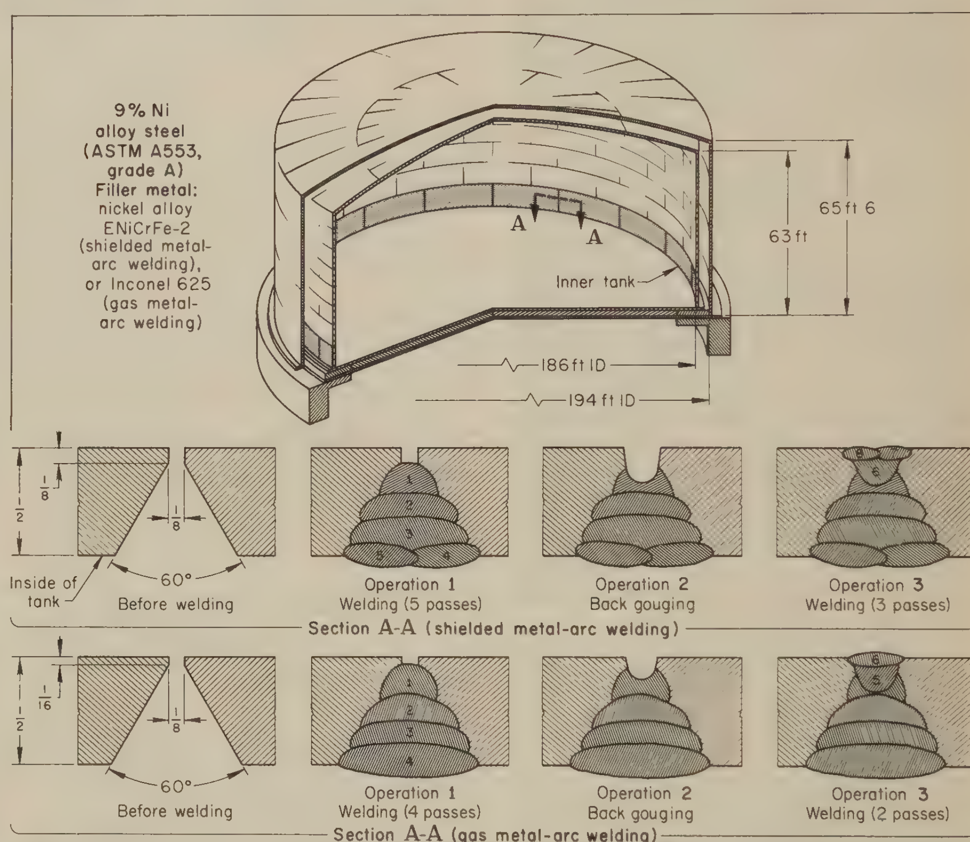
After being welded, the axle assembly was washed, zinc plated, and heated for 3 hr at 375 ± 25 F. This heat treatment served to lessen danger of hydrogen embrittlement resulting from the plating operation. The welds were inspected visually.

Example 218. Costs and Procedures for Shielded Metal-Arc vs Gas Metal-Arc Welding of 9% Nickel Steel Storage Tanks (Fig. 26)

A cost comparison, based on production records, was made between shielded metal-arc welding and pulsed-current automatic gas metal-arc welding of vertical joints in large field-erected tanks used for storing liquefied natural gas. Figure 26 shows the double-wall construction of a typical tank and details of the vertical joints of the 290,000-bbl inner tank for which the comparison was made. Welding conditions and cost data are given in the table accompanying Fig. 26.

The inner tank was fabricated of a 9% nickel steel (ASTM A553, grade A), which provided the required low-temperature strength properties at a reasonable cost. Although the welding procedures of the two processes differed in detail, each produced welded joints that met the required minimums of 95,000-psi tensile strength and 52,500-psi yield strength. Charpy V-notch impact values greater than 20 ft-lb at −320 F in the weld and in the heat-affected zone were also required. Design and fabrication were in accordance with API Standard 620, Appendix Q, for low-pressure liquefied natural gas storage tanks.

The inner tank was constructed of eight courses, or rings. The bottom course was made of ½-in.-thick plates, the second course of 0.44-in.-thick plates, and the six successive courses were made of ⅜-in.-thick plates. The cost comparison was made on the basis of welding the 19 vertical joints in the ½-in.-thick bottom course. Details of bottom-course joints welded by the two processes are shown in section A-A in Fig. 26.



Item	Shielded metal-arc welding	Automatic gas metal-arc welding
Comparison of Welding Conditions		
Number of passes	Eight	Six
Shielding gas	...	85% argon – 15% helium, at 35 cfh
Electrode wire	⅛-in.-diam ENiCrFe-2	Inconel 625(a)
Power supply	300-amp rectifier	300-amp rectifier, with half-wave rectifier pulser
Current	Passes 1, 2, 3, 6(b): 50-80 amp, dcrp; Passes 4, 5, 7, 8(c): 60-90 amp, dcrp	All passes(c): 90-130 amp, dcrp(d)
Voltage	22 to 26 v	18 to 23 v
Auxiliary equipment	None	Automatic travel, wire feeder, and oscillator
Travel speed	No estimate	4 to 7 in. per minute
Comparison of Costs per Foot of Weld		
Labor and overhead(e)	$38.36	$16.21
Materials	6.75	9.87
Total cost	$45.11	$26.08
Repair rate allowed	20%	10%(f)

(a) Modified composition: 0.1 C, 0.5 Mn, 0.5 Si, 21.5 Cr, 9.0 Mo, 5.0 Fe, 1.0 Co, 0.4 Al, 0.4 Ti, rem Ni. (b) Vertical up. (c) Vertical down. (d) Half-wave-rectified (60-cycle) pulsed current, superimposed on a dc background current. (e) At $14 per hour, including operator factor, but excluding edge preparation and assembly. (f) Actual repair rate was less than 1%.

Fig. 26. Cutaway view of a double-wall tank used for storing liquefied natural gas. Welding conditions and costs data in table are for the bottom course of the inner tank, which was selected as typical and as a basis for comparing procedures and costs. (Example 218)

The table with Fig. 26 omits the operations that were the same for both processes. These included beveling of plate edges by gas cutting, the wire brushing and grinding of joint surfaces, plate fit-up, and plate inspection. Plates were not preheated, but if the temperature fell below 32 F, the steel was heated so that it was warm to the touch. No postheating was used.

One of the difficulties encountered during welding was arc blow, which resulted from the relatively high magnetic permeance and remanence of the 9% nickel steel. Pulsed-current gas metal-arc welding could be done in magnetic fields up to 100 gausses, but the maximum field for shielded metal-arc welding was 50 gausses.

For shielded metal-arc welding, as shown in Fig. 26, eight passes were required. The root pass (1) and the three filler passes (2, 3 and 6) were made vertical up, and the relatively wide and thin cover passes (4, 5, 7 and 8) were made vertical down. Thorough slag removal between passes was essential in order to obtain the high-quality welds that were required by the 100% radiographic inspection.

Only six passes were required for gas metal-arc welding (Fig. 26); all passes were made vertical down. For the root pass (1), the electrode holder was guided manually. For the remaining passes, the electrode holder was mounted on a variable oscillator, which, in turn, was mounted on a carriage for automatic travel. The electrode holder was oscillated for passes 2 through 6. In addition to these features, the power supplied for welding was of the pulsed type, which provided uniform spray transfer of filler metal, low heat input and greater resistance to arc blow.

The automatic gas metal-arc process was not only faster, by permitting the weld to be made in fewer passes, but also reduced repair costs and produced welds of higher quality. The actual repair rate was less than 1%; that is, after radiographic inspection, less than 1 in. out of 100 in. of weld required chip-out and rewelding. The repair rate for shielded metal-arc welding varied considerably among individual welders and averaged about 20%.

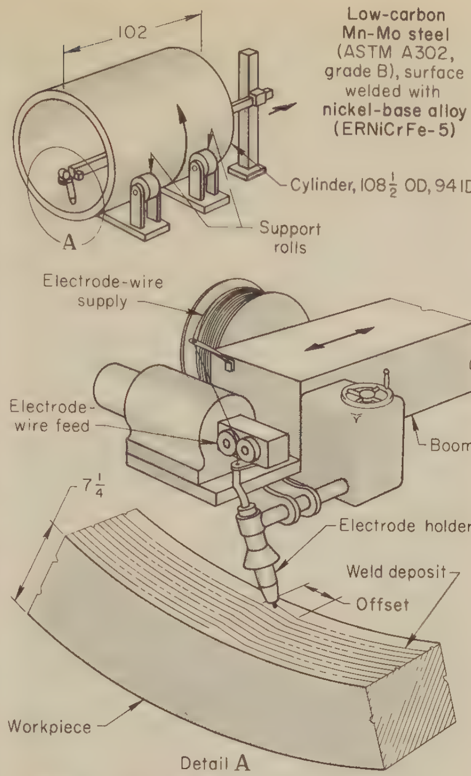
These process and quality differences are reflected in the lower cost per foot of weld for gas metal-arc welding (see table with Fig. 26). The major disadvantages of gas metal-arc welding were the higher equipment costs and the need to shield the operation from drafts.

Example 219. Surfacing a Low-Carbon Mn-Mo Steel Cylinder With a Nickel-Base Alloy (Fig. 27)

The 7¼-in.-wall cylinder shown in Fig. 27 was fabricated from quenched and tempered low-carbon Mn-Mo steel plate (ASTM A302, grade B). It was required that the inside of the cylinder be surfaced with a high-quality deposit from ERNiCrFe-5 electrode wire (a nickel-base alloy wire with a composition similar to that of Inconel 600) to meet rigorous requirements for chemical and mechanical properties.

Gas metal-arc surfacing was done with automatic welding equipment, which was mounted on a manipulator boom and placed inside the cylinder in a manner that permitted it to traverse the length of the cylinder (see Fig. 27). The cylinder was placed on support rolls, and was rotated by variable-speed drive rolls that provided a rotational speed corresponding to the speed desired for weld deposition. The design of the welding head provided for constant oscillation of the holder in the direction transverse to that of travel, thereby producing a relatively wide and thin deposit.

During surfacing, the electrode holder was held at a fixed point for each revolution of the cylinder. As completion of each 360° rotation was approached, and without interruption of welding, a timer was actuated and the welding boom was moved longitudinally at a fixed rate and for a fixed distance to provide the desired bead pitch. This sequence was repeated as the electrode holder traversed the length of the cylinder to produce overlapping deposits of uniform dimensions and quality. The offset weld-overlay pattern produced by the operation is shown in detail A in Fig. 27. Additional welding details are given in the table that accompanies Fig. 27.



Conditions for Gas Metal-Arc Surfacing

Power supply	400-amp rectifier, with drooping voltage
Preheat and postheat	None
Electrode wire	0.062-in.-diam ERNiCrFe-5
Shielding gas	Argon
Deposition rate at 100% arc time	11 lb/hr

Fig. 27. Setup and deposition pattern for surfacing the inside of a large steel cylinder (Example 219)

Submerged-Arc Welding

As indicated in Table 10, the submerged-arc process can be used to weld a variety of alloy steels. Advantages of the process for welding alloy steels are, for the most part, the same as for low-carbon steels — high deposition rate and low cost. For welding of alloy steels the high deposition rate may be especially advantageous, because a larger area is heated and thus cooling rate is slower. In addition, the flux used in submerged-arc welding serves as a blanket and retards the cooling rate, and may help to prevent cracking. Consequently, the submerged-arc process is sometimes selected in preference to other arc processes because of the lower risk of weld cracking (see Example 222).

The major limitation of the submerged-arc process for welding alloy steels is the same as for carbon steels — namely, that it restricts the number of welding positions that can be used (see the article on Submerged-Arc Welding, which begins on page 46).

Production Examples. The five examples that follow give details for submerged-arc welding of several different alloy steels (see also Example 207).

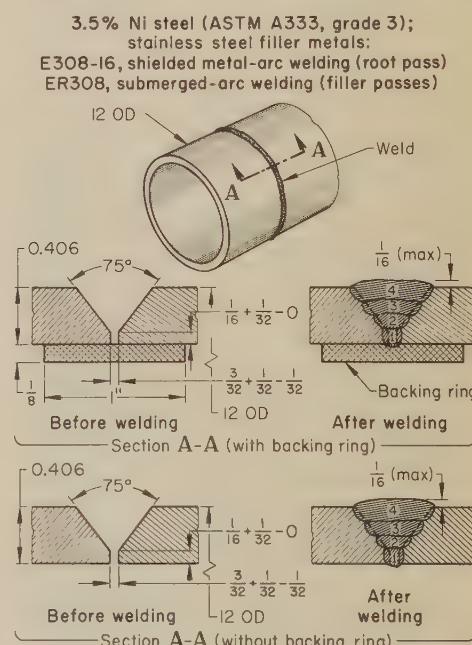
Example 220. Welding 3.5% Nickel Steel Pipe Sections for Low-Temperature Service (Fig. 28)

The pipe shown in Fig. 28 was nickel steel (3.2 to 3.8% Ni) and was welded with stainless steel filler metal to meet the mechanical-property requirements of ASTM A333, grade 3, which included a minimum tensile strength of 65,000 psi and a minimum notched-bar impact value of 15 ft-lb at −150 F (10-mm-by-10-mm specimens).

The joint design shown in Fig. 28 was used for the 0.406-in. wall thickness, as well as for similar pipes having wall thicknesses up to ¾ in. The mechanical-property requirements could be met by welding either with or without backing rings.

Where service conditions and specifications permitted, backing rings were used (which were allowed to remain in place) to reduce the time and welder skill needed to make the root pass. The root pass was made without a backing ring when internal obstructions were not allowed. Making the root pass required skill to obtain complete fusion of the root with a smooth inside root condition. Care was used with both procedures to ensure full root penetration.

Because it was less costly, automatic submerged-arc welding was used for all passes except the root pass. It was not suitable for the root pass because drop-through would occur if no backing were used, or the welding flux could be trapped between the backing ring and the pipe, which could cause incomplete fusion and other defects. The root pass was made by shielded metal-arc welding with ⅛-in.-diam E308-16 electrodes. This metal was sluggish, requiring the weld puddle to be "pushed" with the arc. A skilled welder could produce a smooth root pass approximately 3/32 in. deep. To guard against cracking, weld starts were made by backstepping over previous deposits. Although no preheat was



Item	Shielded metal-arc welding (root pass)	Automatic submerged-arc welding (filler passes)

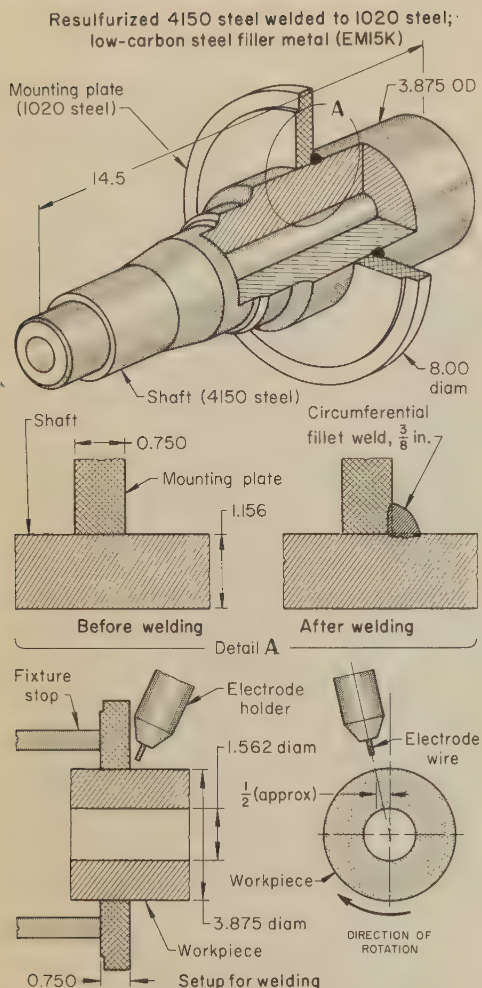
Travel speed, ipm	...	12-15

Fig. 28. Circumferential welding of pipe for low-temperature service, showing joint designs for welding with and without a backing ring (Example 220)



Conditions for Submerged-Arc Welding

Joint type	Circumferential T
Weld type	Fillet
Welding position	Horizontal rolled
Number of passes	One
Preheat and postheat	None
Electrode wire	3/32-in.-diam EM15K
Flux	F72
Wire feed (automatic)	156 in. per minute
Electrode stickout	½ in.
Electrode holders	600 amp, fixed position
Power supply	Constant-current rectifier, with slope control
Current	340 amp, dcrp
Voltage	26 v
Electrode consumption	0.3 lb per assembly
Deposition rate	18 lb per hour
Weld overlap	⅜ in.
Welding speed	1.12 rpm
Weld time per assembly	0.993 min
Production rate	33½ assemblies per hour
Postweld finishing	Slag chipped away

Fig. 29. Shaft of resulfurized 4150 steel welded to a 1020 steel plate, showing joint design and setup for welding (Example 221)

used, interpass temperature was held in the range of 150 to 350 F to avoid overheating and subsequent cracking.

Details of both the manual root-pass welding and the automatic submerged-arc welding are given with Fig. 28. Data for root-pass welding with and without backing were not separated because welding current and speed varied with welders and were not accurately predictable.

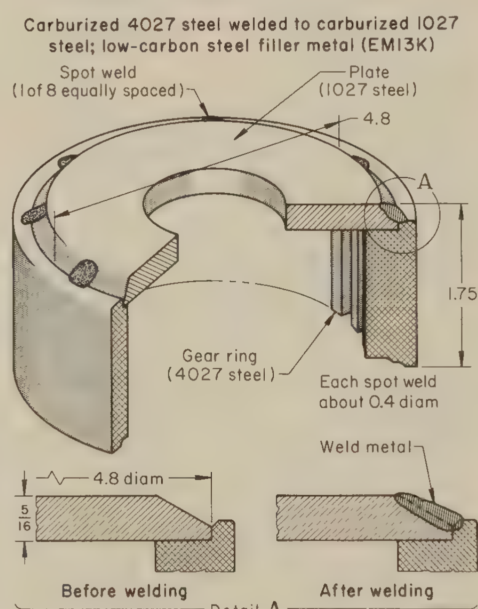
Edge preparation and preweld cleaning, as well as quality-control methods, inspection and testing, were in accordance with the ASME code. Weld surfaces had to be clean of solid matter, oil, and grease. All slag and flux had to be removed before successive beads were deposited. Cracks and blowholes on bead surfaces had to be removed by chipping or grinding. Undercutting was not permitted. Impact values for welds made with and without backing did not differ, provided that the root pass was smooth and uniform. Qualification welds were inspected visually, by radiography, by magnetic-particle or liquid-penetrant methods, and metallographically. Radiographic interpretation was more difficult when backing rings were used.

Essentially the same procedure as that described above was used for welding pipe sections of the following steels: A203, grades D and E; A334, grade 3; A350, grade LF3; and A352, grade LC3.

Example 221. Welding Resulfurized 4150 to 1020 Without Preheat or Postheat (Fig. 29)

The axle for an industrial lift truck consisted of a drive axle shaft welded to a brake mounting plate (Fig. 29). The shaft was machined from a 4-in.-diam bar of resulfurized 4150 steel heat treated to 293 to 352 Bhn, the plate from 1020 steel. After machining, the shaft was fitted to the brake mounting plate for welding. A ⅜-in. fillet weld with 0.100-in. minimum joint penetration was required.

Resulfurized 4150 (0.08 to 0.13% sulfur) was selected for its good machinability because the design of the shaft called for extensive machining. Generally, high-sulfur steels are not selected for parts that are to be welded, since the high sulfur content often causes hot cracking and porosity in the weld. In this application, an electrode-flux combination (EM15K-F72) that prevented excessive porosity was used. Typical composition of the weld deposit produced by this combination was: 0.076% C, 1.54% Mn, 0.79% Si, 0.025% P, and 0.021% S.



Conditions for Submerged-Arc Spot Welding

Joint type	Corner
Weld type	Spot(a)
Welding position	Flat
Joint preparation	Machined, press fit
Preheat and postheat	None
Electrode wire	1/16-in.-diam EM13K(b)
Flux	F62
Electrode holders	Two, air cooled, set in automatic indexing fixture
Electrode stickout	¾ in.
Wire-feed rate	2 in. of wire per weld
Power supply	Two 600-amp constant-voltage transformer-rectifiers
Current	400 amp, dcrp
Voltage	31 to 32 v
Production per machine	150 assemblies/hr

(a) One-spot welds, made two at a time. (b) Single-deoxidized. Initially, a triple-deoxidized electrode wire (E70S-2) had been used.

Fig. 30. Annulus gear assembly welded in the carburized-and-hardened condition by submerged-arc spot welding (Example 222)

Although the welding of 4150 steel normally requires preheating and postheating, neither treatment was used and no cracking occurred. At least two conditions favored successful welding without preheating: (*a*) the blanketing effect of the flux used in the submerged-arc process often provides slow cooling and eliminates the need for preheating, and (*b*) a ductile weld was produced because one component of the weldment was 1020, which has excellent weldability, and the deposited weld metal was of low carbon content.

The assembly was welded with the axis of the hollow shaft in the horizontal position. A mandrel, inserted in the shaft, was held between the headstock and tailstock of a lathe-type rotating positioner. The relatively small diameter of the shaft at the weld, and the fact that the workpiece was rotating (clockwise), required placing the electrode holder ½ in. before the 12 o'clock position (Fig. 29). This placement permitted the molten weld metal and the flux to remain in a near-horizontal position long enough for the metal to solidify before the flux ran off the rotating workpiece. The normal 1-in. stickout was reduced to ½ in. and a flux nozzle with a diameter of ¾ in. was used to obtain a satisfactory flow of flux.

In tests, the welds of the assembly withstood loads of 142,000 to 240,000 lb — equivalent to a tensile strength of 31,000 to 52,000 psi (the minimum tensile strength required was 12,000 psi).

Each weld was inspected visually by the operator. A periodic examination of welds was also made by the line inspector with a fillet gage and by magnetic-particle inspection. There have been no failures of axles in several years of service.

The original cost of the submerged-arc welding equipment used was $18,000.

Example 222. Use of Submerged-Arc Spot Welding To Join Carburized and Hardened 4027 to 1027 (Fig. 30)

The annulus gear assembly shown in Fig. 30 consisted of a forged steel plate that was press-fitted into a cylindrical gear ring and then secured by eight submerged-arc spot welds. Welding conditions are given with Fig. 30.

Originally, these components for an automatic transmission were held together by a high-carbon steel snap ring that fitted into a machined groove in the gear ring. Conversion to welding yielded a saving of $0.256 per assembly.

The 1027 steel plate and 4027 gear ring were carburized, hardened and finish machined before assembly. Welding by gas metal-arc or gas tungsten-arc resulted in cracked gear rings and weak welds, but the submerged-arc spot welding procedure, in which the blanketing action of the flux was used in combination with a deoxidized electrode wire, produced a weld that was sound and ductile.

The welded joint was specified to resist a minimum push-off load of 8000 lb for service applications. The quality of the welds was checked by testing one gear to destruction at the end of each 2-hr production run. Most of the destroyed gears withstood push-off loads of 13,000 to 14,000 lb.

The gear was originally welded with a triple-deoxidized electrode wire at a saving of $0.250 compared with the cost of the gear assembled with the snap ring. It was later found that a single-deoxidized electrode wire could be used satisfactorily; this increased the saving per assembly to $0.256.

Example 223. Selection of Submerged-Arc Welding for High-Quality Welds and High Production Rate (Fig. 31)

The aircraft drive-shaft assembly shown in Fig. 31 was made by pressing a cold drawn 4130 steel tube (3-in. OD by 0.083-in. wall) onto a recess in a 4140 steel gear hub to form a tight, square butt joint. The joint had to be welded in a single pass and with full penetration (see section A-A in Fig. 31). The cold drawn tube had a tensile

strength of 105,000 psi, and the 4140 steel gear hub was quenched and tempered to Rockwell C 32 to 38 before being welded.

Because of the production rate required, only automatic welding processes were considered. In developing a welding procedure, three processes that were readily available were investigated — shielded metal-arc, gas metal-arc, and submerged-arc welding. (The automatic shielded metal-arc process considered is one utilizing a continuous electrode with a light wash coating of flux. Because it affords poor shielding, the process is seldom used.)

The welding conditions for each of the three processes evaluated are given in the table accompanying Fig. 31. For all processes the parts were grit blasted and degreased before press fitting. The assembly was mounted horizontally between the headstock and tailstock of a lathe-type positioner, and a full-penetration weld was made in a single pass. No preheat was used but, after welding, the assemblies were heated to 900 F for 5 min in a furnace to temper the martensite that formed during cooling from the welding temperature.

The three cross sections of welded joints in Fig. 31 show the relative weld configurations, heat-affected zones, and porosity contents obtained by the three processes. The gas metal-arc welds were smallest in size and in heat-affected area but had considerable porosity and an objectionably high weld reinforcement. Fatigue life, under the test described in footnote (e) in the table with Fig. 31, was 6 million cycles, which was acceptable. The shielded metal-arc welds were so full of porosity and had such a high weld reinforcement and generally inferior appearance that fatigue testing was omitted and further investigation of shielded metal-arc welding for this application was discontinued.

Although the submerged-arc welds were the largest in size, the heat-affected zone was intermediate in depth, porosity was completely absent, and the low reinforcement blended smoothly into the base metal. [It may be noted in Fig. 31 that the sizes of the heat-affected zones were approximately proportional to the heat inputs, which were (in joules per inch): 10,700 for gas metal-arc, 13,800 for submerged-arc, and 14,900 for shielded metal-arc.] These factors, as well as higher fatigue life (7 million cycles) and slightly higher production rate compared with gas metal-arc welding, provided the basis for selecting automatic submerged-arc welding.

Example 224. Change to Welded Design That Simplified Manufacture of Wheels for Military Tracked Vehicles (Fig. 32)

The production of wheels with special wear rings for use on military tracked vehicles entailed costly operations. As shown in Fig. 32 (original design), the wheel surface subject to wear from contact with the track shoes was protected by a hardened 4130 steel wear ring fixed to the wheel with 18 rivets. Attaching the wear ring was a cumbersome procedure. The ring had to be straightened, after hardening, and carefully fitted, drilled and then riveted. The wheel was formed from a disk of 1025 steel by drawing, annealing, flanging the small outer lip, and restriking for size.

The wear ring was eliminated in an improved design of the wheel (see top and bottom views in Fig. 32). By making the wheel from a disk of 4130 steel or a high-strength structural steel, the area subject to wear could be induction hardened to a depth of ⅛ in. minimum (287 to 461 Bhn). This design entailed a welded reinforcing ring being substituted for the flanged outer lip, because the higher-strength steel could not be formed to the ⅜-in. bend radius of the flange. The reinforcing ring could be made of any carbon steel from 1008 to 1025.

Procedures for welding the reinforcing ring varied with wheel size, thickness and production requirements. The joint, as shown at lower right in Fig. 32, was designed for a full-penetration groove weld with a fillet-weld reinforcement of approximately ⅜ in. After fitting and tack welding of the ring, the wheel was mounted on a rotating fixture, which was inclined to permit welding in essentially the flat position, and the weld was made in a single pass, after which the weldments were rolled along a chute to the induction heating station. Welding conditions are given in the table accompanying Fig. 32.

Finished welds were inspected visually for general appearance, surface defects, and size. Visible defects were repaired by grinding and rewelding. One piece per shift (a minimum of two pieces per setup) was

sectioned and examined to ensure that the welding was under control. In terms of labor costs, time and materials, the design and manufacturing operation for the welded wheels was less costly than the original design and production method.

Gas Tungsten-Arc Welding

In gas tungsten-arc welding, the composition of the weld metal can be accurately controlled, because in gas tungsten-arc welding any filler metal used is fed into the weld puddle and not into the arc (see the article on Gas Tungsten-Arc Welding, beginning on page 113 in this volume). Control of weld-metal composition is generally more important in the welding of alloy steel than in the welding of plain low-carbon steel; in most applications, composition control becomes more important as the alloy content of the base metal increases.

The close control of heat input that is a characteristic of gas tungsten-arc welding is frequently advantageous when welding alloy steel in the heat treated condition (see Example 201).

The main disadvantage of the gas tungsten-arc welding of alloy steel is the same as for other steels; the process is slower and consequently somewhat more expensive than the other metal-arc processes. However, for many critical applications the need for the high-quality welds that can be obtained by the gas tungsten-arc process does not permit substitution of another metal-arc process.

The four examples that follow describe details of practice for gas tungsten-arc welding of medium-carbon alloy steels (see also Example 201).

Example 225. Welding of 4140 Steel Stampings to a Heat Treated 4340 Forging (Fig. 33)

When undesirable vibrations were traced to the 4340 forged steel torque plates of an aircraft brake assembly, the design was revised to incorporate an integral ring of metal that changed the resonance frequency of the part. In order to make use of 1500 existing torque plates, they were altered by gas tungsten-arc welding a torque ring stamped from annealed 4140 steel to the inside of each heat treated 4340 steel torque plate as shown in Fig. 33. This weldment served the same purpose as the redesigned torque plate. As shown in Fig. 33, the torque ring, which was stamped in three segments, had a corrugated configuration to avoid interference with brake flange mounting bolts. The three segments of the ring were joined by square-groove butt welds, and the ring was attached to the torque plate with two fillet welds at each of the 12 corrugations (24 fillet welds), as shown in Fig. 33.

Although the welds were required only to hold the ring in solid contact with the torque plate, no cracking could be tolerated. In addition, the heat treated hardness of the 4340 steel torque plate (Rockwell C 35 to 39) had to be retained. Therefore, it was necessary to establish precise procedures for preheating, maintaining temperature during welding, and postheating.

Before welding, the parts were cleaned in an alkaline cleaning solution and rinsed. The ring segments were positioned and clamped in a locating jig and tack welded to the torque plate. The assembly was then furnace preheated to 400 F in an argon atmosphere. From this time until the welded assembly was ready for stress relieving, the temperature was not permitted to drop below 350 F, nor to rise above 500 F. Temperature-sensitive crayons were used. When

Filler metal	Hastelloy W (AMS 5786)

Fig. 33. Heat treated torque plate to which a three-piece torque-ring assembly was welded to eliminate vibrations (Example 225)

temperature dropped to 350 F, the weldment was heated with torches; when temperature rose to 500 F, welding was temporarily stopped.

Argon shielding and a Hastelloy W filler rod were used. Heat input was controlled solely by manipulating the arc; no remote current-control device was employed. To minimize residual shrinkage stress, the butt joints were welded last. Each weld was made in one pass, which was interrupted three or four times, depending on heat buildup. Welding conditions were the same for the fillet and butt welds.

After being welded, weldments were maintained at the welding temperature in an argon-atmosphere furnace until a furnace retort load was ready for stress relieving. Weldments were stress relieved at 980 to 1000 F for 3 hr and furnace cooled, after which the joints were sand blasted and inspected for cracks by visual and fluorescent liquid-penetrant examination. Following an alkaline cleaning cycle similar to preweld cleaning, the joints were shot peened, using an S-330 shot, to produce a surface compressive stress (150% coverage; 0.010 to 0.014-in. intensity). On the first ten pieces only, radiographs were taken to ensure that the weldments were acceptable.

Example 226. Use of Preliminary Buttering To Permit Welding of 4340 Steel Without Preheating (Fig. 34)

A conventional gas tungsten-arc welding process could not be used for joining two shell sections of a naval torpedo, because of difficulties in preheating. The shell sections, as shown at left in Fig. 34, were machined from normalized 4340 steel forgings, which required preheating at 500 to 700 F to prevent cracking after welding. However, the forward shell contained a shrink-fitted tank forged from aluminum alloy 5254, which could not be heated above 250 F without loss of strength. This restriction was overcome by a two-stage procedure that permitted the final closure to be made by gas tungsten-arc welding without the need for preheating. The procedure involved the use of a submerged-arc buttering deposit, as described below and illustrated in Fig. 34.

Both shells were received as oversize pierced forgings, requiring considerable machining. During initial machining, a large circumferential groove was cut in each shell in the location that subsequently would become the joint area (see top middle view in Fig. 34). These grooves were filled by submerged-arc welding, after a 700 F preheat, using a low-carbon steel electrode. Immediately after welding, the shells were given a stress-relieving treatment at 1250 F for 2 hr, and then were heat treated to a hardness of 311 to 375 Bhn.

Machining was resumed to obtain the configurations shown in the bottom middle view in Fig. 34. Next, the aluminum tank was shrink-fitted to the forward shell. The two shells were then aligned in a fixture to form the weld groove shown at upper right in Fig. 34. Finally, the assembly was mounted on a rotating positioner, and joined by automatic gas tungsten-arc welding with a low-carbon steel filler metal (Fig. 34, lower right). Because the buttering welds formed the base and sides of a continuous groove of low-carbon steel, the weld that joined the shells could be made without preheating and without the risk of cracking.

Both welding operations were carefully planned and executed, and the welds were thoroughly inspected. Submerged-arc welding was done with a $\frac{3}{32}$-in.-diam electrode and electrode-and-flux combinations having the AWS classifications EM12K-F71 and EM12K-F72.

Up to eight passes were required for buttering by submerged-arc welding. Interpass temperature was maintained within the range of 500 to 800 F. The first two passes were made using the EM12K-F71 combination at 300 amp, 27 to 28 volts, with straight polarity. Passes 3 to 8 were made using the EM12K-F72 combination at 420 amp, 28 to 29 volts, with reverse polarity. It was important to avoid excessive alloying of the filler metal with the base metal, which could have caused cracking. The change in flux type (same filler metal) for passes 3 to 8 was made to improve impact properties by reducing dilution of the weld metal. The joint areas (Fig. 34, middle views) were machined from low-dilution weld metal. These areas were required to meet stringent radiographic inspection. Slag was carefully removed after each pass. Weld starts, crossovers and any doubtful areas were ground to clean metal.

Gas tungsten-arc welding of the girth joint was done in five passes, using an automatically programed procedure. Details of welding conditions are given in the table with Fig. 34. Since both joint and filler metal were of low-carbon steel, preheating was not needed, but in order to prevent overheating the aluminum tank, it was necessary to limit interpass temperature to 200 F. Temperature at the joint was checked with temperature-indicating crayons. At the end of each pass, current automatically tapered off over a 10-sec trailing time, and the weld was wire brushed. After welding, the assembly was finish machined and ground to a 32-micro-in. finish.

Alloy steel forward and aft shells of a naval torpedo that were joined by gas tungsten-arc welding using no preheating (to avoid weakening of a pressed-in aluminum alloy tank), by first employing submerged-arc welding to make a buttering deposit of low-carbon steel filler metal in joint areas before machining (Example 226)

tions of a 54-in.-OD solid-propellant rocket-motor case. Figure 35 shows a section taken through the forward end of the 72-in.-long vessel (the aft end has been omitted). The branched section shown constituted the forged and machined Y-ring, made of AMS 6428 (4335 modified) alloy steel, which joined the cylindrical spun shell and the spherically dished forward head, both of AMS 6434 (4335 modified) alloy steel. The short stub of the Y-ring served for the later attachment of a supporting skirt. The Y-ring design provided optimum stress distribution for the welded joints and also afforded easy access to the joints for welding, radiographic inspection, and repair.

The motor case was designed to be welded in the annealed condition. After being welded, the vessel was heat treated to develop a minimum yield strength of 190,000 psi. At this strength level, a wall thickness of only 0.100 in. satisfied service requirements for strength and low weight. However, extremely reliable, defect-free welds were necessary. Weld design consisted of circumferential square-groove butt joints, with no root opening, welded from the outside only. There were no longitudinal seams. To obtain weld-metal properties matching those of the base metal, AMS 6458 was used for filler metal. This filler metal had been prepared by vacuum melting (composition is given in the table with Fig. 35).

Sections of the motor case were assembled on turning rolls, using internal and external clamping fixtures to ensure accurate alignment of the joint. Internal stainless steel backing that incorporated electrical resistance heaters for preheating and copper backing grooves for gas shielding was installed. Joints were welded in a single pass by rotating the assembly under a stationary welding head equipped with automatic wire feed and automatic voltage control. Additional welding conditions are given in the table with Fig. 35.

Example 228 (Fig. 36). The principal welded components of a typical D-6ac rocket-motor case, shown at upper left in Fig. 36, were a machined forward dome, two spun cylindrical sections, and a machined aft adapter (mechanically joined to an aft closure). Thus, the vessel design eliminated longitudinal joints, which would be subjected to hoop stresses, and required only three girth welds, which would be subjected to stresses of a lower order. To

reduce operating stresses in the welded joint further, the sheet thickness at the joint was increased approximately one-third, as shown in section A-A in Fig. 36. Mechanical properties of the welded joint closely comparable to those of the base metal were desired. The first step was to ensure cleanness of base metal and filler metal. Investigation established that using a 2.5Cr-1.0Mo steel filler metal resulted in the optimum combination of strength, fracture toughness, and resistance to cracking. A typical filler-metal composition was: 0.14 C, 0.54 Mn, 0.39 Si, 2.55 Cr, 1.02 Mo.

To obtain the desired joint strength properties repeatably and reliably, the gas tungsten-arc process was selected because of its capability for precise control. The gas-shielded arc and relatively low welding speed afforded good operator visibility for monitoring the operation. A voltage-controlled welding head, which facilitated precise control of arc length, was employed. The thickness at the joint (0.200 in.) made it possible to complete the joint in two welding passes, working from the outside of the vessel.

It was necessary to design a large, complex welding fixture, the functions and features of which were:

1 Two large end frames, at the headstock and tailstock, gripped the ends of the assembly by means of air-actuated toggle clamps and provided precise rotational speed through coordinated variable-speed drives.
2 Three two-piece round-out rings of box-shape cross section were bolted on the shell exterior to prevent the thin-wall vessel from bulging under its own weight. Each ring was supported by a set of freely rotating tank rolls.
3 An external clamp-ring assembly, bolted in place at either side of the joint, forced the joint edges into alignment against an internal, segmented backing ring expanded into position by an air-operated spider supported on a central mandrel. Figure 36 (upper right) shows the joint held between external and internal clamp rings with the electrode holder in position for welding. A continuous groove cut into the backing ring served to confine the underside of the weld and to supply gas shielding by means of a series of gas ports drilled through the backing. External shielding was supplied by the torch nozzle and by a short trailing

shield that protected the newly formed weld from atmospheric contamination until it had cooled sufficiently to be unaffected.

As shown in Fig. 36, preheat units (resistance heaters) were embedded in the external clamps and the backing ring. These units were used to maintain a preheat temperature of 500 to 650 F during the welding operation. Not shown is the split wraparound induction coil that supplied a 1200 to 1250 F local postheat cycle immediately after welding. The coil was powered by a 50-kw, 400-Hz motor-generator.

4 The welding fixture incorporated an observation platform that straddled the workpiece and enabled the operator to monitor the operation. The platform, tank rolls, end frames, headstock and tailstock were driven on the ways of the fixture bed.

The welding equipment comprised a 400-amp, dc power supply, a wire-feed drive with flow control for gas and cooling water, a gas tungsten-arc voltage-controlled welding head, and an electronic programing unit that coordinated the initiation, duration and termination of all elements of the welding cycle. The power supply was additionally equipped with upslope and downslope control of welding current to provide easy starts and to avoid formation of terminal craters. A high-frequency generator was integrated into the welding circuit to aid arc initiation. The above equipment, apart from the power supply and the high-frequency generator, was mounted on the boom of a manipulator within easy reach of the operator on the observation platform.

After the square-groove butt joint had been machined, the joint edges were polished bright with an 80-grit abrasive drum sander and cleaned by wiping with acetone. Roundup rings were then bolted on the forward dome and the first shell section. The forward dome was inserted in the end frame, the internal backing adjusted, and the external clamp ring attached. The first shell section was then loaded in position and clamped. Maximum allowable mismatch at joints was 0.020 in.

Welding was started when the joint attained preheat temperature, and the two passes were made without stopping. Pass 1 was made without filler metal. For the start of pass 2, the operator initiated wire feed by pushbutton. Welding was done in the flat position with the torch fixed at the top, or 12 o'clock position. The pass was terminated with downslope control.

After being welded, the joint was induction heated at 1200 to 1250 F for 1 hr. After cooling, both surfaces of the weld were ground smooth with abrasive belts of grit sizes 50 through 150, to facilitate inspection by radiographic and magnetic-particle methods.

The sequence was repeated for each of the two other joints. When completed, the entire vessel was heat treated to a hardness of Rockwell C 46 to 49. Further details of welding conditions are given in the table with Fig. 36.

Tensile properties of weld metal and base metal after heat treatment are shown in the graphs in Fig. 36. As the graph at the right shows, weld-joint yield strengths were in excess of 210,000 psi. In addition, the joints consistently withstood hydrostatic proof testing at 90% design pressure. Proof tests established the integrity of the entire vessel under stresses equivalent to those expected in service.

Plasma-Arc Welding

Plasma-arc welding is generally considered as a refinement of gas tungsten-arc welding. It offers the close control of composition and heat input that are obtainable with gas tungsten-arc welding, but is much faster. Thus, the process is sometimes used for welding alloy steel when quality requirements are stringent and production quantity is moderate or high.

Disadvantages of the plasma-arc process for welding alloy steel are the same as for welding other metals — namely, high initial cost of equipment and high maintenance cost (see the article on Plasma-Arc Welding, beginning on page 138 in this volume).

Codes, Standards and Regulations

Boilers and Pressure Vessels. Codes, standards and regulations applicable to the construction and maintenance of welded boilers and pressure vessels include:

1 ASME Boiler and Pressure Vessel Code, Sections I to X, and Case Interpretations
2 U. S. Navy: MIL-STD-248, 271, and 278; NAVSHIPS 250-1500-1
3 Marine Engineering Regulations and Materials Specifications; U. S. Coast Guard
4 American Bureau of Shipping Rules for Building and Classing Steel Vessels
5 Standards; Tubular Exchanger Manufacturers' Association, Inc.
6 Lloyd's Rules and Regulations; Lloyd's Register of Shipping
7 CSA Standard B51-1965, Code for Construction of Boilers and Pressure Vessels; Canadian Standards Association.

Bridges and Similar Structures. The following specifications apply to bridges and similar welded structures that are subjected to frequent variations in loading intensity:

1 Specifications for welded highway and railroad bridges: AWS D2.0-66
2 Specifications of the American Association of State Highway Officials
3 Specifications of the American Railway Engineering Association.

Buildings. Specifications for welding in building construction are covered by AWS D1.0-66. These specifications are in general agreement with the AISC Specification for Design, Fabrication and Erection of Structural Steel for Buildings.

Field-welded storage tanks are usually constructed in accordance with codes prepared to meet the needs of a specific industry only. Tanks for water are covered by: Standard for Steel Tanks, Standpipes, Reservoirs and Elevated Tanks for Water Storage (AWWA D100-65; AWS D5.2-65). Welded tanks for oil storage are covered by API Standard 650 (Dec 1961).

Industrial piping is covered by several codes and standards, including:

1 ANSI Standard B31, Code for Pressure Piping, Sections 1 through 8
2 ASME Boiler and Pressure Vessel Code, Sections I, III, VIII and IX
3 API Standard 1104
4 AWWA standards covering fabricated piping
5 Pipe Fabrication Institute standards
6 U. S. Navy Bureau of Ships Specifications NAVSHIPS 250-582 and 250-1500-1
7 Procedures by The Heating, Piping and Air Conditioning Contractors National Association.

Nuclear-power pressure vessels are covered by ASME Boiler and Pressure Vessel Code, including Section III and Case Interpretations; also by ANSI Standard B31, Code for Pressure Vessel Piping (together with its Case Interpretations).

Railroad Tank Cars. The Interstate Commerce Commission and the Association of American Railroads regulate the design, specifications and codes for manufacture of tank-car frames and vessels.

Transmission pipelines are covered by API Standard 1104, Field Welding of Pipelines; also by ANSI Code for Pressure Piping — Oil and Gas Piping Systems.

Arc Welding of Cast Irons

*By the ASM Committee on Welding of Cast Irons **

SATISFACTORY JOINTS have been obtained in gray, ductile and malleable cast irons by arc welding. The tensile strength of welded cast iron joints is usually less than that of the base metal, and the heat-affected zone is usually harder and more brittle than the original casting. Lack of reproducibility in joint tensile strength has also been observed. Nevertheless, large quantities of iron castings are welded successfully by the processes discussed in this article.

Most welding is done on gray iron and the least on malleable iron. The welding of ductile iron occupies an intermediate position.

The three major areas of application of welding to cast iron are:

1 Repair of casting defects in the foundry
2 Repair of castings that have become damaged or worn in service
3 Production of welded assemblies.

Repair of Casting Defects. Repair welding of defects in new iron castings represents the largest single area of application of welding to cast iron. Minor defects, such as porosity, sand holes, washouts, cold shuts, or shift, can usually be repaired. Thousands of tons of new automotive engine blocks are repaired annually by arc and oxyacetylene welding. Braze welding is also used in applications where the color contrast of the copper-base filler metal is not objectionable. Repair welding of defective castings is described in Examples 229, 230 and 234.

Casting defects discovered during machining, or resulting from machining errors, are also repaired by welding. Repairing of machined castings is often done by shielded metal-arc welding using nickel-iron electrodes (ENiFe-CI). This filler metal provides welds that are less brittle than those made with cast iron electrodes (ECI), and a better color match than can be obtained with braze welding.

Arc welding is faster than oxyacetylene welding, and causes less distortion. Although the welding temperature is high in arc welding, the total heat input is lower than for oxyacetylene welding, because of the high speed and the small area heated in arc welding. Thus, the heat-affected zone is less for arc welding than for gas welding.

Repair of Damaged Castings. Castings that have cracked or broken in service can often be repaired by arc welding. Worn surfaces of castings can also be rebuilt. Filler metals are available for building up worn parts to obtain bearing surfaces or resistance to abrasion and corrosion.

In repairing damaged castings, the conditions under which the welding must be done may be unsuitable for good welding practice, and they may call for extra care and improvisation, sometimes under the pressure of an emergency. Castings that have been in service for a long time may need special attention to the removal of oil and other foreign matter that has impregnated the casting by way of graphite flakes or microcracks. Edge preparation may involve veeing out a crack. These operations must be thorough if the repair is to stand up in service. If furnace heating is impractical, improvised methods of preheating and postheating may be required. For example, a furnace may have to be constructed around the part, or local preheating may be required, depending on the size, shape and intended use of the part.

If the cost can be borne, shielded metal-arc welding, using nickel-iron electrode ENiFe-CI, is preferred. Generally, however, the repair of broken castings is done under whatever conditions and with whatever electrode the circumstances demand or will permit.

Production of assemblies by welding iron castings to other iron castings or to other metals offers several advantages. An increasing number of ductile and malleable iron castings are joined in this manner, and some gray iron castings as well. Assemblies produced by welding are described in Examples 232 and 233 (gray iron), Examples 235 and 236 (ductile iron), and Examples 238 to 241 (malleable iron).

For speed, an arc welding process is usually preferred, but oxyacetylene braze welding and oxyacetylene welding (see the articles that begin on pages 579 and 583) are also used.

Weldability

Cast iron is considerably less weldable than low-carbon steel. Cast iron contains much more carbon and silicon than does steel, with the result that cast iron is less ductile, and, when welded, is subject to more metallurgical complications in both the weld metal and the heat-affected zone.

Weld-Metal Area. In addition to the normally expected constituents (graphitic carbon, pearlite and ferrite), the microstructure of a gray iron weld deposit may contain massive (free) carbide and martensite. The presence of these constituents, and their size, form and distribution, are the combined effects of: (*a*) the carbon and silicon contents of the weld deposit and (*b*) the cooling rate in the weld area.

If a weld is made, with a cast iron electrode, in a malleable iron or a ductile iron casting, the carbon is mostly in the combined form. The graphite that precipitates from the molten weld metal during cooling is in flake form, as in a gray iron casting, and not in spheroidal form, as in a malleable iron or ductile iron casting. The flake graphite reduces the ductility of the area in which it occurs. For these reasons, welds having the ductility of the base metal usually cannot be made with cast iron electrodes.

Heat-Affected Zone. The temperature produced in the heat-affected zone is usually high enough to transform the base metal to austenite, provided carbon is available. When rapidly cooled, high-carbon austenite transforms to brittle martensite.

The ferritic grades of gray and ductile iron do not readily form austenite on heating (and martensite on cooling) because nearly all of the carbon is in the form of graphite and the time at temperatures above the transformation range is too short for diffusion of carbon from the graphite.

The pearlitic grades of gray and ductile iron readily form martensite when rapidly cooled from above the transformation range, because the combined carbon content of the pearlitic matrix is rapidly dissolved to form high-carbon austenite when heated.

Martensite. The martensite formed in the weld deposit and in the heat-affected zone behaves in the same way as the martensite in a quenched steel; it can be transformed into softer products by tempering. The heat for tempering can be supplied by preheating and welding, followed by protected cooling, or by preheating, welding and postheating, or (less commonly) by welding and postheating.

The heat of welding alone in single-pass arc welding will not temper the martensite enough to provide reasonable machinability or to reduce the danger of postweld cracking to an acceptable level. In multiple-pass welding, each succeeding bead tempers the one underneath or adjacent to it. Additional tempering is provided by the cumulative heating effect of the passes.

The alternative to tempering the martensite is to modify the welding procedure by reducing the heat input to produce a narrower heat-affected zone and thus to decrease the amount of martensite formed.

Free Carbides. Once free carbides are formed in the weld or the heat-affected zone, the only way they can be broken down into softer constituents is by an-

nealing at 1600 F or higher. Such treatment may be undesirable because it increases the cost of the weldment and may reduce the tensile strength of the base metal.

The alternative is to prevent, whenever possible, the formation of carbides or, failing that, to reduce their occurrence to manageable proportions. Several methods for preventing or reducing carbide formation can be employed, either singly or in combination.

First is the use of a cast iron electrode (Table 1) of a composition that will produce, after deposition losses of silicon, carbon and manganese, a solidified weld metal of approximately the same composition as the base metal. This eliminates dilution of the weld metal, a first step in reducing the formation of free carbides.

The second method is to preheat the casting to the maximum temperature that is consistent with the acceptable losses in casting hardness and strength. In practice, this temperature seldom exceeds 1200 F for general preheating. Increasing the time for dissipation of heat delays the cooling of the weld area to enable the previously formed free carbides to break down.

When properly applied, a combination of these two methods will, for all practical purposes, reduce the carbide problem in gray or ductile iron.

A third method is to use one of the high-nickel or nickel-copper filler metals (Table 1). Because both nickel and copper are effective graphitizers and do not form carbides in cast iron, their presence in the weld effectively reduces carbide formation.

A fourth method is to reduce the heat input. In gas metal-arc welding, the short-circuiting arc is often used because it can be accurately controlled to the point where only enough base metal is melted to effect a bond with the filler metal. This reduces the amount of base metal available for formation of free carbide during subsequent solidification. When a nickel or nickel-copper electrode is used with a short-circuiting arc, the formation of free carbide is inhibited to the extent that the weld is usually machinable, although at a reduced rate.

Graphite. Once graphite forms in the weld deposit, it will precipitate as flakes. This behavior creates a problem in the welding of malleable and ductile irons.

Malleable iron weldments can be given a full malleablizing treatment. Although this treatment will be reasonably successful if the composition of the weld deposit is about the same as that of the base metal, it is economically unattractive. If a steel filler metal is used, hard phases will form in that portion of the deposit in which there is dilution by the base metal.

Flake graphite in the weld deposit in ductile iron cannot be converted to the nodular form.

Stresses. The weld area will be under shrinkage stress. Cracks may occur on or beneath the surface of the weld deposit, in the heat-affected zone, or in the base metal, depending on the stress intensity and distribution. The methods employed to control or to prevent the formation of free carbide and to reduce the formation of martensite, or to transform it to softer products, also act to reduce the stress level in the weld and adjacent areas. The degree of effectiveness of these measures depends on the maximum temperature attained and the cooling rate.

Welding Procedures

An important step in many procedures for welding cast iron is the designation of those areas on a casting where welding is permitted, including restrictions as to the type of weld allowed. Such designations, or their converse — areas where welding is *not* permitted — may be in the form of marked drawings, specially prepared sketches, or marked photographs of castings.

As a rule, welding of any kind is prohibited in highly stressed areas or in areas where the failure of a weld would result in failure of the casting. Welds on surfaces to be machined are acceptable, provided the area is not highly stressed.

Repair welding is used extensively on cast engine cylinder blocks and heads, but it is generally prohibited on the fire deck, water jacket, main bearing supports and their supporting ribs, cylinder-head stud bosses, and cylinder bores. Repair of defects on pan rails, bell-housing flanges, and valve-cover flanges, and buildup of short-run attachment pads and bosses for hold-down stud holes in heads, are often allowed. There are no fixed rules; each user sets his own requirements. Some prohibit the welding of any porous area or crack or any defect that penetrates the casting wall; others permit such repair, provided a hole is drilled at each end of the crack and a complete-penetration weld is made. One user permits welding in the unjacketed part of a cylinder bore.

Preparation for any weld repairs, except faulty bosses and pads and similar surface defects, is a relatively simple procedure that involves:

1. Removing enough material to eliminate the defect completely
2. Producing a weld area of such configuration that there is room to manipulate the electrode or electrode holder.

When the defect requires V-shape preparation, an included angle of 60° is usually sufficient. The smaller the included angle, consistent with accessibility, the shorter the welding time, because less filler metal is required. When the defect penetrates the section, a suitable land should be provided whenever possible. In thin sections, a backing may be needed; in thicker sections (1 in. or more), preparation of the joint by double-V grooving is desirable.

Preheating

The presence of a brittle zone at the weld, caused by rapid freezing of weld metal and rapid cooling of weld metal and adjacent base metal, reduces the ability of the joint to withstand tensile stress in service and makes the joint susceptible to cracking immediately after welding, as a result of local contraction stress. By heating the casting before welding, both of these adverse effects can be reduced. Preheating slows the rate of cooling in the critically heated zone, which induces the formation of a more favorable structure. Preheating also enables the entire casting, or a large part of it, to contract with the weld zone, thereby minimizing the development of residual stress in metal near the weld area. Metal in the weld area can also benefit from preheating, because the weld metal cools more slowly through the transformation range and therefore develops softer microstructures.

High preheats produce softer, less brittle microstructures than do low preheats. With high preheats, however, welding is more difficult. The casting must be insulated from rapid loss of heat so that the preheat temperature can be maintained throughout the welding operation. The heat input from welding can be used to help maintain interpass temperature in small and medium-size castings. In large castings, steep thermal gradients should be avoided to prevent cracking.

To ensure proper control, temperature should be measured by contact pyrometers or temperature-indicating crayons at or near the weld zone and at as many other places as the casting size and heating method may indicate.

During welding of large preheated castings, the welder must be protected from the heat. This is usually done by exposing only the area being welded at the time, and by changing welders if the operation is of long duration. Preheat temperature must be maintained uninterruptedly until welding is completed. Recommended preheat temperatures are discussed in the individual sections of this article devoted to gray, ductile and malleable irons.

When repairing castings cracked or broken in service, cost is often of less concern than obtaining a satisfactory repair. In production welding, however, both time and cost are important. The manufacturer of the weldment cannot afford to lose the advantage of the low cost of iron castings by using costly welding procedures. For production welded assemblies, preheat costs are low when the castings are small and rapid welding procedures of low heat input are used. Joints are preferably located away from areas of high stress and surfaces to be machined. Since fast welding at low heat input produces a small heat-affected zone, preheat requirements are low. Under optimum conditions, arc welded joints have been made between ductile or malleable iron castings and low-carbon steel without preheat or postweld heat treatment. For most applications, however, preheating and postheating are advisable, either to reduce joint brittleness and residual stress or to improve machinability, or both.

Postweld Heat Treatment

Postweld heat treatment may consist of either full annealing or stress relieving. When heat treatment is not applied, the welded casting is usually cooled slowly from the welding temperature to room temperature by covering it with insulating material such as lime, ground asbestos, or vermiculite.

Stress relieving at 1150 F and then furnace cooling to at least 700 F is recommended whenever feasible.

Full annealing at 1650 F is sometimes employed to produce greatest softening of the weld zone or a more complete stress relief. However, annealing lowers the as-cast tensile strength of all but the softest irons.

In critical applications that require radiographic or ultrasonic inspection after heat treatment, castings often are inspected before treatment also, to save unnecessary costs if an internal defect should be present.

Preparation of Castings

Edge preparation is similar for all cast irons. Castings that have been in service are likely to be impregnated with oil or grease, and accordingly surface contamination should be removed with solvents, commercial cleaners, or paint removers, as required. Casting skin should be removed from surfaces to be welded and from adjacent areas by grinding, chipping, shot blasting, rotary filing, or equivalent means.

Blind cracks and pits must be completely dressed out to sound metal; otherwise, the heat of welding or subsequent service may propagate the defect. For this purpose, chipping, grinding, rotary filing, and machining are preferred to arc or gas cutting, which may propagate the defect through differential expansion. Magnetic-particle inspection is recommended to ensure that the crack has been completely removed. Some castings contain sealed internal passages that must be vented to prevent explosion during preheating.

Completely broken sections are dressed by any suitable method to form a single-V groove, leaving a $\frac{1}{16}$ to $\frac{1}{8}$-in. root face to align the parts. For arc welding, a 60° included angle (30° bevel) is usually adequate, although for thick sections a U-groove with a smaller groove angle may be used.

Heavy sections can be prepared for arc welding by using a double-V groove — that is, a V cut from both sides of the joint with a root face at or near the center to permit alignment.

Cleaning. Impregnated oil or other volatile matter can be eliminated by heating the casting or weld groove to approximately 900 F (dull red heat) for about 15 min and then wire brushing, grinding or rotary filing to remove the residue. This method has the advantage of degassing the casting and removing some of the surface graphite as well. Impregnated oil, gas and possibly carbon are major causes of excessive porosity in cast iron welds.

New castings present less of a cleaning problem than castings returned from service. However, casting skin, sand, and other foreign matter must be removed from the joint to be welded and the adjacent surfaces of the casting. Weld grooves are prepared as described above, according to the size of the defect or the desired joint. Castings that are gassy can be heated as described for impregnated castings.

Filler Metals

Cast iron, low-carbon steel, nickel-base alloys and copper-base alloys are the filler metals used in arc welding of cast iron. The covered electrodes classified in AWS-A5.15-69 for shielded metal-arc welding of cast iron are discussed below, where their principal features are summarized; nominal compositions are given in Table 1. In addition to those shown, the covered low-carbon steel, low-hydrogen electrode E7018 has been used (see Examples 233, 236 and 238). Where processes such as gas metal-arc welding are applicable, bare wire electrodes of low-carbon steel and nickel-base alloys also are used.

Covered nickel-base electrodes are classified as "pure" nickel (ENi-CI), nickel-iron (ENiFe-CI, 55% nickel), and nickel-copper (ENiCu). They are relatively expensive. The nickel and nickel-iron electrodes are widely used and the most successful.

Welds made with nickel electrodes are relatively ductile even when applied on thin sections without preheat, and are, therefore, easily machinable. Nickel welds are susceptible to cracking from phosphorus when the latter is present in the high quantities that are often present in gray iron. Because the phosphorus contents of ductile and malleable irons are lower than that of gray iron, nickel electrodes are well suited to these irons.

Nickel-iron electrodes are less expensive than the nickel type and are less susceptible to phosphorus-induced cracking.

The hardness of deposits from both nickel and nickel-iron electrodes will depend on dilution and cooling rate. Melting of the base metal should, therefore, be held to the minimum necessary. Preheating at temperatures of 300 to 600 F will aid machinability and help to reduce thermal stress. Peening with moderate blows, using a round-nose tool, can also be employed to reduce thermal stress.

Cast Iron Electrodes (ECI). Shielded metal-arc welding with cast iron electrodes must be on preheated parts, because of the high heat input of the arc. The method is fast for correcting small flaws, but because a high-temperature preheat is required, it offers no advantage over gas welding.

Steel electrodes (ESt) contain low-carbon steel cores with specially designed coverings to permit use at low amperage. Since the deposit is steel, it picks up carbon and produces a hard constituent in the fusion zone, unless it is used with a high preheat or the resulting weld is annealed.

Copper-base electrodes are of the copper-tin (ECuSn) or the copper-aluminum (ECuAl-A2) type. Arc welding with these electrodes can be considered a form of braze welding, since the filler metal melts at a much lower temperature than the iron. Heat input is higher than in gas or braze welding, although high deposition rates at low amperage are obtained. Deposits do not harden from carbon pickup, can absorb shrinkage stresses, and are machinable. Color match is poor. Wide grooves and thoroughly cleaned joints are essential for maximum bond strength. Preheats of 300 to 400 F should be used; slow cooling is necessary to benefit the heat-affected zone.

Differences in coefficient of expansion between filler metal and base metal are sometimes blamed when rupture tests show parting at the bond line, but if the weld is properly made, satisfactory strength can be obtained.

Copper-aluminum welds have higher strength than copper-tin welds and are used with higher-strength irons. These electrodes are also used in surfacing applications for bearings and for producing surfaces that resist corrosion and wear.

Various techniques can be used with these filler metals to improve joint quality. The following practices have been found to be helpful:

1. Use stringer beads.
2. Use low amperage.
3. When no preheat is used, the interpass temperature should not exceed 200 F. (Interpass temperature is the lowest temperature attained by the deposited weld metal before the next pass is started.)
4. When preheat is used, the interpass temperature should not exceed the preheat temperature.
5. To minimize welding stress, use a backstep sequence, with stringer beads no more than 2 to 3 in. in length. (In the backstep method, the weld is started about 2 to 3 in. from the normal starting point and welded back the same distance; subsequent beads are started and deposited similarly.
6. Avoid melting more of the cast iron than is necessary for fusion.
7. Whenever possible, deposit two or more layers, for best machinability.
8. Always strike the arc in the weld groove, never on the casting.

Gray Iron

High-carbon, high-silicon (ASTM class 20) gray irons are ferritic in structure, with coarse graphite flakes throughout the matrix. Low-carbon, low-silicon irons such as class 50 irons are pearlitic. The intermediate grades are mixed in structure, partly ferritic and partly pearlitic. (For detailed information on the relations among composition, section thickness, structure, and mechanical properties of gray iron, see the article on pages 349 to 365 in Volume 1 of this Handbook.) Ferritic gray irons are readily welded, but the irons of complex structure are, like high-carbon steel, difficult to weld.

When welded with no preheat, gray iron is heated quickly above the upper transformation temperature, absorbs carbon and is immediately chilled by the surrounding cold metal to temperatures at which martensite forms. Hence,

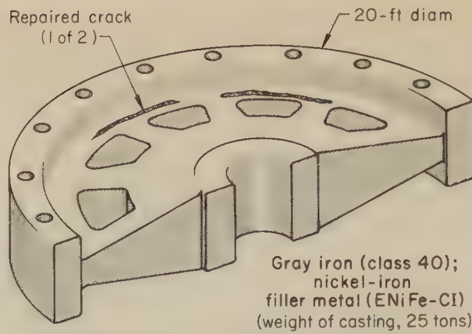
adjacent to the weld, there is a heat-affected zone that is hard and brittle. The weld, which consists of a mixture of base metal and filler metal, may be softer, but this depends largely on the composition of the filler metal used. If the iron is preheated, the heat-affected zone subsequently cools more slowly and transforms to softer products, rather than to hard, brittle martensite. The effect of preheating on the hardness of welds made by the shielded metal-arc process using nickel-iron electrodes is shown in Table 2.

Gray iron that has been welded with no preheat is difficult to machine. Cracking can also occur, since the metal shrinks in cooling and puts a tensile stress across the joint. If cooled slowly, the weld and the heat-affected zone are more likely to accommodate the stress before becoming cold. Similarly, stress relieving the weld areas at 1150 F while the weld areas are still hot will equalize stresses and help to prevent cracking.

Process Comparisons. Table 3 compares the processes most frequently used for welding gray iron and shows the color match and tensile strength ordinarily expected with good welding practice. Table 4 indicates the hardening effect of arc welding and of gas welding.

Gas metal-arc and gas tungsten-arc welding are expensive, chiefly because of the cost of the shielding gas used. Gas welding with cast iron filler metal gives the best color match, but it requires a high preheat — preferably at 1100 F or above — and a flux is required, to absorb the iron silicate slag. Generally, the choice of method is between shielded metal-arc welding with nickel or nickel-iron electrodes and gas welding with cast iron filler metal.

Shielded metal-arc welding with covered ("stick") electrodes is used on gray iron and ductile iron, and to a small extent on malleable iron. The type of deposit, and to some extent the procedure for welding, will vary according to the electrode used. Electrodes for manual welding of cast iron by the shielded metal-arc process are discussed in the foregoing section on Filler Metals.



Welding Conditions

Process ....Shielded metal-arc welding
Electrode ....3/16-in. ENiFe-CI(a)
Current ....160 amp, dcrp
Voltage ....24 v
Preheat (local) ....400 to 450 F
Postheat ....Cooled slowly to room temperature, then stress relieved at 1100 F(b)

Hardness After Stress Relief

Base metal ....178 to 187 Bhn
Weld metal ....169 to 176 Bhn
Heat-affected zone ....210 to 241 Bhn

(a) Covered electrode with 55% nickel – 45% iron. (b) Weld area was packed in asbestos; furnace was not immediately available.

Fig. 1. Large gray iron casting in which cracks were repaired by shielded metal-arc welding (Example 230)

Table 5 shows current ranges for four sizes of nickel-iron and nickel electrodes used in shielded metal-arc welding, and Table 6 shows ranges of welding current for three sizes of cast iron electrodes.

When using nickel electrodes (ENi-CI), the groove is prepared (see the section on Preparation of Castings in this article) and then the weld area or the entire casting is preheated to a temperature between 400 and 600 F. The weld is built up in successive passes not more than 1/8 in. thick, until the groove is completely filled. The casting can be cooled slowly under insulation, or can be stress relieved at 1100 to 1200 F and cooled slowly in the furnace.

Table 2. Effect of Preheat on Hardness of Shielded Metal-Arc Welds in Class 20 Gray Iron Welded With 3/16-In. Nickel-Iron (ENiFe-CI) Electrodes

Preheat temperature, F	Brinell hardness: Weld	Heat-affected zone	Base metal
No preheat	342-362	426-480	165-169
225	297-362	404-426	165-169
450	305-340	362-404	169
600	185-228	255-322	169-176

Table 3. Approximate Tensile Strength and Color Match Obtainable in Welded Joints in Gray Iron Using Different Processes(a)

Process	Filler metal	Base-metal class	Tensile strength of joint, psi(b)	Color match
Gas welding	RCI	30	25,000 to 30,000	Good
	RCI	40	30,000	Good
	RCI-A	40	30,000	Good
Shielded metal-arc welding	ENi-CI	30	25,000 to 30,000	Fair
	ENiFe-CI	30	25,000 to 30,000	Fair
	ENiFe-CI	40	36,000	Fair
	ESt	30	30,000	Poor to fair
	ESt	40	40,000	Poor to fair
Braze welding	RCuZn-A	30	(c)	Poor
	RCuZn-B	30	(c)	Poor
	RCuZn-C	40	(c)	Poor
	RCuZn-D	40	(c)	Fair
Gas metal-arc welding	Ni or Ni-Fe wire(d)	30	40,000	Fair
	Ni or Ni-Fe wire(d)	40	40,000	Fair
Gas tungsten-arc welding	Ni or Ni-Fe wire(d)	30	40,000	Fair
	Ni or Ni-Fe wire(d)	40	40,000	Fair

(a) Based on results reported from various tests and on production experience. (b) Approximate strength expected if good welding procedures and skilled operators are used. Wide variations in strength may occur as a result of variation in welding practice or in base-metal condition or size. (c) Joint strength approaching or equal to base-metal strength has been obtained, but large variations in strength have been observed because of variations in base-metal conditions or welder skill. (d) These filler metals are not classified, but wire coils and rods of compositions equivalent to ENi-CI and ENiFe-CI are obtainable.

Gas metal-arc welding is less well suited to welding gray iron than to welding ductile and malleable irons (see the discussion of gas metal-arc welding in the section on Malleable Iron, page 242). However, this process was used in welding a gray iron sump base to a steel plate in Example 233, which gives the welding conditions used.

Gas tungsten-arc welding can be used for joining gray iron. Joint preparation is the same as for shielded metal-arc welding, but a higher preheat is recommended. Argon or argon with an oxygen additive is used as the shielding gas. Welds have been made using nickel, nickel-iron, gray iron, and series 300 stainless steel filler metals, with straight-polarity direct current. Results are comparable to, but no better than, those obtained by other welding processes. Because no particular advantage is gained, gas tungsten-arc welding is not used when another, less costly process is available.

Examples of Practice. More welding of gray iron is done in the foundry repair of defects in new castings than in any other type of application. The arc welding process most frequently used is shielded metal-arc welding. The five examples of commercial practice that follow show how gray iron was welded in the repair of defects in new castings, in the salvage of worn or broken castings, and in the production of welded assemblies.

The repair of several defects in a pump casting intended for use in a paper mill is described in the first example that follows. Because the defects were discovered after final machining had been completed, scrapping the casting at this stage of production would have been expensive.

Example 229. Use of Shielded Metal-Arc Welding To Repair Casting Defects

During hydrostatic testing, two casting defects were detected in the machined gray iron housing of a large multiple-impeller pump. The defects were chipped out with an air gun, exposing two small voids that extended through unmachined sections of the housing wall, approximately 1½ in. thick. Further inspection showed a third defect, which was completely removed by chipping to a depth of ¾ in. Because the housing was fully machined, scrapping it would have been costly, and it was decided to repair the defects by welding.

The problem was to avoid distortion of the machined surfaces during welding and to deposit leakproof welds capable of withstanding a 150-psi hydrostatic test. Tapered weld grooves were chipped out, the largest measuring about 4 in. long and 1 in. wide at the surface. All traces of cutting oil were removed by solvent cleaning. To minimize heat input, shielded metal-arc welding, without preheat, was selected in preference to gas welding. A 1/8-in. ENi-CI electrode (85% nickel, min) was used.

To avoid overheating, beads not more than 1 in. long were deposited along the length of the weld groove, and the welding was alternated on the two sides; current was set at 90 amp, 22 volts, dcrp. Weld grooves were allowed to cool to 200 F (measured by temperature-indicating crayons) between successive passes. All beads

except the finish bead were peened. After welding, the casting passed the hydrostatic test. No distortion of the repaired and machined surfaces was detected.

The following example describes the repair welding of one half of a large gray iron retaining plate.

Example 230. Repair Welding of Cracks in a 25-Ton Casting (Fig. 1)

Shielded metal-arc welding was selected for repairing two cracks in the new 25-ton, 20-ft-diam gray iron casting shown in Fig. 1, because it was simpler, faster and less expensive than gas welding. Gas welding would have entailed high preheat in a large furnace, difficult welding conditions, and care in maintaining high interpass temperature. Shielded metal-arc welding, using a nickel-iron electrode (ENiFe-CI), was done with local preheat at 400 to 450 F.

Both cracks were dressed out to form 60° V-grooves by chipping and grinding. Crack depth varied from 1 to 1¾ in.; length was about 30 in. Magnetic-particle and dye-penetrant inspection methods were used to determine completeness of crack removal. The casting was then locally preheated, using gas torches; preheat temperature was checked by temperature-indicating crayons and a surface pyrometer. Stringer beads were deposited the full length of the cracks. After welding, the casting was allowed to cool slowly, with asbestos packing around the weld area. The casting was stress relieved at 1100 F. Welds were machined.

Additional details of the welding procedure, as well as results of hardness tests taken after stress relief, are given in the table with Fig. 1.

Table 4. Effects of Welding Process, Preheat and Postheat on Hardness of Gray Iron (a)

Welding process	Preheat	Postheat	Brinell hardness: Base metal	Brinell hardness: Heat-affected zone
Gas(b) ..	None	None	167	277
Arc(c) ..	None	None	163	241
Gas(b) ..	500 F(d)	None	159	269
Arc(c) ..	500 F(d)	None	170	235
Gas(b) ..	None	1150 F	159	262
Arc(c) ..	None	1150 F	159	197

(a) Based on six specimens taken from a single heat with a composition of 3.46 C, 1.53 Si, 0.65 Mn, 0.096 P, 0.024 S. (b) With RCI filler metal. (c) Shielded metal-arc welding, with ENiFe-CI filler metal. (d) Higher preheat was not feasible because of small size of samples.

In addition to repair of defective or damaged castings, welding can be used to rectify production errors, as in the next example, in which a manufacturer of electric motors had to weld ribs omitted from cast motor frames in order to meet the production schedule for a specific line of motors.

Example 231. Alteration of Castings by Shielded Metal-Arc Welding (Fig. 2)

A tight production schedule on four motors was interrupted because the motor frames had been cast without ribs. Because the foundry was unable to supply replacements in less than three weeks, the motor manufacturer decided to correct the error by welding steel ribs to the frames, as shown in Fig. 2.

The ribs, 12 in. long, were cut from 1½-by-2-in. 1020 steel bar stock and tack welded in position. All surfaces to be welded were cleaned by sand blasting. Shielded metal-arc welding with 3/16-in. nickel electrodes (ENi-CI) was used to deposit ¼-in. fillet welds on all sides of the ribs. Welding current was 160 amp, 40 volts, dcrp. The castings were welded without preheat or postweld heat treatment. The only mechanical test of the welds occurred

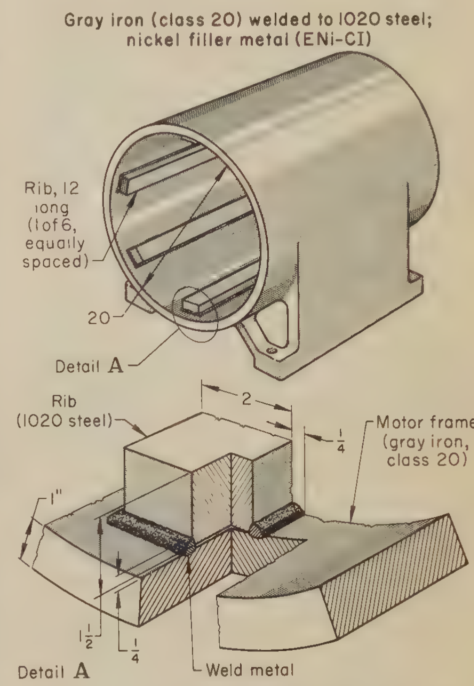
Table 5. Welding-Current Ranges for Shielded Metal-Arc Welding of Cast Iron With Nickel-Iron and Nickel Electrodes (a)

Electrode diameter, in.	ENiFe-CI electrodes(b): Current (dc), amp(d)	ENiFe-CI electrodes(b): Current (ac), amp	ENi-CI electrodes(c): Current (dc), amp(d)	ENi-CI electrodes(c): Current (ac), amp
3/32	40 to 70	40 to 70	40 to 80	40 to 80
1/8	70 to 100	70 to 100	80 to 110	70 to 110
5/32	100 to 140	110 to 140	110 to 140	110 to 150
3/16	120 to 180	130 to 180	120 to 160	120 to 170

(a) For welding in the flat position; current for overhead welding should be 5 to 15 amp less than shown; for vertical welding, 10 to 20 amp less. (b) Percentage composition, based on analysis of deposit on standard test pad: 2.00 C, 4.00 Si, 1.00 Mn, 0.03 S, 45 to 60 Ni, 2.50 Cu, 1.00 other, remainder Fe. (c) Percentage composition, based on analysis of deposit on standard test pad: 2.00 C, 4.00 Si, 1.00 Mn, 0.03 S, 8.00 Fe, 85 min Ni, 2.50 Cu. (d) Either polarity.

Table 6. Welding-Current Ranges for Shielded Metal-Arc Welding of Gray Iron With Cast Iron Electrodes

Electrode diameter, in.	Current (ac), amp
1/8	150 to 175
3/16	175 to 200
1/4	200 to 250



Cost of Altered Castings

Four castings	$307.36
Twenty-four ribs	19.52
Nickel electrodes	25.20
Labor and overhead	51.84
Total cost	$403.92
Alteration time	1 day

Cost of Replacing Castings

Four original castings	$307.36
Less scrap value	8.00
Net cost	$299.36
Four new castings	307.36
Total cost	$606.72
Replacement time	21 days

Fig. 3. Pump impeller cast in two pieces and joined by plug welding as shown, to avoid vane-passage obstructions encountered when impeller had been cast in one piece (Example 232)

during machining the inside diameter for stator clearance: each rib was struck more than 750 times as the boring tool was fed through the 12-in. rib length.

As the table with Fig. 2 shows, altering four castings by welding cost only 66% as much as replacement, and saved 20 days.

Welding can be used in the production of assemblies that require joining of cast iron to cast iron or to a dissimilar metal, often under special conditions. The two examples that follow illustrate this use of welding. In the first example, shielded metal-arc welding eliminated a casting problem. In the second, gas metal-arc and shielded metal-arc welding gave satisfactory results at the desired low cost.

Example 232. Shielded Metal-Arc Welding Cast Components of an Impeller Redesigned for Production as a Two-Piece Weldment (Fig. 3)

When impellers for high-pressure pumps were cast in one piece, they were frequently rejected because of obstructions in the vane passages. Pump performance was affected by even small obstructions, which were difficult to reach for repair. This problem was overcome by casting the impeller in two pieces (Fig. 3a), clamping the pieces in a fixture (Fig. 3b), and joining them with 20 plug welds (Fig. 3c, and detail A in Fig. 3).

Holes were drilled and countersunk in the shroud to give access to vane surfaces for plug welding (Fig. 3a). The components were degreased after machining, assembled in the fixture as shown in Fig. 3(b), and welded in the sequence given in Fig. 3(c).

The welds were required to withstand centrifugal forces created at 3600 rpm, and had to be machinable. Machinability was important because impellers of various diameters were made by turning down larger sizes. Shielded metal-arc welding, using a nickel electrode (ENi-CI), satisfied all requirements. Deposits of this electrode were found to be tough, yet machinable. Sequence welding distributed welding stresses evenly and resulted in better distribution of operating stresses. Additional welding details are given in the table with Fig. 3.

Example 233. Use of Gas Metal-Arc and Shielded Metal-Arc Welding for Joining Low-Carbon Steel to Gray Iron (Fig. 4)

Two welds were required on the class 30 gray iron sump base shown in Fig. 4. One joined the sump base to a low-carbon steel plate and the other joined a low-carbon steel oil-return tube to the sump base.

In joining the sump base to the low-carbon steel plate, gas metal-arc welding was used, because it was the lowest-cost process. Since this weld was noncritical, being used to hold the parts together to permit completion of the sump, the presence of hard constituents and cracks in the weld metal was of no consequence. As a result, the parts to be joined were not preheated or postheated. However, two sets of welding conditions were evaluated:

	Conditions 1	Conditions 2
Current, amp	120	150
Voltage, v	22.5	25
Wire-feed rate, ipm	340	400
Shielding gas (both)	96-97% A – 4-3% O_2	
Passes	Two	Two
Hardness, max, Rc	60-63	43-53

Microscopic examination of the welds made under both conditions showed the expected carbide in the fusion zone and martensite in both the fusion and heat-affected zones. Because Conditions 2 resulted in lower maximum hardness and better impact resistance, it was selected for production welding.

The oil-return tube was joined to the sump base before assembly because the joint was inaccessible after assembly. The shielded metal-arc process and an E7018 electrode were used for this weld.

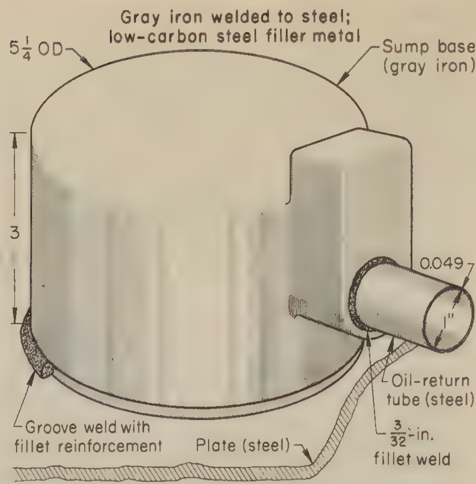

Fig. 4. Sump base that was gas metal-arc welded to a low-carbon steel plate, and to which a low-carbon steel tube was shielded metal-arc welded (Example 233)

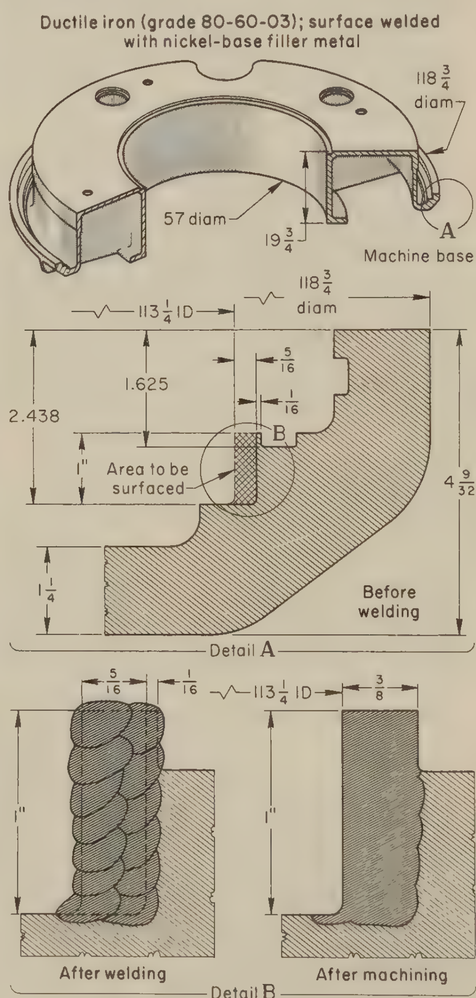


Welding Conditions for Revised Procedure

Process	Shielded metal-arc welding
Electrode	5/32-in. proprietary
Position	Horizontal
Power supply	300-amp motor-generator
Current	120 amp, dcrp
Voltage	22 v
Sequence	Staggered, 12 in. on 24-in. centers
Preheat	Warmed to about 150 F
Postheat	None
Number of passes	About 13

Fig. 5. Ball-race section of a ductile iron machine base showing undersize area before and after welding (Example 234)

Ductile Iron

When pearlitic or ferritic ductile iron is welded, the heat-affected zone contains hard carbides and martensite, and so ductility, impact strength, and machinability are considerably reduced. Because the pearlitic types produce a larger amount of martensite in this zone, they are more susceptible to cracking, and are less weldable. These problems, however, do not preclude a useful service life for many kinds of pearlitic ductile iron weldments.

Preheating is desirable to reduce the possibility of cracking by reducing shrinkage stresses, but has little effect on the strength properties of the heat-affected zone.

Postweld heat treatments have some beneficial effect, but do not restore the original ductility of the heat-affected zone. Reheating at 1000 to 1200 F alters the hard martensite to tempered martensite. A full anneal is required to soften the heat-affected zone, but the original structure is not completely restored by this treatment. Some of the combined carbon, instead of forming large nodules, is broken down into small graphite particles that reduce ductility. Ferritic weld joints in grade 60-45-10 ductile iron have shown tensile strength well over 50,000 psi, with elongation up to 5% or slightly more. However, strength values obtained in testing ductile iron weldments are similar to those obtained in testing gray and malleable iron weldments, in that large variations are found in any group of test results.

Welding processes that have proved most successful on ductile iron are shielded metal-arc welding using an ENiFe-CI nickel-iron electrode, and gas welding with a ductile iron welding rod (see the article on Oxyacetylene Welding of Cast Irons, which begins on page 583 in this volume). With either process, joint preparation and joint cleanness require the same careful attention and are accomplished by following the same procedures as are described in the section "Preparation of Castings", on page 237 in this article.

Shielded metal-arc welding using an ENiFe-CI electrode is usually done with preheats of 300 to 400 F, although preheats up to, but not exceeding, 600 F have been recommended for large castings. In small or lightly stressed castings, preheat may not be necessary. The electrodes should be baked or otherwise kept dry, to help prevent underbead cracking of welds. Reverse-polarity direct current is used at an amperage sufficient to permit moderate welding speed, using stringer beads. If machinability or optimum joint properties are desired, the casting should be annealed immediately after welding.

Gas metal-arc welding (see page 78) is used in joining ductile iron. Examples 236 and 237 describe applications in which production welding required a semiautomatic or automatic method, and the gas metal-arc welding process was selected.

Repair welding is used on ductile iron castings, but correction of major surface defects by welding may create a new problem, as illustrated in the example that follows:

Example 234. Buildup of Undersize Surface on Ductile Iron Castings (Fig. 5)

The wall of a ball-race groove on a 118¾-in.-diam machine base for the rotary drive used in chemical and sanitary equipment was found, after six castings had been finish machined, to be only 1⁄16 in. thick instead of the required ⅜ in. thick (Fig. 5). Because the ductile iron bases were valued at about $1000 each as-machined, salvaging the castings was desirable. Shielded metal-arc welding was used to build up the undersize wall on one of the units, using an ENiFe-CI electrode. Subsequent machining of the weld deposit resulted in excessive tool wear and breakage, which were attributed to the hardness of the deposit. The fact that the 1⁄16-in. wall melted into the weld puddle may have contributed to high carbon pickup in the deposit and the high hardness.

A portion of the welding procedure was changed in repair welding of the five remaining castings. Shielded metal-arc welding was used, but:

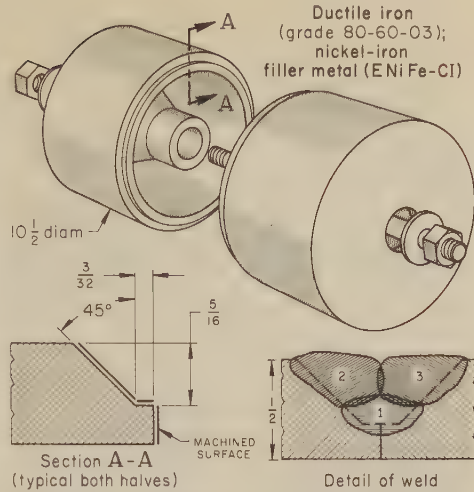
1 A proprietary electrode that contained a higher percentage of nickel was used. This electrode also had a specially formulated flux covering.
2 A block welding sequence was employed to reduce heat buildup and the attendant shrinkage stress.

Surface preparation involved wire brushing only, since the electrode covering was able to counteract the effect of limited amounts of surface contamination. Castings were warmed with a gas torch to about 150 F. With the castings supported for horizontal-position welding, a series of welds was deposited in blocks 12 in. long, staggered at 12-in. intervals.

In setting up the welding procedure, preheating of the entire casting, or even local preheating to a greater extent than the 150 F warming, was judged undesirable because of the size of the castings and the danger of distortion occurring in the many machined surfaces.

Reduction of hardness was the principal improvement sought. Hardness measured across the welds varied from 280 to 340 Bhn for the welds produced with the revised procedure, compared with an average hardness of about 370 Bhn, and hardnesses as high as 430 to 450 Bhn in many areas, for welds produced by the initial procedure. Additional details of the welding conditions for the ball-race groove are given in the table that accompanies Fig. 5.

Production arc welding of ductile iron is illustrated in the two examples that follow. In the first, manual welding by the shielded metal-arc process was used to simplify casting procedure and to save material.



Process	Shielded metal-arc welding
Electrode	ENiFe-CI(a), ⅛-in. for root pass; 5⁄32-in. for remaining passes
Number of passes	Three
Current	100 amp, dcsp
Power supply	300 amp, dc
Welding time	1st pass, 5 min; 2nd and 3rd passes, 6 min each
Position	Horizontal rolled
Preheat	1050 F
Postheat	(b)
Fixturing	Arbor-mounted and rotated in a lathe-type positioner

(a) Covered electrode with 55% nickel – 45% iron. (b) Heat to 1700 F, hold 4 hr, cool in air; heat to 1050 F, hold 5 hr, furnace cool to 550 F at 100 F per hour; then cool in air to room temperature.

Fig. 6. Ductile iron piston produced as a two-piece weldment (Example 235)

Example 235. Shielded Metal-Arc Welding of Ductile Iron Pistons With Nickel-Iron Electrodes (Fig. 6)

Pistons for low-speed high-pressure air compressors were originally cast in gray iron. When compressor speeds were increased, the need for a piston of lighter weight and higher strength was met by reducing wall thicknesses and casting the pistons in ductile iron. Changing to the two-piece design shown in Fig. 6 simplified casting procedures and permitted further weight reduction. Although aluminum pistons of this design were joined by epoxy bonding, reliable bonding of ductile iron was difficult to obtain, probably because of graphite on the joint surfaces. Shielded metal-arc welding with nickel-iron electrodes (ENiFe-CI) was finally selected, together with the following procedure.

Mating surfaces and weld bevels (Fig. 6) were machined without cutting fluid, and the piston halves were bolted together on an arbor and furnace heated to 1050 F. The preheated assembly was placed in an operator-controlled variable-speed positioning lathe, with the arbor horizontal. The partial-penetration groove weld was made in three passes (Fig. 6), and the assembly was then heat treated in a furnace to the desired strength range, corresponding to a hardness of 201 to 269 Bhn. Slag was removed and the weldment was finish machined to size.

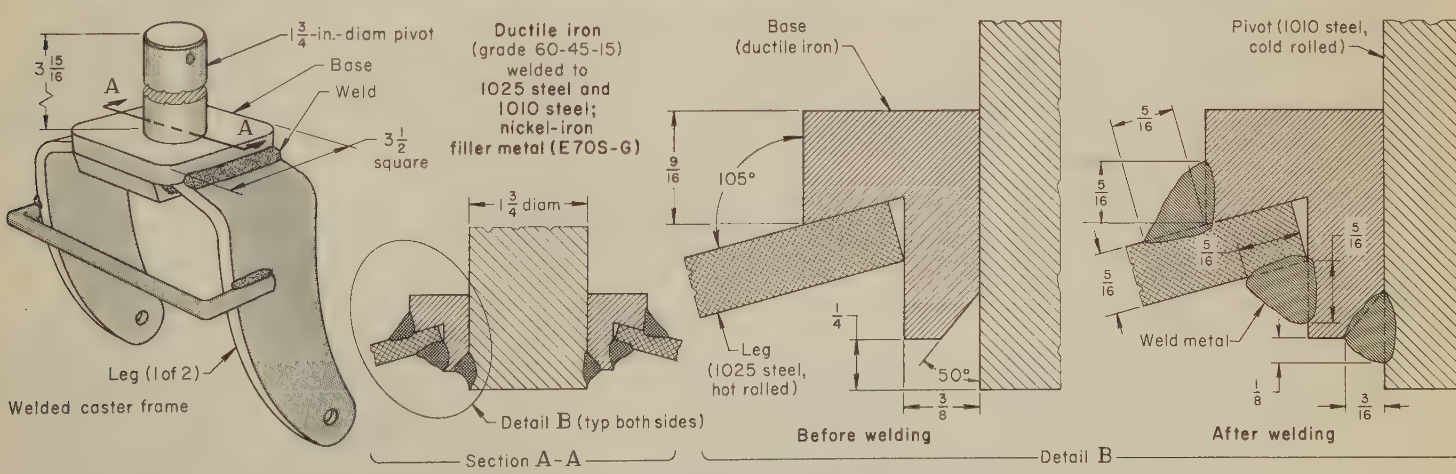
Because finished surfaces had to be free of any cracks, the welds were subjected to 100% magnetic-particle inspection. Small subsurface defects could be tolerated, because in operation the joint was required to develop only a small fraction of the nominal section strength of the base metal. Pistons up to 16 in. in diameter were produced, with weld rejection rates virtually nil. For additional welding conditions, see the table that accompanies Fig. 6.

Although shielded metal-arc and gas welding, when done by welders skilled in using these processes on cast iron, produce welds of excellent quality, automatic welding processes may be more economical in quantity production, as in the next example.

Example 236. Change to Semiautomatic Gas Metal-Arc Welding To Increase Production Rate (Fig. 7)

Caster frames for the front wheels of portable air compressors were made by welding the low-carbon steel and ductile iron assembly shown in Fig. 7 by the shielded metal-arc process. Manual welding was done using low-hydrogen electrodes (E7018, costing 29¢ per pound) without preheat. Production rate was approximately 24 pieces per 8-hr shift.

In an effort to improve efficiency, other welding methods were considered. Nickel-iron covered electrodes (ENiFe-CI) were recommended, and preheating was suggested. However, since the electrodes were expensive ($2.41 per pound) and the preheating operation was also costly, this recommendation was not adopted.



Conditions for Semiautomatic Gas Metal-Arc Welding

Electrode wire	0.045-in. diam, E70S-G	Fixture	Clamping jig	Number of passes per joint	One
Wire-feed rate	80 ipm	Current	200 amp, dcrp	Preheat and postheat	None
Shielding gas	75% CO_2 – 25% A	Voltage	26 v	Production per 8-hr shift	49 pieces

Fig. 7. Caster frame of ductile iron and low-carbon steel, for which production rate was doubled when semiautomatic gas metal-arc welding replaced a manual process, shielded metal-arc welding (Example 236)

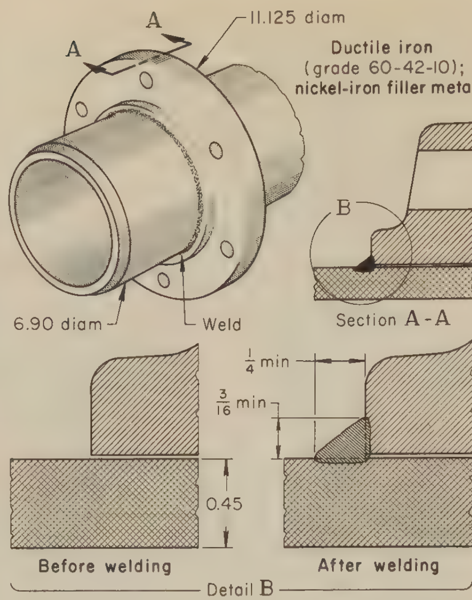
When gas metal-arc welding was investigated, it was found that semiautomatic welding could be done using a low-carbon steel electrode (E70S-G) costing only 32¢ per pound. Preweld cleaning and preheating were not necessary. In addition, welding was faster, flux removal was eliminated, and weld appearance was better. Parts were assembled in a fixture and tack welded, and each joint was welded in a single pass. Production rate increased to 49 pieces per 8-hr shift. The cost of filler metal and of shielding gas (75% carbon dioxide, 25% argon) was more than offset by the increase in production. Details of the welding procedure are given in the table that accompanies Fig. 7.

Shop vs Field Welding. Although field welding is satisfactory for many applications, shop welding is usually preferred when service requirements call for optimum weld properties. Besides allowing closer control over the welding operation proper, shop welding makes possible more effective use of preheat and postheat (which may be difficult, impractical, or hard to control in the field) and also allows the use of automated techniques not always possible in the field.

Example 237. Use of Gas Metal-Arc Welding in the Shop, Which Permitted Postweld Annealing Not Practical in Field Welding (Fig. 8)

Sections of ductile iron pipe, to one end of which ductile iron slip-on flanges had been fillet welded (see Fig. 8), and which were flared at the opposite end, were coupled by means of a lock joint. The slip-on flanges were gas metal-arc welded to the pipe sections in the manufacturer's plant. Each assembly was annealed after welding. The flanged sections were then assembled in the field and locked together by bolting. When necessary, some flanges were welded in the field, apparently with satisfactory results; but, since postweld annealing in the field was impractical, the heat-affected zones had lower corrosion resistance and toughness. This pipe installation was built for transporting water over mountainous terrain.

The shop welding procedure was essentially automatic. First, the joint surfaces were cleaned with detergent and ground to remove the casting skin. Next, the flange and pipe were mounted together on turning rolls under a stationary gas metal-arc welding head. To reduce the possibility of



Process	Gas metal-arc welding
Joint type	Lap
Weld type	Fillet
Preheat (flange only)	600 F
Electrode wire	0.045-in.-diam nickel-iron alloy(a)
Wire feed	432 ipm
Electrode holder	Machine type, water cooled
Shielding gas	Helium, at 30 cfh (or argon, at 20 cfh)
Welding position	Horizontal rolled
Current	200 amp, dcrp
Voltage	26 v
Number of passes	One
Power supply	200-amp rectifier
Welding speed	22 ipm (1 rpm)
Postheat	Ferritizing anneal(b)

(a) Coiled wire, nominally 55% nickel – 45% iron. (b) Heat to 1700 F in 15 min, hold at 1700 F for 15 min, cool to 1300 F in 15 min, air cool.

Fig. 8. Straight end of a ductile iron pipe section to which a ductile iron slip-on flange was fillet welded by the automatic gas metal-arc process (Example 237)

cracking in the ductile iron flange during cooling after welding, the flange (but not the pipe) was preheated to 600 F. Both the flange and the pipe were in the annealed condition.

After preheating, the flange was tack welded to the pipe in three places, using a nickel-iron electrode under helium shielding (argon was also used on occasion, but a sounder weld, free of any tendency to crack, was produced when helium was used). The electrode holder was then positioned at 45° from the vertical face of the flange, with the electrode aimed at a point about 1/16 in. from the flange, to ensure an even weld on both pipe and flange surfaces. Welding was done in a single pass, using the same electrode and shielding gas as for tack welding. (Other welding conditions are given with Fig. 8.) During welding, gas cup and contact tip were positioned as close to the work as possible, to increase arc efficiency and shielding coverage. After welding, the entire assembly was annealed. The procedure produced joint efficiencies approaching 100%.

Tests made on two-pass welded butt joints in the same pipe gave the following results:

Tensile Properties(a)		
Tensile strength	69,100 psi	
Yield strength	48,700 psi	
Elongation in 1 in.	19%	
Impact Properties(b)		
	At 70 F	At –40 F
Ft-lb, center of weld	14.9	13.3
Ft-lb, fusion zone	17.8	15.8

(a) Specimens measured 0.250 in. in diameter by 1 in. long. Tensile results are average values for ten specimens per weld. (b) Standard V-notch Charpy impact specimens.

Malleable Iron

During welding, the ductility of the heat-affected zone of malleable iron is severely reduced because graphite dissolves and precipitates as carbide. Although postweld annealing will soften the hardened zone, very little ductility is regained. Despite these limitations, for certain applications malleable iron castings are welded satisfactorily and economically if several precautions are followed. It is not recommended that malleable iron castings be welded to repair a failure caused by overstressing of the part.

Satisfactory welds have been obtained in arc welding malleable iron to steel where the joints were not to be severely stressed in service. Where the weld is to be subjected to fatigue of the type described in Example 240, stress should not exceed 10,000 psi.

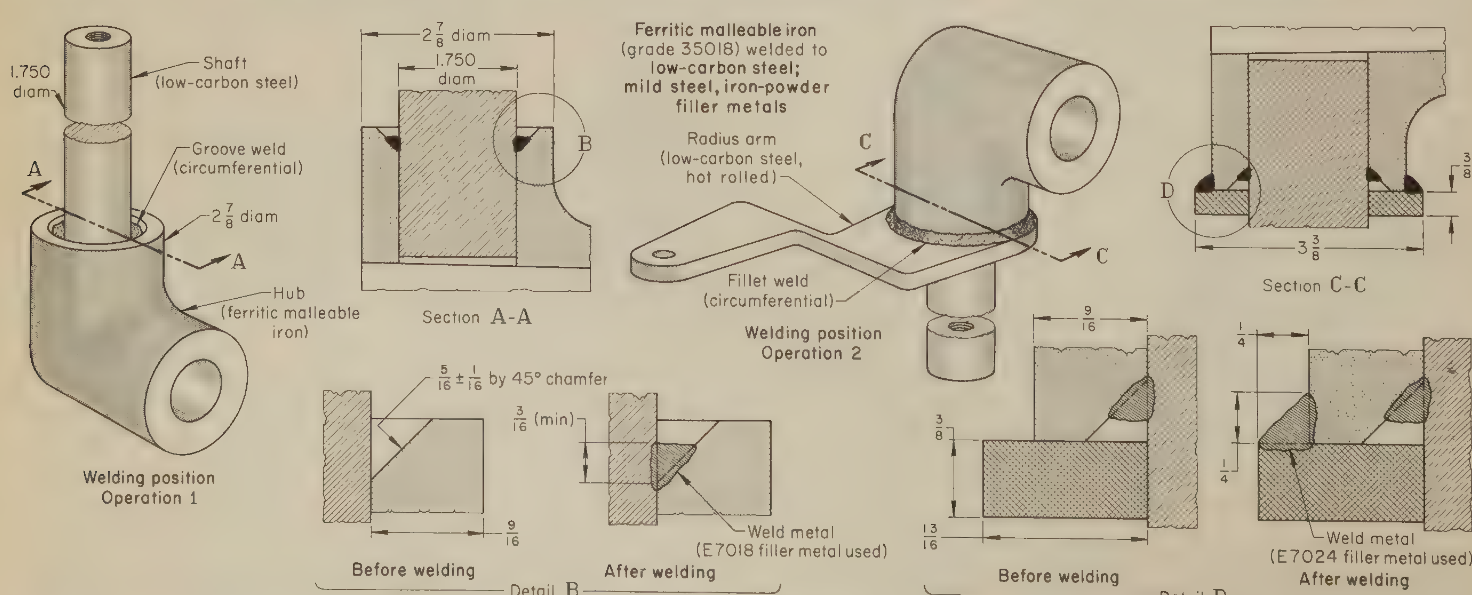


Fig. 9. Steering-knuckle assembly, and details of shielded metal-arc welds made to join the ferritic malleable iron and low-carbon steel components (Example 238)

If possible, welded joints should be loaded in compression, torsion or shear, rather than in tension or bending. With properly made welds, joint tensile strengths of 30,000 to 40,000 psi are obtainable.

Because most malleable iron castings are small, preheating is seldom used. If desired, small welded parts can be stress relieved at temperatures up to 1000 F. For heavy sections and highly restrained joints, preheating at temperatures up to 300 to 400 F and postweld malleablizing annealing have been recommended. However, this costly practice is not always followed, especially when the design of the assembly is based on reduced-strength properties of the welded joint. Because no welding procedure can satisfy all types of service conditions, each application for welding malleable iron assemblies should be carefully reviewed and tested before production is begun.

To avoid porosity and unnecessarily low joint strength, it is most important that the joint be cleaned before welding. Parts used in welded assemblies are usually machined at the joint to provide a suitable weld groove. Joints should at least be chipped or ground, the casting skin removed from the weld area, and the part thoroughly degreased with a solvent.

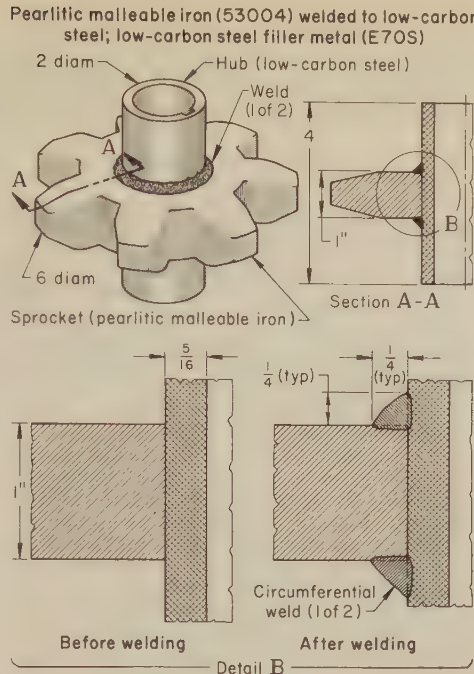
Ferritic malleable grades 32510 and 35018, although they lose some impact strength when welded, are the better welding grades of malleable iron. The pearlitic malleable irons, because of their higher combined carbon content, have lower impact strength when welded. Small leaks, gas holes, and other small casting defects can be repaired in grades 32510 and 35018 by arc welding. If it is necessary to machine a repaired area, arc welding should be done with nickel electrodes. If low-carbon steel electrodes are used, the part should be annealed to reduce any increased hardness in the weld (due to carbon pickup) and in the heat-affected zone.

Shielded metal-arc welding using low-carbon steel, low-hydrogen electrodes, at low amperage, has been used to produce satisfactory welds in malleable iron (see Example 238).

Gas metal-arc welding is better suited to producing welded assemblies of malleable and ductile irons than to general applications on gray iron. The important advantages of gas metal-arc welding, as compared with shielded metal-arc welding, are:

1. The amount of hydrogen in the vicinity of the gas-shielded arc is much less than that with flux-covered electrodes, and so welds made by this process are less susceptible to cracking.
2. Higher welding speeds reduce weld distortion.
3. Dilution of the weld metal is small; therefore, less carbon pickup can be expected.
4. The equipment is easily adapted to the welding of small assemblies.

In most applications, particularly where automation cannot be used to reduce labor cost, gas metal-arc welding is more expensive than shielded metal-arc welding, principally because of the high cost for the gas used. This



Process	Gas metal-arc welding
Electrode wire	0.045-in.-diam steel(a)
Shielding gas	Argon – carbon dioxide, at 15 cfh
Current	200 amp, dcrp
Voltage	28 v
Time per weld	About 15 sec

(a) Low-carbon steel deoxidized wire, corresponding to E70S types.

Fig. 10. Chain-drive sprocket made by welding a pearlitic malleable iron body to a low-carbon steel hub, using gas metal-arc welding (Example 239)

can be offset to some extent by the smaller amount of filler metal needed to fill the smaller joint grooves required by the gas metal-arc process.

The electrode wire usually recommended for use with gas metal-arc welding is a nickel-iron alloy having the same composition as the ENiFe-CI covered electrode used for shielded metal-arc welding. Low-carbon steel electrode wires have been used for joining malleable iron to low-carbon steel.

Submerged-Arc Welding. An application of joining malleable iron to low-carbon steel by submerged-arc welding is described in Example 241. However, submerged-arc welding has been used to a very small extent in welding any of the cast irons. The process generally is not suited to the repair of casting defects or damaged castings, because it requires unidirectional operation in the flat position. Other factors that limit its applicability are lack of visibility and high heat input.

Examples of Arc Welding Practice. The following four examples describe the welding of assemblies involving malleable iron and steel. Neither preheat nor postweld heat treatment was employed. Different arc welding processes were used with commercially available low-carbon steel electrodes in production welding setups. In each example, welding resulted in a low-cost assembly that adequately fulfilled service requirements. None of the welds was located in an area of the assembly that required machining.

Example 238. Shielded Metal-Arc Welding of Ferritic Malleable Iron to Steel (Fig. 9)

Part of the steering-knuckle assembly for 7-to-9-ton farm wagons consisted of a ferritic malleable iron hub to which a shaft and a radius arm, both of low-carbon steel, were welded (Fig. 9). In service, the two welded joints were subject to torsional shear stress, due to steering loads. A second shaft, which served as the wheel axle, was bolted to the hub. The hub was originally of cast steel, but malleable iron was substituted to reduce cost.

The weld groove was made by casting the hub with a 45° chamfer (Fig. 9). Preparation for welding consisted of shot blasting the malleable iron hub and degreasing the steel parts. There was no preheating and no postheating. Welding was done by the shielded metal-arc process, using low-carbon steel iron-powder electrodes. First, the vertical shaft was inserted in the hub and tack welded. This assembly was then mounted on a turntable and joined with a circumferential groove weld, using a 5/32-in. E7018 electrode at 90 amp, dcrp. To avoid interference with the radius arm, the groove was not completely filled. Next, the assembly was turned over and the radius arm was tack welded in position. Then, the arm and hub were joined with a circumferential 1/4-in. fillet weld, using a 1/8-in. E7024 electrode at 175 amp, dcrp. These welded joints have performed satisfactorily for several years.

Example 239. Joining Pearlitic Malleable Iron to Steel by Gas Metal-Arc Welding (Fig. 10)

Sprockets used for driving the digging chain of a trenching machine were made by welding low-carbon steel hubs to pearlitic malleable iron sprocket bodies (Fig. 10). This design combined good wearing qualities at the teeth with toughness in the keyseated hub. Production of these parts was simple, since no preheat and no postheat were used and no machining was required after welding.

The malleable iron castings were shot blasted, bored to size, and degreased. Premachined steel hubs were then tack welded in place, and the assembly was mounted on a turntable. The 1/4-in. low-carbon steel fillet welds deposited on each side were ample for the shear load on the sprocket, which was rated for 18 hp at about 260 rpm. Welding was done by the gas metal-arc process in a single pass, using relatively high amperage, voltage and welding speed, as shown in the table accompanying Fig. 10.

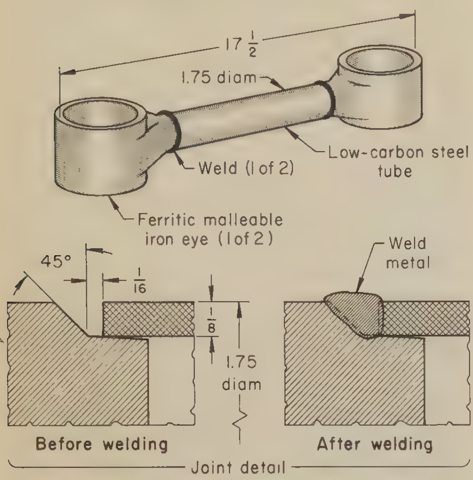
Originally, these sprockets had been welded by the shielded metal-arc process. With gas metal-arc welding, welds were cleaner, were deposited faster, were more uniform in appearance, caused less spatter, and produced fewer cracks. Although some cracking still occurred, it was not serious enough to interfere with the operation of the part, which had a good service record.

Example 240. Fatigue Strength of Gas Metal-Arc Welded Joints Between Ferritic Malleable Iron and Steel Tubing (Fig. 11)

Figure 11 shows a weldment on which fatigue tests were made to obtain data for use in production of welded malleable iron assemblies. The test piece, which consisted of two ferritic malleable iron eyes welded to a length of steel tubing, closely simulated an eye-bar or link commonly used to carry axial tension-compression loads. Accordingly, fatigue testing was done by applying full-cycle axial loads, alternately in tension and compression, at the rate of 120 full cycles per minute.

Before welding, the parts were cleaned with a solvent and assembled in a fixture rotating on a horizontal axis. As shown in Fig. 11, the weld groove was formed by the square end of the tubing and the 45° bevel machined on the plug end of the eye. The tapered plug end of the eye was inserted in the tube, and served as backing for the

Ferritic malleable iron (grade 32510) welded to low-carbon steel; 1% silicon mild steel filler metal



Conditions for Gas Metal-Arc Welding

Electrode wire	0.035-in.-diam E70S-6 type(a)
Wire-feed rate	298 ipm
Shielding gas	Carbon dioxide, at 15 cfh
Current	140 amp, dcrp
Voltage	23 v
Welding speed	13 ipm

Fatigue-Test Results

Max load, psi	Cycles to failure(b)
25,000	22,993(c)
25,000	66,352(c)
25,000	36,098(c)
25,000	46,892
20,000	72,403
20,000	139,394
20,000	244,347

(a) Composition: 0.11 C, 1.65 Mn, 1.12 Si, 0.021 P and 0.024 S. (b) Each cycle consisted of one axial load in tension and compression; 120 cycles per minute. (c) Failure occurred in eye of casting, not in weld.

Fig. 11. Gas metal-arc welded assembly of malleable iron and low-carbon steel, seven of which were used for preproduction fatigue testing (Example 240)

weld. The assembly was joined by gas metal-arc welding with carbon dioxide shielding gas and an electrode wire of the E70S-6 type (1% silicon, low-carbon steel), without being preheated. Seven test pieces were welded. The arc was held between 1 and 2 o'clock, and rotation was counterclockwise at 2.4 rpm. Other welding conditions are given in the table with Fig. 11, together with results of fatigue tests.

An eighth specimen was welded under the same conditions except that electrode wire composition was 0.12 C, 1.90 Mn, 0.80 Si, 0.020 P, 0.020 S, 0.50 Mo, and 0.10 Ni. This specimen failed after 8692 cycles at 18,000-psi tension and compression. Although the single test could not be conclusive, it suggested sensitivity to different steel electrode compositions.

Example 241. Submerged-Arc Welding of Ferritic Malleable Iron to Forged Steel (Fig. 12)

The snap coupler shown in Fig. 12 was used on various types of farm machinery as a power take-off. Because this part was impractical to make in one piece, it was produced by welding a ferritic malleable iron casting to the stub end of a forged steel universal joint. Ferritic malleable iron was used because it was less costly than steel and offered adequate strength. A 1/8-in. weld was sufficient to carry the service load.

Both mating surfaces were machined to form a stepped joint (Fig. 12) that provided good alignment and proper joint depth. The assembly was fitted over a spline that rotated on a horizontal axis. Submerged-arc welding was used with a low-carbon steel electrode wire and a standard flux, in a combination corresponding to AWS F62-EL12. The welding head was positioned near 12 o'clock, and welding was done in a single pass. Additional welding conditions are given in the table that accompanies Fig. 12. These snap couplers had a service-failure record of less than 0.1%.

Alloy Cast Irons

Alloy irons are used for service requiring resistance to abrasion, corrosion or heat. Some of these irons can be welded and some cannot.

Chilled and White Cast Irons. Both of these types of abrasion-resistant cast iron have structures free of graphitic carbon. Because of their extreme hardness and brittleness, they are generally considered unweldable.

Corrosion-Resistant Cast Irons. Alloys of this type are usually identified as high-silicon, high-chromium or high-nickel irons. Specifications for many of these irons permit welding for repair of minor casting defects. For more extensive welding, the effect on the service properties of the casting should first be determined, since applications of this group of cast irons are highly specialized. Because weld deposits must usually duplicate base-metal compositions, filler metals may not be generally available. Little information exists on welding procedures for these alloys.

Heat-resistant cast irons provide high strength at elevated temperature, as well as resistance to scaling. They are normally produced as flake-graphite irons, but may also be produced with the free carbon in the form of nodules or spheroids. The statements made in the paragraph above concerning the welding of corrosion-resistant cast irons apply to these irons as well.

Hard Facing

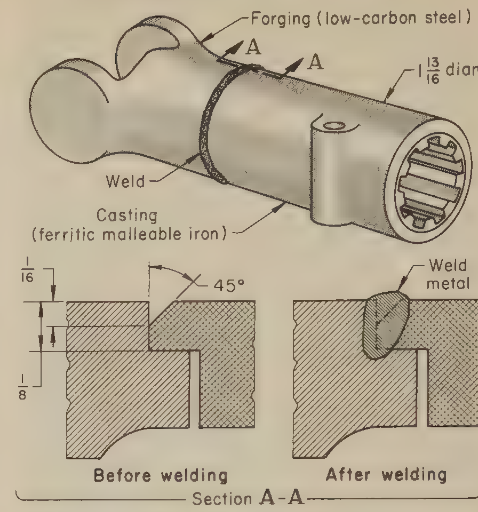
For two reasons, hard facing of cast iron is not generally recommended: (*a*) most cast irons (particularly gray iron) are highly susceptible to cracking from heating and cooling, thus requiring precise control over the hard facing operation; and (*b*) most cast iron parts are relatively inexpensive and are easily replaced, so that the cost of hard facing them is not usually justified unless it is outweighed by the cost of machine downtime required for replacement (see "Typical Application" at the bottom of the next column).

Preheating of castings to be hard faced is mandatory, to prevent cracking. For castings with uniform sections, 650 to 700 F is sufficient. For those with large differences in section thickness, 1100 to 1200 F is often used (dull red heat in normal room lighting). Higher preheating temperatures increase the amount of oxide formed, which impairs alloying. Time at the preheating temperature should be sufficient to ensure uniform heating.

"Buttering" with a buffer metal (one or more layers of type 310 stainless steel or a high-nickel alloy), although not mandatory, helps to prevent cracking of the base metal and provides a better bond between the hard facing alloy and the base metal.

Hard facing alloys that contain 2.5 to 4.0% carbon are generally used. The remainder of the alloy composition is

Ferritic malleable iron welded to low-carbon steel; mild steel filler metal (EL12)



Conditions for Submerged-Arc Welding

Filler metal	3/32-in.-diam EL12
Flux	F62
Current	275 amp, dcrp
Voltage	24 to 25 v
Preheat and postheat	None
Production rate	120 pieces per hour

Fig. 12. Snap coupler in which submerged-arc welding was used to join malleable iron to forged steel (Example 241)

chosen for the specific application. Several alloys of groups 3 and 4 (see Table 2 on page 155) are suitable. The alloy rods used for hard facing of cast iron are usually recognized by their graphite coatings. (For more information, see the article on Selection of Hard Facing Alloys, which begins on page 820 in Volume 1 of this Handbook.)

Manual arc welding is most often used, although when significant amounts of hard facing must be done the electrode holder may be mechanically held and guided.

Postheating is not ordinarily used, although slow cooling after hard facing is essential to prevent cracking. The hard faced casting may be placed in a furnace that is held at a temperature that approximates the preheating temperature. It must then be furnace cooled, although not necessarily right away. Often, several castings are hard faced and placed in the furnace before the cooling cycle begins.

If a furnace is not available, the hard faced casting may be buried in lime or other insulating material for slow cooling.

Typical Application. A manufacturer of bricks experienced severe wear on several cast iron machinery parts (pug-mill knives, sealing augers, shredder knives, barrel liners, and extrusion augers). This resulted in frequent and unscheduled downtime ranging from one to several hours, for replacement of the worn parts. Each hour of shutdown resulted in lost production of 10,000 or more bricks.

Hard facing of the machinery parts increased the wear life sufficiently to permit scheduled repair; no one part was kept in service long enough to wear severely.

Parts were preheated and hard faced by manual arc welding (essentially, shielded metal-arc), using a hard facing alloy composed of 3.2% C, 2.4% Si, 16.2% Cr and 0.74% Mo (a group 3 alloy). Hard faced parts were placed immediately in a furnace and cooled slowly in the furnace.

Arc Welding of Stainless Steel

*By the ASM Committee on Welding and Brazing of Stainless Steel**

ALL WELDABLE STAINLESS STEELS can be joined by the various arc welding processes but, because of the wide variations in composition and in physical and mechanical properties among the different types of stainless steel, they are not equal in weldability.

Gas tungsten-arc, plasma-arc, gas metal-arc, shielded metal-arc and submerged-arc welding are used extensively for joining stainless steel. Flux-cored arc welding is also used, but to a lesser extent. The various arc welding processes are not equally suitable for welding all stainless steels, because of differences in the compositions of the steels, and in fabricating conditions and end requirements.

This article discusses the weldability of the various grades, and the suitability of arc welding processes for specific conditions and requirements.

Austenitic Stainless Steels

Differences in composition among the standard austenitic stainless steels affect both their behavior in welding and performance in service. For example, types 302, 304 and 304L differ primarily in carbon content, and consequently there is a difference in the amount of carbide precipitation that can occur in the heat-affected zone after the heating and cooling cycle encountered in welding. Types 303 and 303(Se) contain 0.20% max phosphorus, plus 0.15% min selenium or sulfur, for free machining. These elements are detrimental in welding and can cause severe hot cracking in the weld metal. Types 316(Cb), 316L and 317 contain molybdenum, for increased corrosion resistance and higher creep strength at elevated temperatures, but during welding, molybdenum promotes carbide precipitation in the heat-affected zone unless restrained by an extra-low carbon content (as in type 316L). Types 318, 321, 347 and 348 are stabilized with titanium, or with columbium-plus-tantalum, to prevent intergranular precipitation of chromium carbides when the steels are heated to a temperature in the sensitizing range, as during welding.

Welding Characteristics. The austenitic stainless steels, except for the free-machining grades, are more weldable than the ferritic and martensitic stainless steels, and they provide welded joints that are characterized by a high degree of toughness, even in the as-welded condition. Satisfactory welded joints are readily obtained if the welding conditions adopted are compatible with the physical and mechanical properties of the steel. For example, the coefficient of thermal expansion of austenitic stainless steel is approximately 50% greater than that of carbon steel, whereas its thermal conductivity is only one-third that of carbon steel. In welding, these differences in physical properties significantly affect heat input and attendant warpage and distortion.

Effect of Carbide Precipitation on Corrosion Resistance of Welded Joints. The precipitation of intergranular chromium carbides is accelerated by an increase in temperature within the sensitizing range, and by an increase in time at temperature. When intergranular chromium carbides are precipitated at welded joints, resistance to corrosion and stress corrosion decreases markedly. The decrease in corrosion resistance is attributed to the presence of the chromium-rich carbides at the grain boundaries and the depletion of chromium in the adjacent matrix material. Although intergranular carbide precipitation generally takes place in the temperature range of 800 to 1600 F, sensitization is restricted to a narrower range by the fairly rapid heating and cooling that usually occur in welding. The narrower range varies with time at temperature and with steel composition, but is approximately 1200 to 1600 F.

The base metal immediately adjacent to the weld is annealed or solution treated by the heat of welding, and because it generally is cooled rapidly enough to hold the dissolved carbides in solution, this zone usually exhibits normal resistance to corrosive attack. A short distance from the weld, perhaps ⅛ in. (the distance depending on the thermal cycle), there is a narrow zone in which lower heating and cooling rates prevail. In this "heat-affected" zone, intergranular precipitation of chromium carbides is most likely to be encountered.

Prevention of Carbide Precipitation. Harmful carbide precipitation can be prevented by any of three methods: (*a*) solution heat treatment, (*b*) use of an extra-low-carbon (0.03% C max) alloy, and (*c*) use of a stabilized alloy containing preferential carbide-forming elements, such as columbium-plus-tantalum or titanium.

Solution heat treatment is a positive method for putting carbides back into solution and restoring normal corrosion resistance, but it is generally inconvenient and seldom entirely feasible. The solution-treating temperature range is very high — 1875 to 2050 F — and unless stainless steel is protected from air at these temperatures, it will oxidize rapidly, forming an adherent surface scale. Even when protected from air, thin sections, unless adequately supported, may sag or be severely distorted at these temperatures or during rapid cooling from them.

The need for rapid cooling in solution heat treatment may present problems. Water quenching, although effective, is seldom feasible except for small workpieces of simple configuration. Unless adequate safeguards are available, water quenching of large workpieces from a temperature in the range of 1875 to 2050 F is hazardous. Often, solution treatment is impractical because the workpiece is too large for available furnace and cooling facilities.

Extra-low-carbon stainless steels (types 304L and 316L) have enough immunity to carbide precipitation in the 800-to-1600-F temperature range to undergo normal welding or stress-relieving operations without impairment of corrosion resistance, but carbides will precipitate in significant quantities when extra-low-carbon steels are heated and held in the sensitizing temperature range for an extended period, as in service. These steels are generally recommended for use below 800 F.

Stabilized Steels. Compared with the extra-low-carbon steels, the stabilized steels exhibit higher strength at elevated temperature. For service in a corrosive environment in the sensitizing-temperature range (800 to 1600 F), an austenitic steel stabilized with columbium-plus-tantalum or titanium is needed. The filler metal used for welding should also be of a stabilized composition. Because an inert shielding gas is employed, gas tungsten-arc and gas metal-

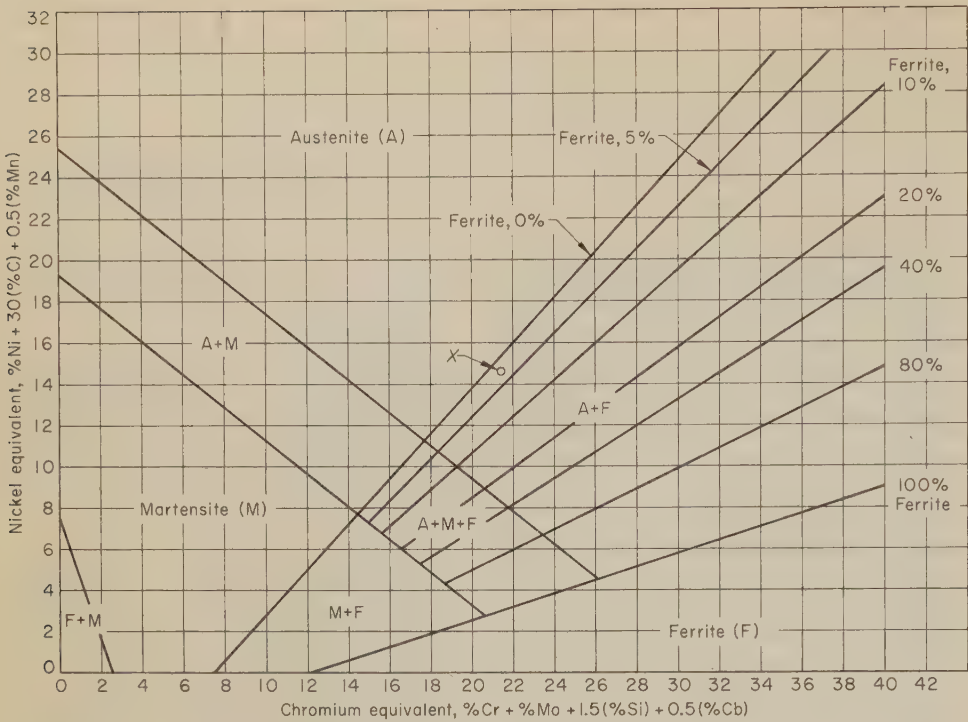
Many of the examples presented in this article were contributed by members of other Metals Handbook welding committees. Several sections of the article are based on an article by George E. Linnert and one by Raymond P. Sullivan, both in *Metals Engineering Quarterly,* November 1967, pages 1 to 15 and 16 to 41, respectively.



Example of Use. Point X on the diagram indicates the equivalent composition of a type 318 (316Cb) weld deposit containing 0.07 C, 1.55 Mn, 0.57 Si, 18.02 Cr, 11.87 Ni, 2.16 Mo, and 0.80 Cb. Each of these percentages was multiplied by the "potency factor" indicated for the respective element along the axes of the diagram, in order to determine the chromium equivalent and the nickel equivalent. When these were plotted as point X, the constitution of the weld was indicated as austenite plus from 0 to 5% ferrite; magnetic analysis of the actual sample revealed an average ferrite content of 2%.

For austenite-plus-ferrite structures, the diagram predicts the percentage ferrite within 4% for the following stainless steels: types 308, 309, 309(Cb), 310, 312, 316, 317 and 318.

Fig. 1. Schaeffler diagram for determining approximate amount of delta ferrite in the microstructure of austenitic stainless steel weld metal (Anton L. Schaeffler)

arc welding processes can be used to weld titanium-stabilized steel without oxidizing the titanium.

Under certain conditions, stabilized stainless steel weldments are susceptible to sensitization, which occurs in narrow zones of the base metal immediately adjacent to the line of weld fusion. Although during welding the carbides in the base metal adjacent to the weld are dissolved and, as a result of rapid cooling, are retained in solution, subsequent reheating to about 1200 F results in preferential precipitation of chromium carbides in a narrow, knifeline zone that exhibits less than normal corrosion resistance and that will corrode extensively in some mediums.

Microfissuring in Welded Joints. Intergranular cracking that results in the formation of microfissures in the weld metal or in the base metal near a welded joint is known as "hot cracking" or microfissuring. The occurrence of microfissuring is related to (*a*) the microstructure of the weld metal as-solidified; (*b*) the composition of the weld metal, especially the content of certain residual or trace elements; (*c*) the amount of stress developed in the weld as it cools; (*d*) the ductility of the weld metal at high temperatures; and (*e*) the presence of notches.

Susceptibility to microfissuring is highly dependent on the first of these factors — the microstructure of the weld metal. Weld metal with a wholly austenitic microstructure is considerably more susceptible to microfissuring than weld metal with a duplex structure of delta ferrite in austenite.

The content of alloying elements and residual elements strongly influences the susceptibility of fully austenitic stainless steel weld metal to microfissuring. Susceptibility can be reduced by a small increase in carbon or nitrogen content or by a substantial increase in manganese content. Residual or trace elements that contribute to microfissuring are, in approximate order of potency: boron, phosphorus, sulfur, selenium, silicon, columbium and tantalum.

It is important to minimize the amount of stress imposed on austenitic stainless weld metal as it cools from the solidus down to about 1800 F. It is in this temperature range that the weld metal is most susceptible to microfissuring, and if the level of stress is high, the fissures will propagate to form visible cracks. Peening is not an effective method of preventing this type of cracking, because it can seldom be applied early enough to reduce stress buildup in the temperature range concerned.

Prevention of Microfissuring. Either of two different practices is followed to prevent microfissuring, depending on whether weld metal with a duplex or a wholly austenitic microstructure is desired. To obtain duplex-structure weld metal that has controlled ferrite content (3 to 5% approximately), a filler metal of suitable composition is selected. Wide use has been made of the Schaeffler diagram (Fig. 1) to determine the amount of ferrite that will be obtained in austenitic weld metal of a given composition. Actual measurements of ferrite content can be made conveniently with the aid of a magnetic analysis device. Microfissuring can be prevented or minimized by proper control of ferrite in the weld metal — even when substantial dilution of weld metal with base metal occurs in the welding of free-machining austenitic stainless steels containing phosphorus and sulfur, or selenium.

Because many heats of austenitic stainless steel contain appreciable amounts of nitrogen — a very strong austenitizer — a revised constitution diagram for austenitic stainless steel weld metal has been developed to include nitrogen in the nickel equivalent (Fig. 2). This diagram is modified in shape and slope to improve the accuracy of ferrite estimation for types 309, 309(Cb), 316, 316L, 317, 317L and 318, compared with that obtained with Fig. 1. In addition, ferrite calculation for types 308 and 347 weld metals is improved on samples that contain either high or low nitrogen.

When it is required that the weld metal be wholly austenitic (as when the metal must be nonmagnetic), the content of crack-promoting residual elements must be stringently controlled, and the composition of the weld metal must be adjusted to increase crack resistance. Crack resistance can be increased by modifying the carbon, manganese, and nitrogen contents of the weld metal. However, even with optimum compositions and the most favorable welding procedures, wholly austenitic weld deposits will be more crack sensitive than those of a duplex structure.

Underbead cracking can occur in the heat-affected zone of the austenitic stainless base metal, immediately adjacent to the weld metal, especially in sections more than ¾ in. thick.

Serious failures due to underbead cracking have occurred in heavy-wall pressure vessels used in nuclear power units; the vessels were made of type 347 stainless steel, which is stabilized with columbium-plus-tantalum. Similar failures have occurred in thick-wall type 347 pipe used in high-temperature central steam stations; these failures occurred after seemingly sound welded joints had been subjected to high-temperature service for an extended period of time. The underbead cracking that caused the failures was attributed to strain-induced precipitation of columbium carbide, arising from shrinkage stresses in the heavy weldments.

Underbead cracking is not limited to columbium-stabilized steels. Tests have shown that all of the common austenitic stainless steels, with the possible exception of type 316L, are susceptible to this type of defect to some extent. Therefore, if underbead cracking is to be avoided, weld restraint must be kept to a minimum, especially in the welding of heavy sections.

Selection of Filler Metals. Electrodes and welding rods suitable for use as filler metal in the welding of austenitic stainless steels are given in Table 1. The notes in this table should be carefully studied before selection. (For AWS standard composition specifications for bare filler metals, see Table 6; Tables 11 and 12 list filler metals for gas metal-arc, submerged-arc and shielded metal-arc welding.)

Selection of filler metals for welding austenitic stainless steels requires consideration of the structural constituents of the deposited weld metal. Ultimately, these structural constituents determine the mechanical properties, crack sensitivity, and corrosion resistance of the weld. The constituents of principal concern are austenite, delta ferrite, and precipitated carbides.

Some filler metals, such as types 310, 310(Cb), 310(Mo) and 330, invariably deposit a fully austenitic weld metal. In these alloys, the ratio of ferrite formers to austenite formers cannot, within permissible limits, be raised high enough to produce any delta ferrite in the austenite. Consequently, when these filler metals are applied to restrained joints or to base metals containing additions of elements such as phosphorus, sulfur, selenium and silicon, only procedures proved suitable by experience should be employed.

The compositions of most filler metals are adjusted by the manufacturers to produce weld deposits that have ferrite-containing structures. Thus, ferrite-forming elements (such as chromium and molybdenum) are maintained at the high side of their allowable ranges, and austenite-forming elements (such as nickel) are kept low. The amount of ferrite in the structure of the weld metal depends on the ratio of "balance" of these elements.

At least 3 or 4% delta ferrite is needed in the as-deposited austenite for effective suppression of hot cracking. The ferrite is present in a dendritic pattern, because it is the primary phase in solidification. Ferrite-containing weld metal also combats the harmful effects of precipitated carbides on corrosion resistance, because carbides normally precipitate in and around the ferrite pools, instead of forming a continuous intergranular network.

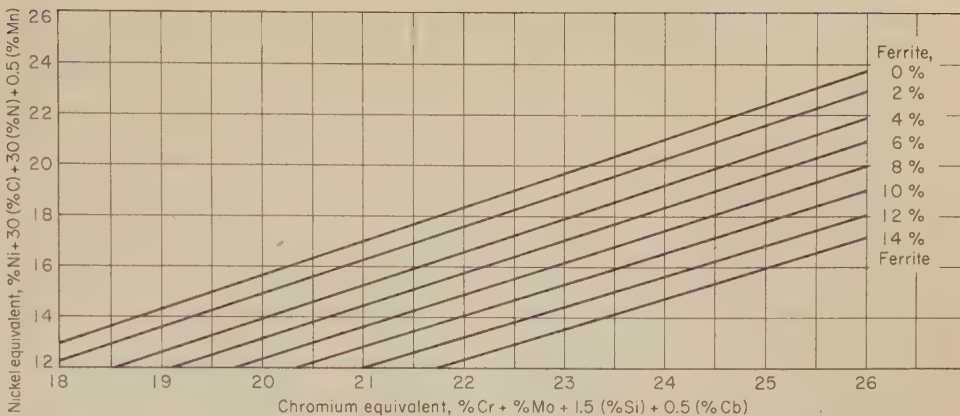


Fig. 2. Modified constitution diagram for austenitic stainless steel that includes nitrogen in the nickel equivalent (W. T. DeLong, G. A. Ostrom and E. R. Szumachowski, *Welding Journal*, Nov 1956, page 526s)

Ferrite-containing weld metal may have certain disadvantages in a welded austenitic stainless steel. Ferrite is ferromagnetic, and the increased magnetic permeability of the weld metal may be objectionable in applications that require nonmagnetic properties. When exposed to service at elevated temperature, the ferrite in some weld metals may transform to sigma phase and adversely affect mechanical properties and corrosion resistance, a problem that has been encountered in power-plant applications.

When a joint is arc welded without the addition of filler metal, the structure of the weld metal is determined by the composition of the base metal. Sometimes this leads to unfavorable results, because wrought base metals may not have the composition limits required for good weld metal.

Preheating. In general, no benefit is derived from preheating austenitic stainless steels. On the contrary, in some applications, preheating can increase carbide precipitation or cause shape distortion of the workpiece.

Postweld Stress Relieving. Although the effects of residual stress on the properties of austenitic stainless steels are limited in comparison with the effects of cold working, residual stress may significantly affect the mechanical behavior of an engineering structure. Because the effective yield strength varies from point to point, the application of further stresses at later stages of fabrication can cause excessive distortion and even premature failure. Nonuniform heating, which relieves some local residual stress, may also contribute to distortion. For these reasons, stress relieving may be required to ensure dimensional stability.

Stress relieving can be performed over a wide range of temperature, depending on the amount of relaxation required. Time at temperature ranges from about 1 hr per inch of section thickness at temperatures above 1200 F, to 4 hr per inch of section thickness

SOURCE: George E. Linnert, Welding Characteristics of Stainless Steels, *Metals Engineering Quarterly*, Nov 1967

(a) 1 = as welded; 2 = annealed; 3 = hardened and stress relieved; 4 = stress relieved; 5 = stabilized and stress relieved. (b) Prefix E or ER omitted.

(c) Type 308 weld metal is also referred to as 18-8 and 19-9 composition. Actual weld analysis requirements are 0.08% max C, 19.0% min Cr and 9.0% min Ni. (d) Type 310 (1.50% max Si) may be used as filler metal, but the pickup of silicon from the base metal may result in weld hot cracking. (e) Free-machining base metal will increase the probability of hot cracking of the weld metal. Type 312 filler metal provides weld deposits that contain a large amount of ferrite to prevent hot cracking.

(f) Welds made with types 316, 316L, 317 and 317(Cb) electrodes or welding rods may occasionally display poor corrosion resistance in the as-welded condition. In such cases, corrosion resistance of the weld metal may be restored by the following heat treatments: for types 316 and 317 base metal, full anneal at 1950 to 2050 F; for types 316L and 317L base metal, 1600 F stress relief; for type 318 base metal, 1600 to 1650 F stabilizing treatment. Where postweld heat treatment is not possible, other filler metals may be specially selected to meet the requirements of the application for corrosion resistance.

(g) Type 321 covered electrodes are not regularly manufactured, because titanium is not readily recovered during deposition. (h) Caution is needed in welding thick sections, because of cracking problems in heat-affected zones. (j) In base metal and weld metal, for nuclear service, tantalum is restricted to 0.10% max, and cobalt to 0.20% max. (k) Annealing softens and imparts ductility to heat-affected zones and weld. Weld metal responds to heat treatment in a manner similar to the base metal. (m) These austenitic weld metals are soft and ductile in as-welded condition, but the heat-affected zone will have limited ductility.

(n) Requires careful preheating and postweld heat treatment to avoid cracking. (p) Requires careful preheating. Service in as-welded condition requires consideration of hardened heat-affected zones. (q) Annealing increases ductility of heat-affected zones and weld metal. Type 405 weld metal contains columbium rather than aluminum, to reduce hardening. (r) Annealing is employed to increase ductility of the welded joint. (s) Type 308 filler metal will not display scaling resistance equal to that of the base metal. Consideration must be given to differences in the coefficients of thermal expansion of the base metal and the weld metal.

at temperatures below 1200 F. Because of the high coefficient of expansion and the low thermal conductivity of austenitic stainless steels, cooling from the stress-relieving temperature must be slow.

The stress-relieving temperature selected must be compatible with the extent of carbide precipitation acceptable, and with the corrosion resistance desired. Nonstabilized steels cannot be stress relieved in the sensitizing-temperature range without sacrifice of corrosion resistance. Extra-low-carbon steels will be affected much less, because carbide precipitation in these steels is sluggish. Stabilized steels present no problem.

For austenitic stainless steels, the estimated percentages of residual stress relieved at various temperatures (for the times previously noted) are:

1550 to 1650 F ....85% stress relief
1000 to 1200 F ....35% stress relief

Examples of Welding Practice. Nineteen examples in this article deal with the arc welding of austenitic stainless steels. Table 2 identifies the steels and the welding processes employed, and relates them to the examples of specific applications.

Martensitic Stainless Steels

The standard martensitic stainless steels are types 403, 410, 414, 416, 416(Se), 420, 431, 440A, 440B and 440C. These steels derive their corrosion resistance from chromium, which they contain in proportions ranging from 11.5 to 18%. Steels with higher chromium content require a higher carbon content, to ensure the formation of martensite during heat treatment. The three type 440 stainless steels are seldom considered for applications that require welding, and filler metals of the type 440 compositions are not readily available.

Modifications of the standard martensitic steels contain additions of elements such as nickel, molybdenum, vanadium and tungsten, primarily to raise the allowable service temperature above the 1100 F limit for the standard steels. When these elements are added, carbon content is increased. With increasing carbon content, the problem of avoiding cracking in the hardened heat-affected zone of weldments becomes more serious.

Martensitic stainless steels can be welded in the annealed, hardened, and hardened and tempered conditions. Regardless of the prior condition of the steel, welding will produce a hardened martensitic zone adjacent to the weld. The hardness of the heat-affected zone depends primarily on carbon content of the base metal. As hardness increases, toughness decreases, and the zone becomes more susceptible to cracking. Preheating and control of interpass temperature are the most effective means of avoiding cracking. Postweld heat treatment is required to obtain optimum properties.

Preheating and Postweld Heat Treating. The usual preheating temperature range for the martensitic steels is 400 to 600 F. The carbon content of the steel is the most important factor in determining whether or not preheating will be necessary. On the basis of carbon content alone, a steel containing not more than 0.10% C seldom requires preheating, and one with more than 0.10% C requires preheating, to prevent cracking. Other factors that determine the need for preheating are the mass of the joint, the degree of restraint, the presence of a notch effect, and the composition of the filler metal.

The following guide can be used to correlate preheating and postweld heat treating practice with carbon contents and welding characteristics of martensitic stainless steels:

Carbon Below 0.10%. In general, neither preheating nor postweld annealing is required. Steels with carbon contents this low are not standard.

Carbon 0.10 to 0.20%. Preheat to 500 F, weld at this temperature, and cool slowly.

Carbon 0.20 to 0.50%. Preheat to 500 F, weld at this temperature, and anneal after welding.

Carbon Over 0.50%. Preheat to 500 F, weld with high heat input, and anneal after welding.

If the weldment is to be hardened and tempered immediately after welding, annealing may be omitted. Otherwise, the weldment should be annealed immediately after welding, without being allowed to cool to room temperature. The temperature ranges for subcritical and full annealing of the martensitic stainless steels are:

Type of stainless steel	Subcritical annealing, F	Full annealing, F
403, 410, 416	1350-1450	1550-1600
420	1375-1425	1600-1650
414	1225-1300	...
431	1150-1225	...
440A, 440B, 440C	1350-1450	1650

Filler Metal. Types 410 and 420 are the only standard martensitic stainless steels available in the form of bare or covered electrodes, for use as filler metal. This limitation is important when attempting to secure similar properties in both weld metal and base metal. Martensitic stainless steel weld metals are low in toughness in the as-deposited condition and are seldom placed in service without being heat treated to improve toughness.

Austenitic stainless steel filler metals are often used to weld the martensitic stainless steels. These electrodes or welding rods provide an as-welded deposit of somewhat lower strength, but of greater toughness, than the martensitic types. Filler metals suitable for welding some martensitic stainless steels are given in Table 1.

Example of Welding Practice. As noted in Table 2, Example 268 in this article describes an application of submerged-arc welding of martensitic stainless steel type 403.

Ferritic Stainless Steels

In general, the ferritic stainless steels are less weldable than the austenitic stainless steels. The ferritic steels also produce welded joints having lower toughness, because of grain coarsening that occurs at the high welding temperatures.

The standard ferritic stainless steels are: type 446 (25% Cr); types 430, 430F and 430F(Se) (17% Cr); and types 405 and 409 (13% Cr). Type 409 is ferritic because it has a low carbon content (0.08% max) and a minimum titanium content equal to six times the carbon content. Type 405, which also contains only 0.08% max C, contains an average of 0.20% aluminum, which is a strong ferrite former.

Effect of Welding Heat on Martensite Formation and Grain Coarsening. Although most ferritic stainless steels have compositions that ensure a ferritic structure at room temperature, variations in composition within the regular limits can result in the formation of small amounts of austenite during heating to elevated temperature. On cooling, the austenite transforms to martensite, resulting in a duplex structure of ferrite and a small amount of martensite. The martensite reduces both the ductility and the toughness of the steel. Annealing will transform the martensite and restore normal ferritic properties, but annealing increases cost and can result in an excessive amount of distortion — particularly in parts that were previously formed by a cold working process.

All ferritic stainless steel mill products are normally annealed at the mill to transform any martensite that may be present to a softer structure of ferrite and carbides. In this condition, the steel can be readily formed, bent or drawn. It is only when the steel is heated near or above the transformation temperature (approximately 1600 F), as during welding, that the risk of austenite formation (and subsequent transformation to martensite) arises. In addition, heating to temperatures above 1750 F results in enlargement of the ferrite grain size, which also reduces the ductility and toughness of the steel. Although martensite can be eliminated by annealing, coarsened ferrite grains remain unaffected. Because martensite responds to annealing and inhibits ferrite grain growth, some applications may benefit from martensite formation, provided that the workpiece can be annealed after welding. In a 17% chromium steel, martensite formation is promoted by lowering the chromium content to 15 or 16%. When this practice is adopted, it is usually necessary to preheat before welding or to select a steel of lower carbon content, in order to guard against cracking in the heat-affected zone.

When postweld annealing is not feasible, the ductility of the welded joint can be controlled by the selection of a stainless steel base metal containing a substantial amount of a strong ferrite former, such as aluminum, columbium or titanium. One such steel, which has the commercial designation of type 430(Ti), is a 17% chromium steel containing 0.12% max carbon and a minimum titanium content equal to six times the carbon content. The metallurgical functions of the titanium in this steel are to form stable titanium carbides and to promote the formation of ferrite. When a completely ferritic steel is welded, no martensite is formed in the heat-affected zone, although some grain coarsening may occur. Grain coarsening can be controlled to some extent by minimizing heat input during welding and by avoiding slow cooling from the welding temperature.

Effect of Temperature on Notch Toughness. For the 17% chromium steels, the temperature range for transition from a tough, shear-type fracture (at the higher temperature) to a brittle, cleavage-type fracture (at the lower temperature), upon impact at a notch, lies just above room temperature. Under impact loading at room temperature and below, these steels are notch sensitive, and impact-test values of less than 15 ft-lb are usual. At 200 to 250 F, the impact-test values increase to approximately 30 to 50 ft-lb.

This relation between notch toughness and temperature is important in the selection of joint design and welding conditions for ferritic stainless steel. In service, a weldment designed primarily to withstand static load may be subjected to accidental or unforeseen impact loading. Furthermore, a weldment with low notch toughness may not withstand appreciable multiaxial stresses even under a low rate of loading. Because multiaxial residual stresses are often developed during welding (especially when welding heavy sections), notches and points of stress concentration that might cause failure in service must be avoided whenever possible.

Because a relatively small increase in temperature greatly increases the toughness of the ferritic stainless steels, preheating before welding is often useful in preventing cracking during welding.

Preheating. The recommended preheating temperature range for ferritic stainless steels is 300 to 450 F. The need for preheating is determined to a large extent by the composition, mechanical properties, and thickness of the steel being welded. Steels less than ¼ in. thick are much less likely to crack during welding than those more than ¼ in. thick. However, other factors, such as the type of joint, joint location, restraints imposed by clamping and jigging, the welding process, and the rate of cooling from the welding temperature, can affect weld cracking (Example 251 describes an application in which crack-free welds were made in type 430 steel without preheating or postheating).

Postweld Annealing. The temperature range for postheating or postweld annealing of ferritic stainless steels is 1450 to 1550 F, which is safely below the temperatures for austenite formation and grain coarsening. Annealing transforms a mixed structure to a wholly ferritic structure and restores the mechanical properties and corrosion resistance that may have been adversely affected by the high temperatures encountered in welding. Thus, except for its inability to refine coarsened ferrite grains, annealing is generally beneficial. However, annealing has two major disadvantages: (*a*) the time and cost of the treatment; and (*b*) the need to prevent the formation of scale during heat treating, or to remove scale that does form. In addition, annealing may require the use of elaborate fixturing to prevent sagging or distortion of the weldment.

Cooling ferritic stainless steel from the annealing temperature may be done in air or by water quenching. To minimize distortion from handling, weldments often are allowed to cool to about 1100 F before they are removed from the furnace. However, slow cooling through the temperature range of 1050 to 750 F must be avoided, because it produces brittleness in the steel. Normally, susceptibility to this type of embrittlement, known as "885 F embrittlement", increases with increasing chromium content. Heavy sections may require forced cooling or a spray quench to bring them safely through this embrittlement range.

Table 2. Examples in This Article That Describe Arc Welding of Austenitic, Martensitic, Ferritic and Precipitation-Hardening Stainless Steels

Type of steel	Welding process(a)	Example
Austenitic Steels		
301 to AM-350	GTAW	261(b)
303 to low-carbon	GMAW	264(b)
304	GTAW	243, 245, 249

PH 15-7 Mo	GTAW	247
AM-350 to 301	GTAW	261(b)
Cast Stainless Steel		
CD-4MCu to CD-4MCu	SMAW	267

(a) GMAW = gas metal-arc welding; GTAW = gas tungsten-arc welding; OAW = oxyacetylene welding; SAW = submerged-arc welding; SMAW = shielded metal-arc welding. (b) Welding of dissimilar metals. (c) Example deals with welding of type 321 to type 321, to alloy A-286, or to Inconel 718. (d) Progressive reselections of process. (e) For root pass and filler passes, respectively.

Selection of Filler Metal. As shown in Table 1, both ferritic and austenitic stainless steel filler metals are used in the arc welding of ferritic stainless steel. Ferritic stainless steel filler metals offer the advantages of having the same color and appearance, the same coefficient of thermal expansion, and essentially the same corrosion resistance as the base metal. However, austenitic stainless steel filler metals are often used to obtain more ductile weld metal in the as-welded condition.

Although austenitic stainless steel weld metal does not prevent grain growth and martensite formation in the heat-affected zone, the ductility of austenitic weld metal improves the ductility of the welded joint. However, the selection of austenitic stainless steel filler metal should be carefully related to the specific application, to determine whether differences in color or in the physical and mechanical properties of the weld metal and the base metal will cause difficulty.

For weldments that are to be annealed after welding, the use of austenitic filler metal can introduce several problems. The normal range of annealing temperature for ferritic stainless steels falls within the sensitizing-temperature range for austenitic steels. Consequently, unless the austenitic weld metal is of extra-low carbon content or is stabilized with columbium, tantalum or titanium, its corrosion resistance may be seriously impaired. Further, if the annealing treatment is intended to relieve residual stress in the weldment, it cannot be fully effective because of the difference in the coefficients of thermal expansion of the weld metal and the base metal.

Corrosion Resistance. Ferritic stainless steels are generally less corrosion resistant than austenitic stainless steels; therefore, any condition of the welded joint that might impair corrosion resistance must be avoided. The presence of martensite or the precipitation of sigma phase at the grain boundaries can cause severe intergranular corrosion in the heat-affected zone. Completely ferritic steels, such as types 430(Ti) and 446, display little or no susceptibility to intergranular attack at the welded joint. Annealing of any welded ferritic steel eliminates the unfavorable structural conditions that promote corrosive attack.

Examples of Welding Practice. As noted in Table 2, Examples 251, 252 and 257 in this article describe the application of gas tungsten-arc welding to ferritic stainless steels.

Precipitation-Hardening Stainless Steels

Designations and nominal compositions of typical precipitation-hardening stainless steels are given in Table 3. The steels are divided into three groups on the dual basis of characteristic alloying additions (particularly the elements added to promote precipitation hardening) and of the matrix structures of the steels in the solution-annealed-and-aged condition. Because these differences among the steels have a direct bearing on the behavior of the steels in heat treatment and in welding, the metallurgical characteristics of each of the three groups of steels are considered separately in the discussion that follows.

Martensitic Precipitation-Hardening (PH) Steels. These steels have a predominantly austenitic structure at the solution annealing temperature (1900 to 1950 F, approximately), but they undergo an austenite-to-martensite transformation when cooled to room temperature. The M_S temperature is usually in the range of 200 to 300 F.

Table 3. Nominal Compositions of Typical Precipitation-Hardening Stainless Steels

Common designation	AISI type	C	Cr	Ni	Mo	Cu	Al	Other
		Nominal composition, %						
Martensitic PH Steels								
Stainless W	635	0.07	17	7.0	...	...	0.2	0.7 Ti
17-4 PH	630	0.04	17	4.0	...	4.0	...	0.3 Cb
15-5 PH	...	0.04	15	5.0	...	4.0	...	0.3 Cb
PH 13-8 Mo	...	0.04	13	8.0	2.0	...	1.0	...
Semiaustenitic PH Steels								
17-7 PH	631	0.07	17	7.0	...	...	1.0	...

AM-350	633	0.08	17	4.0	3.0	...	...	...
AM-355	634	0.12	16	5.0	3.0	...	...	...
Austenitic PH Steels								
17-10 P	...	0.12	17	10.0	...	...	...	0.25 P
HNM	...	0.30	19	9.0	...	...	...	3.5 Mn, 0.3 P

When the martensite is reheated to 900 to 1100 F, precipitation hardening and strengthening occur, being promoted by the presence of one or more alloying additions — notably molybdenum, copper, titanium, columbium and aluminum. These elements and their compounds, which are dissolved during annealing and retained in solid solution by rapid cooling, produce a precipitate (usually, submicroscopic particles) that increases both the strength and the hardness of the martensitic matrix.

The compositional balance in the martensitic PH steels is critical, because relatively slight variations in composition can lead to the formation of excessive amounts of delta ferrite during solution annealing, or if the austenite is too stable, to the retention of large amounts of austenite at room temperature after solution annealing. Either of these two conditions will prevent full hardening during aging.

Welding Procedures for Martensitic PH Steels. These steels can be readily welded. The welding procedures employed resemble those ordinarily used for the series 300 stainless steels, despite differences in composition and structure between the two classes. The formation of martensite, which occurs during cooling from elevated temperatures such as those that occur in welding, does not result in full hardening. These steels are not sensitive to cracking and do not require preheating.

Selection of filler metal depends on the properties required of the welded joint. If strength comparable to that of the base metal is not required at the welded joint, a tough series 300 stainless steel filler metal may be adequate. When a weld having mechanical properties comparable to those of the hardened base metal is desired, the filler metal must be of comparable composition, although slight modifications are permissible to obtain better weldability.

When welds are deposited in a single pass, the weld metal and the heat-affected zone will usually respond uniformly to a postweld precipitation-hardening heat treatment; there is seldom any significant variation in hardness across the joint. Multiple-pass welds, however, exhibit a less uniform response to the same heat treatment, because successive applications of heat in welding result in marked variations in the structure of weld metal, heat-affected zone, and base metal. Annealing will eliminate these variations, and provide a more uniform structure capable of responding uniformly to precipitation hardening.

Semiaustenitic PH Steels. Unlike the martensitic PH steels, semiaustenitic PH steels are soft enough in the annealed condition to permit cold forming, drawing, rolling and spinning. When cooled rapidly from the annealing temperature to room temperature, they retain their austenitic structure, which displays good toughness and ductility in cold forming operations. The M_s temperatures for these steels are well below room temperature, but they vary, depending on composition and annealing temperature.

To obtain hardening and strengthening, the austenitic structure must be transformed to an essentially martensitic one. This can be accomplished by (*a*) heating the steel in the range of 1200 to 1600 F to precipitate carbides and other compounds, thus depleting the matrix of enough austenite-stabilizing elements to allow transformation of austenite to martensite when the steel is cooled to room temperature; (*b*) refrigerating the steel to a temperature well below the M_s point (−100 F, for example); or (*c*) cold working the steel enough so that the austenite transforms to martensite.

After transformation to martensite, the semiaustenitic PH steels respond to precipitation hardening in the temperature range of 850 to 1100 F in a manner similar to the martensitic PH steels. Whether a precipitate forms or a tempering reaction takes place depends on the steel composition.

The M_s temperature of the semiaustenitic PH steels is controlled by the solution annealing temperature, as well as by composition. For example, when AM-350 steel is solution annealed at temperatures below 1700 F, incomplete carbide solution results in raising the M_s temperature above room temperature. On the other hand, when the solution annealing temperature is raised above 1700 F, the M_s temperature drops precipitously. In practice, the solution annealing temperature is not permitted to exceed about 1925 F, because higher temperatures promote the formation of delta ferrite, which may increase the M_s temperature.

Welding Procedures for Semiaustenitic PH Steels. The semiaustenitic PH steels are normally welded in the annealed condition; the tough austenitic structure imparts welding characteristics similar to those of series 300 stainless steels. The semiaustenitic PH steels are not susceptible to cracking when welded, even when welded after transformation to martensite, because the low-carbon martensite developed is not of high hardness nor of low ductility. Also, cold cracking does not occur in the base metal adjacent to the weld, because the heat-affected zone is austenitized during welding and remains substantially austenitic as the joint cools to room temperature.

The choice of filler metal depends largely on the weld properties desired. The filler metal can be an alloy of precipitation-hardening composition capable of developing mechanical properties comparable to those of the base metal; or, if high strength is not a requisite, the filler metal can be a series 300 austenitic stainless steel.

When these steels are welded in the annealed condition, the following microstructural relations generally obtain as a result of relatively rapid heating and cooling at the joint:

1 The weld metal contains a small amount of ferrite in a matrix that is essentially austenite (hardness: approximately Rockwell B 90).
2 The base metal immediately adjacent to the weld displays a high-temperature annealed (austenitic) structure, having a hardness of approximately Rockwell B 90.
3 The base metal in a narrow zone just beyond the annealed zone next to the weld is hardened slightly (hardness: approximately Rockwell B 90 to 98).

If the welded assembly is given the customary double-aging heat treatment, the three areas identified above, as well as the unaffected base metal, will transform and precipitation harden uniformly to a hardness range commensurate with the precipitation-hardening temperature. The weld metal may be somewhat less tough than the wrought base metal (as measured by the results of tensile-elongation and bend tests), depending on the type of joint, the welding process, and the hardening temperature.

Higher precipitation-hardening temperatures will ensure good weld toughness with little sacrifice of strength. Maximum toughness requires annealing of the weldment prior to the transformation and hardening treatments. Although other variations in the welding and heat treating sequence are possible, and may be desirable at times, the choice of the sequence should be such that, after welding, the weld metal and the heat-affected zone are in the annealed (austenitic) condition. To harden these areas, both the transformation and the precipitation-hardening heat treatments must be applied. If the components are given the transformation treatment before welding, the precipitation-hardening treatment alone, after welding, will produce no significant hardening in either the weld metal or the heat-affected zone.

Austenitic PH Steels. The alloy content of these steels is high enough to maintain an austenitic structure after annealing, and after any aging or hardening treatment. The precipitation-hardening phase is soluble at the annealing temperature (2000 to 2050 F), and it remains in solution during rapid cooling from the annealing temperature. When these steels are re-

heated to about 1200 to 1400 F, precipitation occurs, and the hardness and strength of the austenitic structure increase. The hardness attained is lower than that of the martensitic or semiaustenitic PH steels, but the nonmagnetic properties are retained.

Welding of Austenitic PH Steels. Although the austenitic PH steels remain austenitic during all phases of forming, welding and heat treatment, some contain alloying elements (for precipitation-hardening purposes) that greatly affect behavior in welding.

The two austenitic PH steels listed in Table 3, 17-10 P and HNM, have very limited weldability; when heated above about 2150 F, they exhibit hot shortness because of the formation of phosphorus-rich compounds at the grain boundaries. When these steels are arc welded, hot shortness causes underbead cracking in the heat-affected zone. However, 17-10 P steel has been successfully flash welded, apparently because the upsetting force was adequate to extrude the hot short material in the form of flash and thus to produce a sound weld.

Examples of Welding Practice. Table 2 refers to six examples in this article on gas tungsten-arc welding of precipitation-hardening stainless steels.

Gas Tungsten-Arc Welding

Gas tungsten-arc welding is adaptable to both manual and automatic operation, in all welding positions. The process can be used to produce continuous welds, tack welds, and spot welds, and it is capable of producing welds with or without filler metal.

The fundamentals of gas tungsten-arc welding, as they relate primarily to the welding of carbon and low-alloy steels, are covered in the article on Gas Tungsten-Arc Welding, which begins on page 113. Because this basic information applies to the gas tungsten-arc welding of all metals that can be welded by this process, including stainless steel, only those modifications that apply specifically to stainless steel are considered in this article.

Applicability to Stainless Steel. Gas tungsten-arc welding is particularly well suited to the welding of virtually all types and compositions of stainless steel, because: (*a*) the filler metal, when used, does not pass through the arc and, as a result, does not undergo significant alteration in composition; (*b*) the shielding atmosphere enveloping the arc is chemically inert, which eliminates the hazard of gas-metal reactions; and (*c*) no flux is used, so there are no slag-metal reactions and no nonmetallic inclusions. Transfer of elements from the filler-metal welding rod to the weld deposit is high, and the pickup of contaminants is extremely low. Because the properties and characteristics of stainless steels depend greatly on the maintenance of a preferred composition within close limits and on the avoidance of pickup of contaminants during the welding cycle, gas tungsten-arc welding is well suited to welding them, whether a filler metal is used or not.

Alloys Welded. Gas tungsten-arc welding can be applied to all weldable stainless steels, in both the wrought and cast forms, to clad products, such as stainless-clad carbon steel, and to dissimilar stainless alloys. The problems that may be encountered in welding certain alloys are not unique to gas tungsten-arc welding but rather reflect the specific weldability of the alloys. For example, the problem of how to avoid cracking in the hardened heat-affected zones of martensitic alloys becomes more serious with increase in carbon content. Selenium, which is added to certain alloys to improve their machinability, may prove troublesome in welding. These and other metallurgical considerations are discussed in the four preceding sections of this article, which deal with the welding characteristics of austenitic, martensitic, ferritic and precipitation-hardening stainless steels.

Work-Metal Thickness. For stainless steels, the gas tungsten-arc process is best suited, although not limited, to welding metal thicknesses of ¼ in. and less. Foil 0.002 in. thick has been welded successfully, using automatic equipment (see Fig. 18). In general, thicknesses from about 5⁄16 to ½ in. can be satisfactorily welded using multiple passes. Welding of sections thicker than ½ in. by the gas tungsten-arc process is usually ruled out because of high cost, but it may be used to obtain welds of high quality or to employ available equipment.

Workpiece Shape. Stainless steel imposes no limitations on workpiece shape that would not apply equally to the welding of carbon and low-alloy steels. General limitations are considered on page 113 in the article on Gas Tungsten-Arc Welding.

Welding Positions. Gas tungsten-arc welding of stainless steel can be performed manually in the flat, horizontal, vertical and overhead positions. Automatic out-of-position welding is possible with the use of special fixtures.

Current Characteristics. Although the general procedures for gas tungsten-arc welding of stainless steel are similar to those used for low-carbon ferritic steel, certain of the physical properties of stainless steel necessitate some alteration of current characteristics in welding. Specifically, the stainless alloys have higher thermal expansion and lower thermal conductivity, which increases the likelihood of distortion during welding. They also have

(a) Available with a high silicon content (0.50 to 1.0%) and is so designated by an Si following the standard classification. (b) Chromium, (min), equals 1.9 times nickel, when so specified. (c) Columbium plus tantalum: 8 × C (min) to 1.0% (max). (d) 3.0 to 4.0% Cu. (e) Titanium: 9 × C (min) to 1.0% (max). (f) Columbium plus tantalum: 10 × C (min) to 1.0% (max). (g) Columbium plus tantalum: 10 × C (min) to 1.0% (max); tantalum max = 0.10%. (h) Tungsten, 1.25 to 1.75%; columbium plus tantalum, 1.0 to 1.4%; titanium, 0.10 to 0.30%.

generally lower melting points, which results in a slightly higher rate of weld-metal deposition for the same welding current.

Direct current of the constant-current (drooping-voltage) type, with straight polarity, is used, and the considerable heating effect produces a narrow, deep-penetration weld.

Although scratch starting may be acceptable in some applications, it can result in electrode contamination of the weld. For the same reason, and because of the possibility of carbon pickup, the arc must not be struck on a carbon block. High-frequency starting, which necessitates the use of a high-frequency generator to provide an ionized path for the welding current, is, therefore, most commonly used.

Table 4 shows ranges of welding current recommended for use in manual gas tungsten-arc welding of joints of several designs between stainless steel of various thicknesses, in the flat, vertical and overhead positions. These recommendations may be compared with the values for welding current shown in Table 5, which compares actual conditions reported for manual gas tungsten-arc welding in ten of the examples presented in this article.

Tungsten Electrodes. Of the five types of tungsten electrodes available for gas tungsten-arc welding, the most widely used for stainless steel is EWTh-2 (97.5% tungsten and 1.7 to 2.2% thoria). The thoriated electrodes are recommended because of their excellent emissive qualities. They may be used at higher current than pure tungsten electrodes, and they provide exceptional arc stability. The EWTh-2 electrodes are obtainable in standard diameters of 0.010 to ¼ in. Standard lengths generally used are 3, 6 and 7 in.

Contact between the end of the electrode and the molten stainless steel puddle may result in contamination of the weld metal, and this contamination may affect the properties of the weld metal adversely.

Shielding Gases. Depending on the application, argon, helium, or a mixture of argon and helium is used in the welding of stainless steel. The same gases may also be used for backing the weld. Argon is usually preferred, because it provides excellent protection at considerably lower flow rates. Furthermore, in welding thicknesses up to 1⁄16 in., there is less likelihood of burn-through when argon is used. Helium produces the higher heat input and deeper penetration required when welding thicknesses of more than about 1⁄16 in. On the other hand, the welding operation is usually easier with argon, especially in manual applications, because heat input to the weld puddle is less affected by variations in arc length. Finally, argon is less expensive than helium and is more readily available. However, as noted in Examples 247, 248, 253 and 261, helium is preferred as a protective gas or backing gas in some applications, and may be used with argon (as in Example 256).

Filler Metals for Gas Tungsten-Arc Welding

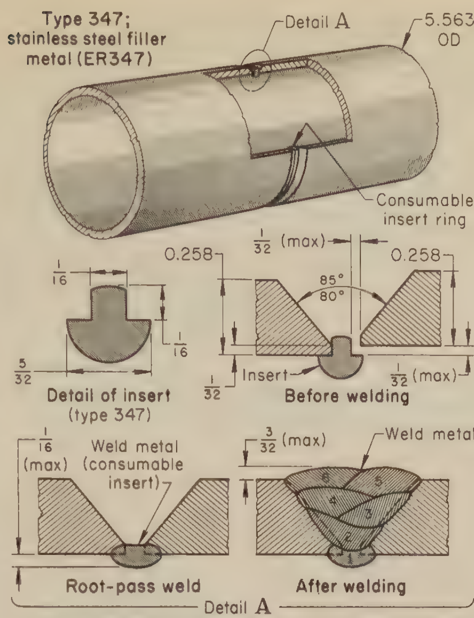
Bare stainless steel filler metals for use in gas tungsten-arc welding are covered by AWS specification A5.9-69. Designations and compositions of the filler metals are given in Table 6.

Sizes and Forms. Table 7 gives the standard sizes (diameters) of stainless steel filler metal in the three forms used in gas tungsten-arc welding of stainless steel — rod in straight lengths, wire in coils, and wire on 12-in.-OD spools. Normally, straight lengths are used in manual gas tungsten-arc welding, and coils and spools in automatic welding.

Selection of Filler Metal. It is evident from the filler-metal compositions listed in Table 6 that there are available filler metals that will deposit weld metal of compositions comparable with those of the standard wrought stainless steels. Generally, however, the problem of selecting a filler metal is not solved solely by matching alloy designations or compositions. Other factors, such as the interalloying of filler metal and base metal, filler-metal selection for welding dissimilar metals, and the metallurgical structure and properties of the weld deposit, must be considered. These factors are discussed in the sections earlier in this article that deal with the welding of austenitic, martensitic, ferritic and precipitation-hardening stainless steels. The filler metals suitable for welding similar stainless steels are given in Table 1; this table also lists the metallurgical condition in which the resulting weldment will be placed in service — a major consideration in the selection of filler metal. Table 8 shows filler metals suitable for welding joints in dissimilar austenitic stainless steels.

Use of Consumable Inserts. Consumable inserts offer an alternative method of supplying filler metal (*a*) when making the root pass in butt joints where accessibility is limited to one side of the joint, (*b*) where smooth, uniform, crevice-free contours are mandatory, or (*c*) where a root pass of highest quality is essential to the integrity of the completed weld. For pipe and tube joints, inserts are available in the form of rings of suitable diameter. Gas tungsten-arc welding results in the consumable insert being completely fused with the base metal.

Stainless steel inserts are of compositions formulated to promote weldability and to reduce the possibility of weld cracking. With inserts, smooth, uniform melting on pipe interiors is relatively easy to obtain, and weld contour appears to be relatively insensitive to welding variables.



Process ......Manual gas tungsten-arc welding
Joint type ....Circumferential butt
Weld type ....Single-V groove
Fixtures .....Turning rolls (shop); none (field)
Power supply ......300-amp motor-generator or transformer-rectifier
Electrode holder ....200 amp, water cooled
Electrode ....3/32-in.-diam EWTh-2(a)
Filler metal:
Root pass ....Type 347 consumable insert ring(b)
Filler passes ....3/32 and 1/8-in.-diam ER347
Shielding gas ....Argon, at 20 cfh(c)
Welding position ....Horizontal-rolled pipe (in shop)
Arc starting ....High frequency
Arc length ....3/32 to 1/8 in.(a)
Current (dcsp) ....Root pass, 85 amp; filler passes, 100 amp
Voltage ....12 to 15 v(a)
Preheat and postheat ....None

(a) For root pass and filler passes. (b) Containing 5 to 12% ferrite. (c) Argon, at 20 cfh, was also used for purging and backing.

Fig. 3. Nuclear-reactor pipe with a circumferential butt joint for which a consumable insert ring was used for the root pass, to ensure weld soundness (Example 242)

In joints that must satisfy high acceptance standards under visual, liquid-penetrant, and x-ray radiographic examination (as in the application described in the next example), the use of insert rings often serves to provide a root pass of highest quality. This benefit must be weighed against the cost of the insert rings and the extra labor cost for their installation.

Example 242. Use of Consumable Insert Rings in Welding 0.258-In.-Wall Type 347 Piping (Fig. 3)

Consumable insert rings were used for root-pass welding of circumferential butt joints in type 347 stainless steel piping. A typical joint, shown in Fig. 3, consisted of a single-V-groove with an insert ring fitted to the abutting ends of 5-in., schedule 40S (0.258-in. wall) piping. The piping was used in either the primary or secondary system of a nuclear reactor, and was required to withstand pressure of 2000 psi at an operating temperature of 600 F under water. The welded joints, therefore, had to meet rigid specifications, which included:

1 Complete joint penetration, with no notches at the root
2 Smooth inner surface, free from scale and oxides
3 Freedom from slag inclusions and cracks
4 Minimum porosity, as determined by radiographic inspection.

The manual gas tungsten-arc process was selected for welding the root pass, because of the reliability of the process in producing high-quality welds with smooth inner surfaces. The same welding process was used for the filler passes, because the wall thickness of the pipe was not great enough to warrant changing to another (and possibly more economical) process. The single-V-groove joint design was adopted because it was simple to prepare, afforded adequate access to the root of the joint, and did not require an excessive quantity of filler metal to make the weld.

The insert rings were of type 347 stainless steel modified to obtain 5 to 12% ferrite in the weld, to control microfissuring and cracking. The melting characteristic of the inserts, and the manner in which the weld puddle rose in the joint because of surface tension, enabled the welder to see exactly when the root pass had been properly made and the insert ring fused.

The bevels at the pipe ends for the V-groove were prepared either by machining or by careful grinding, within the dimensional tolerances shown in the middle right view in Fig. 3. Misalignments of the pipe ends and excessive root opening, which would have interfered with proper

Table 7. Standard Sizes of Filler-Metal Rod and Wire Used in Gas Tungsten-Arc Welding of Stainless Steel (AWS 5.9)

Form of filler metal	Diameter, in.(a)
Rod in straight lengths(b)	0.045, 1/16, 5/64, 3/32, 1/8, 5/32, 3/16
Wire in coils(c)	0.045, 1/16, 5/64, 3/32, 7/64, 1/8, 5/32, 3/16, 1/4
Wire on 12-in.-OD spools	0.030, 0.035, 0.045, 1/16, 5/64, 3/32, 7/64

(a) Tolerances are ±0.001 in. on diameters of 0.045 in. or less, and ±0.002 in. on diameters of 1/16 in. and larger. (b) Standard length is 36 +0, −1/2 in. (c) With or without support.

(a) The H suffix indicates a grade used for tubing for high-temperature service.

fusion, were avoided. The insert ring, in wire form, was carefully fitted and tack welded to the inside surface of one of the pipe sections, any overlap was trimmed off, and the ends were properly matched. The second pipe section was placed in position and aligned, and the complete assembly was held together by tack welds made at regularly spaced intervals.

Before making the root pass, the inside of the pipe was purged with argon, and the flow of argon was continued during welding, to provide backing gas and internal shielding. The general appearance of the root-pass weld is shown in the lower left view in Fig. 3. Filler passes were made with ER347 welding rods 3/32 and 1/8 in. in diameter. A cross section through the completed joint, showing the number of filler passes, is shown at lower right in Fig. 3. Welding conditions for the root pass and filler passes are given with Fig. 3.

After each operation (root pass and filler passes), welds were closely inspected by visual and liquid-penetrant techniques. The completed weld was then subjected to radiographic examination.

The production of nuclear reactor components required the welding of two circumferential butt joints in stainless steel pipes that, when assembled, served as a housing for drives. This nuclear application imposed rigid acceptance standards on weld quality, pipe alignment, and over-all dimensional tolerances. These standards were met by using consumable inserts and automatic welding, as described in the following example.

Example 243. Use of Consumable Inserts in Automatic Welding of 20-Ft-Long Tubular Housings (Fig. 4)

Housings for nuclear reactor components were produced as welded assemblies of type 304 stainless steel pipe sections ranging from 4 to 8 in. in outside diameter. Figure 4 shows a typical housing, 20 ft long, made up of two pipe sections tapered from 6-in. to 5-in. OD (pipes A and C) butt welded to the ends of a 5-in.-OD pipe (pipe B); all three components had a 3/8-in. wall thickness. The housing was required to be straight within 1/32 in. over the 20-ft length, and the welds had to meet stringent standards for soundness. Maintaining alignment and straightness was the major difficulty encountered during welding. To obtain ample control over all the welding conditions, an automatic welding procedure was developed. This incorporated the use of a consumable insert ring of inverted-T shape for the root-pass weld in each joint.

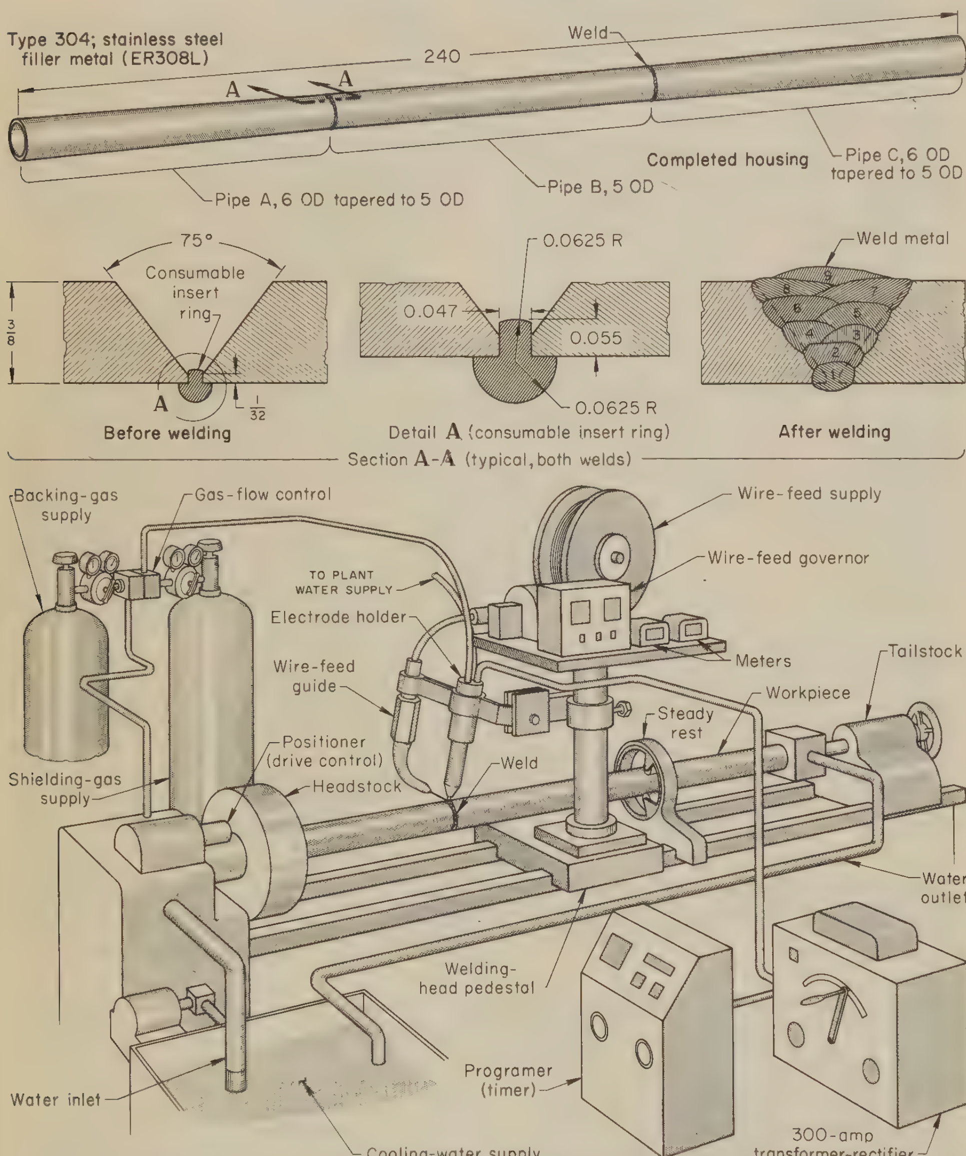
Equipment for the welding procedure (see bottom view in Fig. 4) was built around a large lathe bed that had been modified to support an automatic gas tungsten-arc welding head and wire-feed drive on the lathe carriage. A special drive, installed at the headstock, was controlled electronically by tachometer feedback to maintain less than 1% variation in the rotational speed of the pipe. Provision was also made for automatic control of (*a*) flow of shielding gas at the torch and for purge backing inside the pipe; (*b*) flow of cooling water at the torch, with optional flow inside the pipe; and (*c*) coordinated filler-metal feed, when required. The use of purge backing inside the pipe was restricted to the first three passes; when needed, water was used as coolant during the remaining passes.

Power was supplied by a 300-amp transformer-rectifier equipped with upslope and downslope current control and with provision for high-frequency arc starting. An automatic sequence timer (programer) controlled cycle timing (see item 16 in the list of operations, below) for each pass.

As shown in section A-A in Fig. 4, each butt joint had a 75° V-groove, and was designed with a 1/32-in. root face and a 0.047-in. root opening to accommodate a consumable insert ring. Although the base metal at the joint was only 3/8 in. thick, eight filler passes were specified, to avoid excessive heat input, which could result in distortion. Heat buildup was further controlled by establishing a maximum interpass temperature of 350 F. Cooling water was circulated inside the tubular housing during the last six filler-pass welds to cool the joint rapidly and prevent significant carbide precipitation in metal that had been heated in the sensitizing-temperature range (800 to 1600 F).

Machine settings and other welding conditions are summarized in the table that accompanies Fig. 4. The sequence of operations for welding, and the quality-control methods used, are listed below:

1 The edges of the pipes to be welded were beveled by machining; joint areas were cleaned by brushing with stainless steel brushes that had not been used on metals other than 18-8 stainless steel.
2 Pipe A was chucked in the headstock, using a dial indicator to verify accuracy of alignment.
3 Pipe B was placed in the steady rest, and the tailstock was advanced until pipes A and B were properly positioned; the dial indicator was used to check alignment. Tailstock was retracted.



Process	Automatic gas tungsten-arc welding	Welding position	Horizontal-rolled pipe
Joint type	Circumferential butt	Arc starting	High frequency
Weld type	Single-V groove	Arc length	3/32 ± 1/32 in.
Power supply	300-amp transformer-rectifier(a)	Current (dcsp):	
Auxiliary equipment	Sequence timer(b)	Passes 1 and 2	190 amp
Electrode holder	300 amp, water cooled(c)	Pass 3	200 amp
Electrode	1/8-in.-diam EWTh-2(d)	Passes 4 and 5	210 amp
Filler metal:		Passes 6 and 7	220 amp
Root pass	Consumable inverted-T-shape insert ring, type 308L	Passes 8 and 9	215 amp
Passes 2 to 9	0.035-in.-diam ER308L	Voltage (all passes)	11 v
Shielding gas:		Filler-wire feed rate	45 ipm
At torch	Argon, at 20 cfh	Preheat, postheat	None
Purge backing	Helium, at 10 cfh	Interpass temperature	350 F max
		Welding speed	7 ipm

(a) With high frequency, upslope and downslope control, and remote-control panel. (b) For programing and presetting of gas preflow and postflow, wire feed and weld time. (c) Machine type with gas lens, 1/2-in.-diam cup. (d) Tapered to 0.010-in. diameter over a 1/4-in. length at tip.

Fig. 4. Housing for a nuclear-reactor component (top) that was welded in the lathe setup shown, to maintain critical alignment, and for which consumable insert rings were used for root passes, to ensure weld soundness (Example 243)

4 The flow of purging gas was started and maintained for 5 min before welding began.
5 A consumable insert ring was tack welded in four places at 90° intervals to the joint face on pipe A.
6 Tack welds were wire brushed with a stainless steel brush.
7 Alignment was rechecked.
8 Buildup from tack welds was removed.
9 Tailstock was advanced to butt pipes A and B.
10 Midway between the original tacks, pipe B was tack welded to the insert. Tacks were continued across the insert to include pipe A.
11 Tack welds were wire brushed with a stainless steel brush.
12 Alignment was rechecked.
13 Buildup from tack welds was removed.
14 Welding cycle was started for the root pass (fusion of the insert ring).
15 The first pass was wire brushed when the pass was completed.
16 The headstock was turned 360°, while alignment was checked with a dial indicator. When the high point was reached, the headstock was turned 20°, and the second pass was started. This procedure was repeated after each pass. Typical cycle times for the 5-in.-OD pipe were:

Gas and water preflow	3 sec
Preheat (arc initiation by high frequency and upslope)	1.5 sec
Weld (starting with rotation and filler-metal feed)	2 min
Wire feed	1 min, 47 sec
Downslope	1 min, 55 sec
Gas and water postflow	10 sec

17 After three passes, water was circulated inside the pipes (if required) to keep the interpass temperature from exceeding 350 F. Interpass temperature was measured on the weld bead, using a calibrated contact pyrometer.
18 After each pass, the weld was checked visually for porosity, undercutting, cracks or poor appearance. Before the next pass was made, defects were removed by grinding with wheels that had been used only on 18-8 stainless steel.
19 The above procedures were repeated for the joint between pipes B and C.
20 After the welds were completed, weld metal was ground flush and inspected by the liquid-penetrant method. Welds, made in accordance with the ASME Boiler and Pressure Vessel Code, were inspected radiographically. The ASME Rules for Construction of Nuclear Vessels were also complied with.

Equipment cost for the operation amounted to about \$8000 — \$1000 for the lathe bed, which was purchased used, and about \$7000 for the welding machine, sequence timer, wire feed, electrode holder, cable, hoses, rotating drive, and the lathe modifications that were needed.

Root-Pass Welds Without Inserts. When the use of backing rings is prohibited, it is not essential to use consumable inserts to obtain smooth internal joint surfaces on pipe welds. An alternative method is to provide a groove weld with a root face of a width that permits complete root fusion in a single pass, using manual gas tungsten-arc welding and a gas backing. Filler metal is not used on the initial root pass. Subsequent passes to fill the joint may employ a different process, such as shielded metal-arc welding, because deposition of filler metal by manual gas tungsten-arc welding is relatively slow and expensive. An application of this type is described in the following example.

Example 244. Pipe Welding by Gas Tungsten-Arc Without Filler Metal for Root Pass, Shielded Metal-Arc for Filler Passes (Fig. 5)

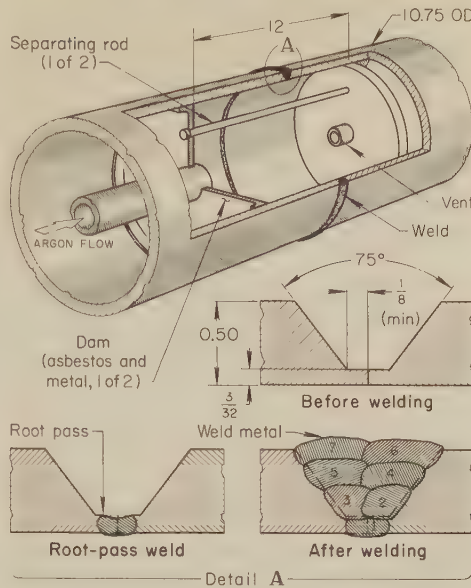
The 10-in., schedule 80S (0.50-in. wall) type 347 stainless steel pipe shown in Fig. 5 was used in oil-refinery equipment. Specifications called for pipe joints to have sound, complete-penetration welds conforming to the radiographic standards and other rules of the ASME code for unfired pressure vessels. The pipe joints also were required to have smooth, well-rounded inside surfaces; therefore, the use of solid backing strips was prohibited. Because there was no access to the inside of the joints, the success of the operation depended on the skillful execution of the root pass from the outside.

Manual gas tungsten-arc welding, with argon shielding and backing, and without the use of filler metal, was selected for the root pass. For the filler passes, shielded metal-arc welding was chosen.

Root-Pass Welding. Before welding, the pipe ends were beveled to the configuration shown in the "Before welding" view in Fig. 5. The joint area was cleaned of all oil, water and foreign matter. The pipe ends were then aligned, with root faces tightly butted, and tack welded.

The tack welded pipes were supported in position for welding, and purged with argon. This was accomplished by inserting two asbestos-and-metal dams as close to the joint as possible, and feeding argon through one dam and venting it (under back pressure) through the other, as shown in Fig. 5. After purging, a low flow of argon was maintained to provide backing during welding.

Type 347 base metal. Filler metals: none for root pass; filler passes, stainless steel (E347-16)



Root Pass (Gas Tungsten-Arc Welding)

Power supply	300-amp transformer-rectifier(a)
Electrode holder	200 amp, water cooled
Electrode	3/32-in.-diam EWTh-2
Filler metal	None(b)
Shielding gas	Argon, at 15 to 20 cfh
Backing gas	Argon, at 8 cfh
Welding position	Horizontal-fixed pipe
Arc length	1/8 in.
Current	70 amp, dcsp
Voltage	12 v

Filler Passes (Shielded Metal-Arc Welding)

Power supply	300-amp transformer-rectifier(a)
Electrode	E347-16 (1/8-in., first filler pass; 5/32-in., others)
Welding position	Horizontal-fixed pipe
Current (dcrp)	100 amp, first filler pass; 130 amp, others
Voltage	18 v, first filler pass; 20 v, others
Interpass temperature	350 F max

(a) With high-frequency generator, to facilitate arc starting. (b) In repair welding of root pass, 3/32-in.-diam ER347 welding rod was used.

Gas backing was used because the welded joint was required to have a smooth, well-rounded inner surface. Dams inserted in the pipe confined argon for purge backing and ensured minimum waste. Two-process welding, for which details are given in the table, resulted in 98% weld acceptability.

Fig. 5. Oil-refinery pipe with a circumferential butt weld for which root pass was made without filler metal (Example 244)

Conditions for welding the root pass are given in the table with Fig. 5. Welding was done in the horizontal fixed position, with the root pass being made in two semicircular halves beginning at the 6 o'clock position. The completed root-pass weld is shown in cross section in the lower left corner of Fig. 5.

In the horizontal fixed position, fusion of the root faces to form a uniformly smooth inside surface called for a high degree of welder skill, because the forces of gravity and surface tension acting on the molten weld puddle were in opposite directions at the top of the pipe and codirectional at the bottom — resulting in either convexity or concavity at the weld face. Thus, to ensure complete penetration, the welder had to avoid the formation of a large, superheated weld puddle by skillful control of heat input and welding speed.

Both visual and liquid-penetrant examinations were made on the completed root-pass weld, for defects such as cracks, porosity, excessive concavity or melt-through, and laminations. All defects were completely removed by grinding, and the defective areas were rewelded by the gas tungsten-arc process using ER347 filler metal. The repair welds were given visual and liquid-penetrant inspection, and if no further defects were found, the joint was cleaned and prepared for making the filler passes.

Filler-pass welding was done by the shielded metal-arc process, under the conditions given in the table with Fig. 5. Welding was done in the horizontal fixed position, using the same starting position and welding directions for each pass as in root-pass welding, but with a weaving technique. During the first filler pass, care was exercised to avoid burn-through of the relatively thin root-pass weld bead. After each of the six filler passes (see view at lower right in Fig. 5), slag was carefully removed by wire brush, or, if necessary, it was chipped out. Each pass was inspected visually for undercutting, slag inclusions, incomplete fusion, and porosity; areas with any of these defects were repaired by grinding and rewelding.

Interpass temperature, measured by a contact pyrometer, was maintained at 350 F max, but no preheat, postheat, or postweld heat treatment was used. The completed weld was inspected by either x-ray or gamma-ray radiography. Because of the care exercised in welding the root pass, defects averaged only 2% of the weld length.

Joint Design for Gas Tungsten-Arc Welding

Some typical joint designs for gas tungsten-arc welding of stainless steel, together with welding conditions for base metal in thicknesses ranging from 1/16 to 1/2 in., are given in Table 4. Joint designs reflecting actual industrial practice are illustrated in most of the examples in this article. Specific applications in which joint design was changed to obtain special advantages as a means of solving a problem in gas tungsten-arc welding are described in the next five examples.

Joint Design for Efficient Welding. In addition to its contribution to basic engineering requirements, joint design is a significant economic factor in welding, exerting a major influence on welding efficiency and cost. In production, some joint designs are difficult and time consuming to weld and, as discussed in the following example (also see Example 249), must be revised to conserve production time and labor.

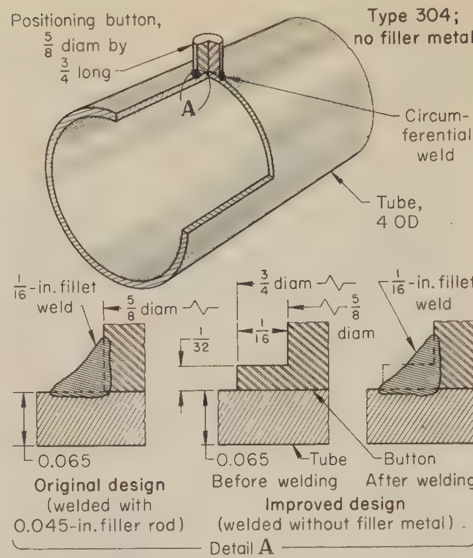
Example 245. Change in Joint Design That Eliminated Use of Filler Rod and Simplified Welding (Fig. 6)

Production of stainless steel molds for processing meat products required the welding of 19,600 positioning buttons to the surface of the mold tubes. The buttons, machined from type 304 bar stock, were ⅝ in. in diameter and ¾ in. long. The mold tubes, also of type 304, were 4 in. in outside diameter and had a 0.065-in. wall thickness. A portion of a meat processing mold with a positioning button welded to its surface is shown in Fig. 6.

The original joint design (see Fig. 6) called for placing the flat end of a button on the curved surface of the mold and depositing a 1⁄16-in. fillet weld around the base of the button, using manual gas tungsten-arc welding with a 0.045-in.-diam filler rod. A clamping fixture positioned the button and held it on the tube during welding. In a review of this procedure before production was started, it was apparent that the welder would have difficulty in maneuvering the electrode holder and filler rod around the button and also in maintaining a uniform fillet size.

The difficulty was avoided by changing the joint design so that the buttons could be welded to the mold surface without the use of filler metal. This was done by machining the buttons from ¾-in.-diam bar stock, so as to provide them with a shoulder, 1⁄16 in. wide and 1⁄32 in. thick, at the joint end. The ¾-in.-diam shoulder end of the button was welded, without filler metal, to the curved surface of the mold tube, with the shoulder forming a 1⁄16-in. circumferential fillet (see "Improved design" in Fig. 6). With the elimination of the filler rod, the welder had only the electrode holder to manipulate; as a result, welding speed was increased, control over penetration improved, and fillet size was more uniform. Welding conditions for the improved joint design are listed in the table accompanying Fig. 6.

The completed welds were wire brushed to remove any discoloration, and visually inspected for smoothness and uniformity of the fillet. Production rate averaged 38 buttons per hour. The improved welding speed and elimination of the filler rod more than offset the additional cost of machining the modified buttons.



Welding Conditions for Improved Design

Process	Manual gas tungsten-arc welding
Joint type	T, with shoulder
Weld type	Circumferential fillet
Fixtures	Clamping jig
Power supply	250-amp, three-phase transformer-rectifier
Electrode holder	300 amp, water cooled
Electrode	1⁄16-in.-diam EWTh-1
Filler metal	None (shoulder was fused)
Shielding gas	Argon, at 15 cfh
Welding position	Horizontal
Arc starting	Scratch
Arc length	⅛ in. (approx)
Current	34 amp, dcsp
Voltage	15 v
Welding speed	2 ipm (avg)
Production rate	38 buttons per hour

Fig. 6. Meat-processing mold with a positioning button that was redesigned for welding without filler metal (Example 245)

Joint Design for Structural Soundness. Joint design is sometimes modified to improve strength or rigidity, or to avoid a welding defect that would reduce structural soundness. In the following example, a visually attractive joint design was changed primarily to avoid burn-through.

Example 246. Redesign of Tube-to-Tube-Sheet Joint That Improved Weld Quality and Strength (Fig. 7)

Heat exchangers, designed for heating or cooling gases of various types, were made of parallel rows of oval-section type 304L stainless steel tubes seal-welded to a type 304L tube sheet, as shown in Fig. 7. Welds were made in a single pass by the manual gas tungsten-arc process, using argon shielding and ER308L filler rod.

In the original joint design (Fig. 7a), the tube sheet, 0.045 in. thick, was flared inward, and each seal weld was deposited between the rounded corner of the tube sheet and the 0.045-in. tube wall. The welds, although smooth and pleasing in appearance, were not of uniform quality, and many were structurally unsound. In attempting to obtain penetration to the point of tangency between tube and tube sheet, the welder sometimes burned through the tube sheet. Furthermore, with this joint design, the weld was in the area where high stress concentration was developed in service.

These shortcomings were overcome by changing to the improved joint design shown in Fig. 7(b). In this design, the thickness of the tube sheet was increased from 0.045 in. to 0.090 in., to provide more strength. The tube sheet was flared outward, making it possible for the welder to deposit a bead on the solid, exposed edges of the tube and tube sheet, and thereby to avoid burn-through. The improved joint resulted in welds being more uniform, and in weld repairs being reduced to a minimum. Conditions for manual gas tungsten-arc welding of the improved joint are given in the table with Fig. 7.

After welding, the joints were inspected visually for continuity, size and general quality. If required, the welds were liquid-penetrant inspected for cracks. Each welder was required to pass a qualification test as set forth in section IX of the ASME code on welding qualifications.

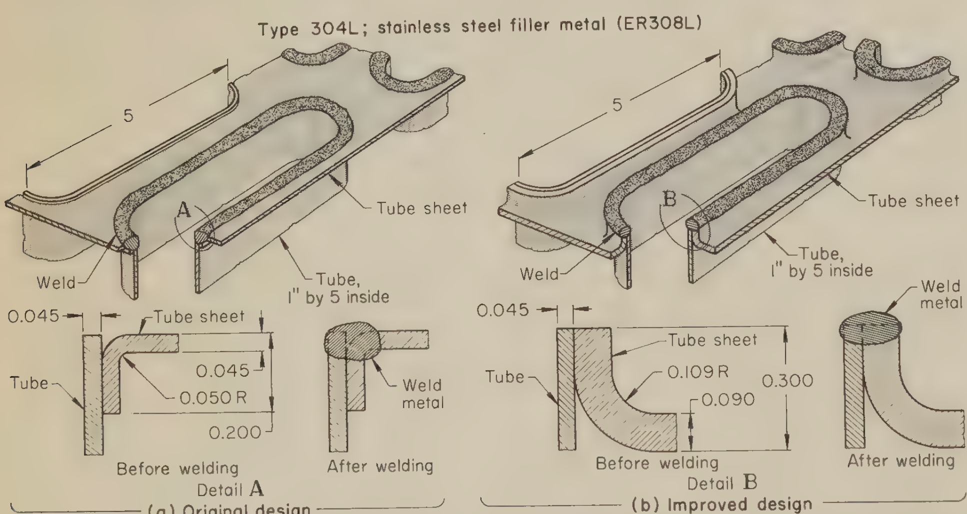
Heat exchangers were also fabricated from types 304, 316 and 316L, using the same basic welding procedures and appropriate filler metals.

Joint Design for Difficult-Access Welding. In addition to the more common problems of welding efficiency and structural soundness, joint design must occasionally cope with the problem of accessibility for welding. The following example demonstrates how this problem was solved in part by the use of a comparatively wide root opening in a butt joint through which access was obtained to weld another joint, and by subsequently welding the first joint with a consumable insert.

Example 247. Welding Inaccessible Butt Joints in an Aircraft Wing Assembly Through a 0.090-In. Root Opening in Opposing Butt Joints That Were Then Welded Using "Keyhole" Inserts (Fig. 8)

The view at upper left in Fig. 8 shows a portion of an aircraft wing assembly that consisted of a one-piece outboard spar and two brazed honeycomb panels, the inner and outer skins of which were butt welded to four projections on the spar. All components of the assembly were made of PH 15-7 Mo stainless steel.

Obtaining sound butt welds between the 0.040-in.-thick inner skins of the honeycomb panels and the corresponding projections on the spar presented a major welding problem, because of the inaccessibility of the joints. The problem was solved by designing the joints between the 0.050-in.-thick outer skins and spar projections with a root opening of 0.090 in., welding the



Welding Conditions for Improved Design

Process	Manual gas tungsten-arc welding
Joint type	Edge
Weld type	Corner flange
Fixtures	Fit-up and welding table
Preweld cleaning	Solvent; stainless wire brush
Power supply	300-amp, ac/dc with high frequency
Electrode holder	300 amp, water cooled
Electrode	3⁄32-in.-diam EWTh-2
Filler metal	3⁄32-in.-diam ER308L
Shielding gas	Argon, at 15 cfh
Welding position	Flat
Number of passes	One
Arc starting	High frequency
Current	80 to 100 amp, dcsp
Voltage	12 to 14 v
Welding speed	2 to 4 ipm (approx)

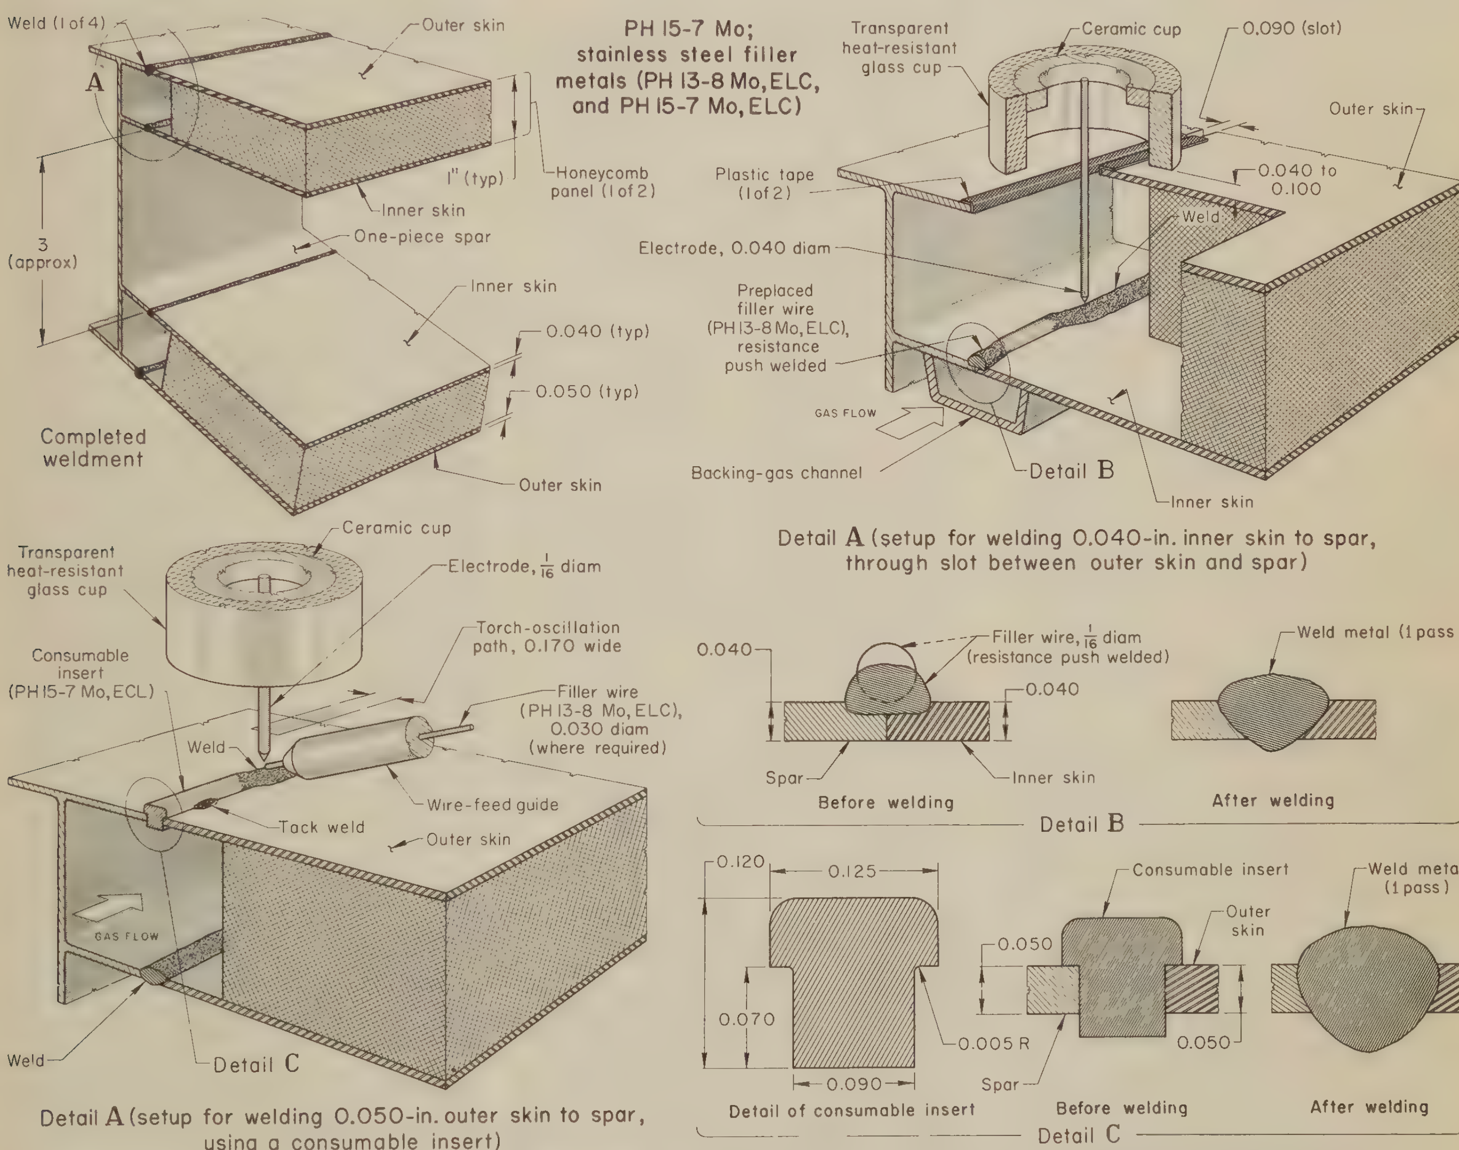
Fig. 7. Redesign of joint in a tube-to-tube-sheet weldment for a heat exchanger, which eliminated burn-through and resulted in stronger, more uniform welds (Example 246)

inner skins through this narrow (although wide for the base-metal thickness) slot, and then welding the outer-skin joints using "keyhole" consumable inserts. Despite the welding difficulties entailed, the design of the wing assembly was adopted because it minimized weight.

For welding each inner-skin joint, 1/16-in.-diam filler wire made of an extra-low-carbon PH 13-8 Mo stainless steel was preplaced along the centerline of the joint and resistance push (spot) welded at ¾-in. intervals to prevent it from being displaced during subsequent gas tungsten-arc welding (see "Before welding" in detail B in Fig. 8). Copper electrodes ¼ in. long and 0.070 in. in diameter were used for push welding, and the ground cable of the welding unit was attached to the spar.

Prior to automatic gas tungsten-arc welding of the inner-skin joint, plastic insulating tape was placed on the edges of the members separated by the 0.090-in. access slot, to prevent high-frequency arcing from the electrode to those edges. The joint was gas tungsten-arc welded using a 0.040-in.-diam thoriated tungsten electrode and welding-grade helium for shielding. The electrode holder was modified by bonding a transparent heat-resistant glass cup to the ceramic cup provided with the holder, to aid the operator in monitoring the position of the electrode with respect to the joint and the edges of the access slot. Argon was supplied to the underside of the weld through a backing channel. The welding setup is shown in detail A at upper right in Fig. 8. Welding conditions for the inner-skin joints are given in the table accompanying Fig. 8. After welding, the joint was radiographically inspected.

For welding the outer joint, a keyhole-section consumable insert formed from ⅛-in.-diam wire of an extra-low-carbon PH 15-7 Mo stainless steel was press fitted into



Welding condition	0.040-in. inner skin to spar	0.050-in. outer skin to spar

Current	26 to 30 amp, dcsp	65 to 70 amp, dcsp
Filler-metal feed rate	....	20 ipm
Torch oscillation	None	72 to 80 per min; 0.170-in. amplitude

(a) Wire was preplaced on the joint by resistance push welding. (b) Insert was press fitted into root opening of joint, and tack welded with ⅛-in. welds at ¾-in. intervals on alternate sides of joint. Filler wire supplied additional filler metal during welding. (c) High flow rate was needed to force adequate quantity of shielding gas through the 0.090-in.-wide slot.

Fig. 8. Aircraft-wing honeycomb-panel assembly in which joints between the one-piece spar and the inner and outer skins were welded by the two different methods shown (and detailed in the table), to overcome inaccessibility of the inner-skin joints (Example 247)

the 0.090-in. root opening (see detail C in Fig. 8). The insert was manual gas tungsten-arc tack welded with ⅛-in.-long welds placed alternately on each side at ¾-in. intervals. After the consumable insert had been tack welded, the joint was welded by the automatic gas tungsten-arc process, under the conditions in the table with Fig. 8, with argon shielding at the torch and argon backing supplied through the enclosure formed by the members. During welding, the torch was oscillated over a width of 0.170 in., and additional filler metal was added from the panel side. A typical setup used for welding is shown in detail A at lower left in Fig. 8.

The process was readily automated with the aid of high-precision welding equipment, including a welding head and wire-feed drive mounted on an air-driven or motor-driven carriage (not shown in Fig. 8) with provision for accurate torch positioning and torch oscillation, when required. The travel of the torch was precisely controlled by means of a drive wheel geared to a track held in position by vacuum-pumped cups.

Although the welding operations were difficult, defect-free welds were obtained when the proper welding procedures were carefully followed. In addition to maintaining fitup, two of the most important factors in achieving defect-free welds were proper joint cleaning prior to assembly and adequate shielding of the weld area by the inert gases during welding.

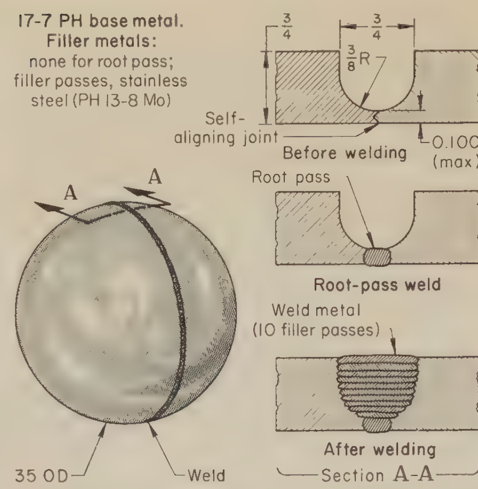
Joint Design for Alignment. When two components must be joined in accurate alignment, the use of fixtures to ensure alignment may not always be feasible or fully effective. In such applications, provision for proper alignment may be incorporated in the design of the weld joint, as illustrated by the next example.

Example 248. Self-Aligning Joint for Welded Hemispheres (Fig. 9)

Two hemispheres, 35-in. OD by ¾ in. thick, which were forged from 17-7 PH stainless steel, were welded by the automatic gas tungsten-arc process to produce a pressure vessel (Fig. 9) for containment of helium under high pressure. Selection of 17-7 PH stainless steel for the hemispheres was based on the resistance of the steel to corrosion and on the response of the steel to heat treatment after welding. To ensure self-alignment of the hemispheres and to avoid mismatch during welding, a specially designed joint containing a notch (Fig. 9, upper right) was used.

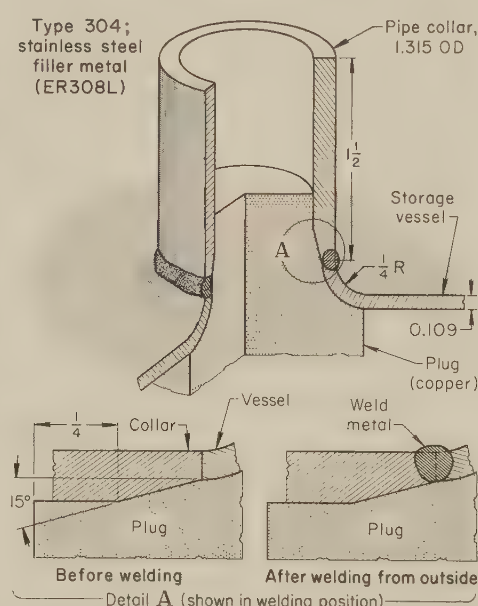
Equipment for welding included a special oscillating head with automatic arc-voltage control. The assembled hemispheres were rotated in a circumferential fixture mounted on turning rolls. Helium shielding was used at the arc, and free-flowing argon was fed to the interior of the sphere through a port (not shown in Fig. 9).

The root pass was made without the use of filler metal and without oscillation of the welding head. Ten subsequent passes were made with oscillation of the welding head, and with filler metal consisting of 0.045-in.-diam PH 13-8 Mo stainless steel wire continuously fed to the joint. The oscillating technique minimized the amount of interpass cleaning required, and also minimized the entrapment of inclusions.



Vessel was welded by the automatic gas tungsten-arc process, using an oscillating technique for the ten filler passes.

Fig. 9. Helium-storage vessel with a self-aligning joint (Example 248)



Welding Conditions for Outside of Joint(a)

Process	Manual gas tungsten-arc welding
Joint type	Circumferential butt
Weld type	Square groove
Fixture	Backing and alignment plug (copper)
Power supply	250-amp transformer-rectifier
Electrode holder	300 amp, water cooled
Electrode	$\frac{1}{16}$-in.-diam EWP(b)
Filler metal	$\frac{1}{16}$-in.-diam ER308L(c)
Shielding gas	Argon, at 15 cfh
Welding position	Horizontal-fixed pipe(d)
Number of passes	Two(a)
Arc starting	Scratch
Arc length	$\frac{1}{16}$ in.
Current	70 amp, dcsp
Voltage	14 v
Filler-metal feed rate	2.5 ipm
Welding speed	4 ipm

(a) After welding from the outside and removing the plug, an inside pass was made without filler metal, to ensure complete penetration. (b) Ground to a sharp point. (c) ER308L was used with type 304 base metal to minimize carbide precipitation. (d) Top half of weld was deposited, assembly was turned 180°, and weld was completed.

Butt-welded joint shown replaced a double-fillet-welded joint between unbeveled pipe collar and wall of an unflared hole in the top of the vessel, and consequently reduced welding and grinding time in addition to providing a radiused neck for easier cleaning.

Fig. 10. Setup and joint design for butt welding a pipe collar to a milk-storage vessel (Example 249)

Joint Design for Food-Processing Equipment. Stainless steel weldments are extensively used in the fabrication of equipment for food processing and for processing organic materials subject to microbial attack or deterioration through decomposition. In designing equipment of this type, emphasis is placed on the thoroughness with which it can be quickly cleaned and sterilized, and care is taken to ensure the absence of pits, sharp pockets or deep corners, where process materials can be entrapped. Smoothly polished, corrosion-resistant interiors with generously filleted corners and large transition radii are recommended, and are often prescribed by sanitary codes.

Manual gas tungsten-arc welding is frequently used for these weldments, because it provides good deposition control and clean welds, and varying contours can be followed with comparative ease. Wherever possible, butt welds are used in preference to fillet welds, because they are easier to grind and finish, and because they are less likely to have crevices that cannot be cleaned. Sometimes, a joint that would ordinarily be fillet welded can be changed to one employing a butt weld, with a resultant saving in cost, as in the following example.

Example 249. Change in Joint Design That Improved Weld Quality and Joint Function, and Reduced Cost (Fig. 10)

A type 304 stainless steel milk-storage vessel of 0.109-in. wall thickness required the attachment of a 1½-in. length of 1-in. schedule 80 (0.179-in. wall) type 304 stainless steel pipe, to serve as a collar for a measuring-stick opening.

Conventional installation of the collar comprised the following steps: (*a*) fitting the pipe in a hole in the flat top of the vessel, (*b*) tack welding the pipe in position, (*c*) depositing a fillet weld on the outer and inner edges of the joint, and (*d*) grinding and polishing the internal corners to the desired radius with a No. 4 finish. The fillet welds were deposited by manual gas tungsten-arc welding, using ER308L filler metal. The principal disadvantage of this procedure was the time and care required in grinding a smooth internal contour from the inside edge of the welded pipe. Too little grinding left undesirable rough spots; too much grinding removed the weld, necessitating repair welding and more grinding. In addition, weld shrinkage caused distortion of the thin wall of the vessel.

The difficulties were overcome by redesigning the joint as shown in Fig. 10. In the improved design, the opening at the top of the vessel was swaged to a flared neck with a flat top edge to which the pipe collar, now with a short length beveled on the inside to the 0.109-in. wall thickness of the vessel, was butt welded. Before welding, a solid copper plug, machined to fit the inside contour of the swaged neck and the beveled end of the collar, was inserted in the neck, and the beveled pipe was slipped onto the projecting plug for retention during welding. The joint was welded in a single pass by the manual gas tungsten-arc process, under the conditions given in the table with Fig. 10. After removal of the plug, the inside of the joint was given a fusion pass (no filler metal) to ensure complete penetration.

The improved joint design provided a smooth weld with a minimum of grinding, resulted in a reduction of welding and grinding costs, and avoided distortion of the relatively thin wall of the vessel. In addition, the radius of the swaged neck made the vessel easier to clean.

Cleaning and Preparation for Gas Tungsten-Arc Welding

In gas tungsten-arc welding of stainless steel, it is especially important that the weld area be clean and free of grease, oil, crayon markings and other foreign matter. Organic materials on the surface can break down in the heat of the arc and cause porosity or

carburization of the weld metal. Many inorganic contaminants, such as sulfur and sulfur compounds, are sources of corrosion and embrittlement.

Heavily soiled workpieces are usually cleaned by immersion in emulsion or solvent cleaners followed by vapor degreasing in a chlorinated solvent. During welding, fumes from chlorinated solvents break down in the heat of the arc and form a toxic gas. Therefore, when workpieces have been cleaned with such solvents, the welding area, as well as the cleaning area, must be properly ventilated to remove fumes and vapors. The cleaning and welding areas should be separated to ensure that fumes from the cleaning area do not reach the welding area.

Surface oxides are normally removed from stainless steel by acid pickling or, if present as a heavy scale, by mechanical cleaning operations such as wire brushing, grinding, and abrasive blasting. Wire brushing should be done with stainless steel brushes only, and these brushes should not be used on materials other than stainless steel. Similarly, grinding wheels and abrasives used on stainless steel should be used on these steels exclusively, to avoid contamination by inclusion of foreign materials.

One plant has reported the following methods to be most effective for cleaning and preparing stainless steel sheets prior to welding by the automatic gas tungsten-arc process:

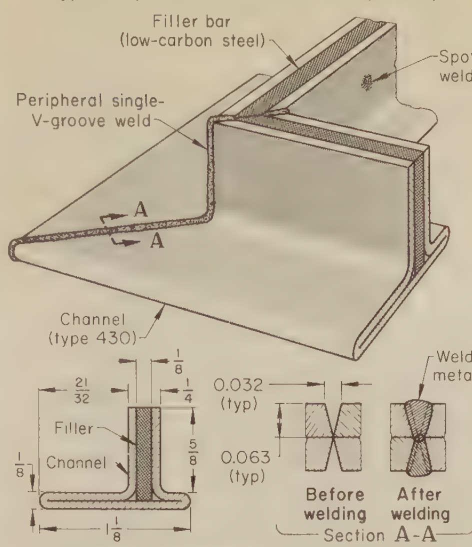
1 Sheets contaminated by grease or oil are degreased.
2 Edges to be joined are drawfiled to remove residues of dirt and grease smeared into the metal by shearing operations.
3 Sheets are sanded for a distance of ½ in. back from the edge of the joint to ensure removal of all surface oxides.
4 Loose residues from sanding and filing are removed by wiping the entire joint area several times with a cloth soaked in methyl ethyl ketone.
5 After the joint has been cleaned, extreme care is taken not to contaminate the joint area by touching it or dragging it across a dirty table. Operators are required to wear clean gloves.
6 Welding tools are wiped clean with a cloth soaked in methyl ethyl ketone.
7 When more than one hour elapses between the completion of cleaning and the beginning of welding, the joint area is wiped again with a cloth soaked in methyl ethyl ketone, immediately prior to welding.

Cleaning for Minimum Porosity. The relative cleanness of the weld area before welding will directly affect the amount of porosity that is found in the weld. Thus, when radiographic standards for allowable porosity are stringent, more than the usual amount of cleaning may be required to satisfy these standards, as described in the following example.

Example 250. Improvement in Cleaning Procedure That Reduced Porosity of Welds in PH 14-8 Mo Sheet to Radiographic Acceptability

A joint-cleaning procedure that was thought to be adequate proved otherwise when 50-in.-long butt joints between 0.052-in.-thick sheets of PH 14-8 Mo stainless steel were gas tungsten-arc welded. The sheets had been sheared to size, the joint edges and ½ in. of adjacent surfaces had been sanded, and the edges of the joint were detergent cleaned by wiping

Type 430; stainless steel filler metal (ER430)



Process	Manual gas tungsten-arc welding
Joint type	Butt and corner
Weld type	Peripheral single-V groove
Fixtures	Clamping jig and rotating positioner
Power supply	300-amp transformer-rectifier(a)
Electrode holder	200 amp, water cooled
Electrode	1/16-in.-diam EWTh-2
Filler metal	1/16-in.-diam ER430
Shielding gas	Argon, at 5 cfh
Welding position	Flat
Arc starting	Scratch
Current	31 amp, dcsp
Preheat and postheat	None

(a) With high frequency, upslope and downslope adjustment, and time delay for gas and water

Fig. 11. Corner of a door frame that was satisfactorily welded without preheat or postheat, because of rapid cooling provided by thinness of base metal and presence of a filler bar (Example 251)

with a cloth. After ten sheets had been welded, however, radiographic inspection showed that all welds contained pores larger than the maximum allowable size (0.008-in. diameter).

Close examination of the sheared edges of unwelded sheets showed that, despite the thinness of the sheets, shear-blade action had smeared over a portion of the edges. Oil and small particles of dirt that had not been removed by sanding and detergent cleaning were found lodged in tiny crevices. This condition was corrected by hand drawfiling the sheared edges prior to sanding and detergent cleaning. Three joints welded after the adoption of this improved method of edge preparation were well within the radiographic requirements for this application. To verify the results, sample welds were made between sheets that had been drawfiled and between sheets that had not. Radiographic inspection showed that only the welds joining the drawfiled sheets satisfied specification requirements. Of more than 100 production welds made using the revised joint-cleaning procedure, fewer than 5% were rejected because of porosity.

Preheating may be considered an essential step in the preparation of certain stainless steels for welding, notably the ferritic and martensitic alloys. The principal reason for preheating is to ensure that cracking does not occur in the weld or in the heat-affected zone. Recommendations for the preheating of ferritic and martensitic stainless steels are given in the two sections that begin on page 248 in this article, which deal specifically with the welding and metallurgical characteristics of these steels.

In the example that follows, preheating of a ferritic steel was not required, because of the thinness of the base metal (0.063 in.) and the rapid rate of cooling of the joint from the welding temperature.

Example 251. Welding Mitered Corners of Structural Frames Without Preheat or Postheat (Fig. 11)

Frames for glass doors were fabricated by joining the mitered corners of channel sections (Fig. 11) formed from type 430 stainless steel strip. Each channel section was reinforced with a ⅛-in.-thick low-carbon steel filler bar, which was spot welded to the inside of the channel.

The corners to be joined were mitered with a saw, and the edges were hand ground to a 1/64-in. bevel so that the abutting edges made a single-V groove 0.032 in. wide. Before welding, the edges of the joint were degreased with trichlorethylene. The frame sections were assembled in a clamping jig for proper alignment and mounted on a rotating positioner, and welded without preheat. Using manual gas tungsten-arc welding with argon shielding and ER430 filler metal, a continuous single-pass weld bead was deposited at the mitered joint under conditions listed in the table accompanying Fig. 11. To ensure that the continuous weld was deposited in the flat position, the positioner was capable of moving in both horizontal and vertical planes, as required. A frame was not removed from the positioner until welding was completed. At peak production, two positioners were used, permitting one assembly to cool in the positioner while a second assembly was being welded. After welding, the joints were cleaned on a belt sander to remove excess weld metal, and the inside and outside corners were trued by filing and grinding. The welded assembly was finally polished on a belt sander.

Although the channels were not preheated before welding, no cracks developed in either the weld metal or the heat-affected zone. The ability to deposit a relatively ductile and crack-free weld was attributed to the thinness (0.063 in.) of the channel and the mass of the filler bar — which caused rapid cooling of the joint from the welding temperature. Because of the extremely brief dwell time at the elevated temperature, grain coarsening and embrittlement were largely prevented. Consequently, postheating was not required, because the weld was both sufficiently ductile and corrosion resistant to satisfy the anticipated service conditions.

Automatic Gas Tungsten-Arc Welding

Gas tungsten-arc welding can be mechanized to assume some or all of the functions and controls performed by a welder. In general, the degree of mechanization is determined by the number of identical welds to be made, and by the speed and quality desired (see "Automatic Welding", which begins on page 133 in the article on Gas Tungsten Arc Welding).

Closure of Small-Diameter Tubes. Various types of stainless steel are used in the manufacture of small instrument components that embody a welded joint or closure. Accurate placement of small welds often demands machine-guided, rather than manual, welding, and a welding procedure that will not necessitate postweld cleaning and oxide removal is highly desirable. The gas tungsten-arc process is often selected when automatic welding is required, because it permits accurate, re-

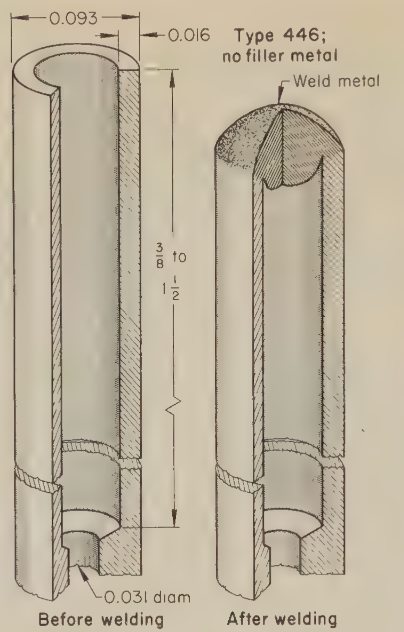
producible control of all welding conditions, together with a type of shielding that ensures a clean, oxide-free weld zone. When large quantities of delicate parts are required, high production rates can be obtained by employing suitable tooling, as described in the following example.

Example 252. Closing Ends of 1000 Temperature-Sensing Tubes per Hour by Automatic Welding Without Filler Metal (Fig. 12)

Figure 12 shows a 0.093-in.-OD type 446 stainless steel temperature-sensing tube that was bored at one end to increase the inside diameter from 0.031 to 0.061 in., for a depth of ⅜ to 1½ in. (depending on application). A leakproof seal at the bored end of the tube was obtained by automatic gas tungsten-arc welding without filler metal, under the conditions given in the table with Fig. 12.

Before being welded, the tubes were vapor degreased, and then freed from surface oxides by being heated at 1750 F in a conveyor furnace containing a hydrogen atmosphere. The tubes were then furnace cooled to room temperature and manually loaded into the ten holding chucks of a rotary indexing table. The chucks accurately positioned each tube under the electrode tip during welding.

The tubes were purged with argon immediately before welding, to prevent oxidation of the bore during welding. Preweld argon flow, weld time, and postweld argon flow were automatically controlled by a sequence timer. Using an arc time of 0.5 sec, the bored ends of the tubes were welded at the rate of 1000 per hour. After the tubes had cooled sufficiently (under argon), they were automatically ejected from the holding chucks. Quality control was maintained by visually inspecting the finished temperature-sensing tubes on a sampling basis. Rejection rate was less than 1%.



Automation	Rotary indexing table(a)
Power supply	200-amp transformer-rectifier
Electrode holder	Machine held, air cooled
Electrode	0.040-in.-diam EWTh-2(b)
Filler metal	None

Arc starting	High frequency
Arc length	0.030 in.
Current	60 amp, dcsp
Voltage	8 v
Weld time	0.5 sec
Production rate	1000 tubes per hour

(a) Equipped with ten workholding chucks, and automatic unloading mechanism; indexing speed, 3.6 sec per piece. (b) Ground to a pencil-point tip configuration. (c) Argon was also used for purging, immediately before welding.

Fig. 12. Temperature-sensing tube in which closure was produced at high speed by automatic gas tungsten-arc welding without filler metal (Example 252)

Welding of Sheet. Automatic gas tungsten-arc welding can be readily adapted to the welding of stainless steel sheet and products formed from sheet. It is widely used in the aircraft industry for this purpose because of its reliability and high joint efficiency. The following three examples illustrate joint designs and describe welding procedures used by a manufacturer of aircraft engines.

Examples 253 to 255. Production of Aircraft-Quality Butt Welds by Automatic Welding of Stainless Steel Sheet (Fig. 13)

Example 253. The joint design and workholding setup for butt welding two sheets of type 316 stainless steel sheet of slightly different thicknesses (0.093 and 0.095 in.) in a single pass are shown in the top view in Fig. 13. The 0.095-in.-thick sheet had been formed to the shape of a tank head, and the butt joint was circumferential. As shown in Fig. 13, the joint was of 90° single-V-groove design, with a 0.030-in. root face. The sheets were held down by steel hold-down bars and clamped by a steel hydraulic expander. During welding, argon was fed through a backing groove in a copper insert in the expander, and to a trailer shield (not shown in Fig. 13), designed to protect the weld zone from oxidation during cooling. Helium was fed to the torch to provide a hotter arc. Other welding conditions are listed in the table with Fig. 13.

Example 254. In this application, a linear, square-groove butt joint, between two 0.034-in.-thick type 321 stainless steel sheets, was welded in one pass, using ER347 filler metal. The welding setup, which included two nickel-plated copper hold-down bars, a nickel-plated copper chill bar with a backing groove, and a steel clamping fixture, is shown in the middle view in Fig. 13. Argon was used for shielding at the torch and for backing, and in a trailer shield (not shown in Fig. 13). Welding speed was only 5 in. per minute, but this low speed was justified by the high quality of the welds in an application in which welding speed was not a major criterion. Additional welding conditions are given in the table that accompanies Fig. 13.

Example 255. This application entailed welding in one pass of a square-groove butt joint between two 0.050-in.-thick type 347 stainless steel sheets, using ER347 filler metal. The welding setup, shown in the bottom view in Fig. 13, was nearly identical to that used in Example 254. As shown in the table accompanying Fig. 13, welding speed was only 4.5 in. per minute.

Gas Tungsten-Arc Spot Welding

Gas tungsten-arc spot welding is well suited to the welding of austenitic stainless steel, particularly in thicknesses of 0.020 to 0.090 in. Manual equipment and completely mechanized equipment are available. The essential components are a torch (usually equipped with a vented nozzle), a power supply, a tungsten electrode, a trigger switch, and a timing unit. In operation, the torch is placed against the work, the trigger is depressed, and a spot weld is made in a predetermined time. Ordinarily, filler metal is not used. Straight-polarity direct current is most commonly used.

Arc Starting. Because the electrode is usually recessed, and because arc length must be closely controlled, starting of the arc may pose a problem. Manual scratch starting is never used. The methods that are used are high-frequency starting, retract starting, and pilot-arc starting.

High-frequency starting is the method most commonly used, although it is unreliable below about 30 amp.

Retract starting consists in advancing the electrode to the work and then retracting it to establish an arc.

Pilot-arc starting makes use of a low-intensity arc to establish a high-intensity arc. The low-intensity arc is maintained from the tungsten electrode to an auxiliary electrode, usually the nozzle. It ionizes the shielding gas, thus facilitating arc starting.

Advantages Over Resistance Spot Welding. The main advantage of gas tungsten-arc spot welding over resistance spot welding is that welds can be made when only one side of the workpiece is accessible, whereas resistance welding necessitates access to both sides of the work. In addition, the thickness ratio of the pieces being joined is less important in gas tungsten-arc spot welding than in resistance spot welding. No special cleaning is necessary to obtain arc spot welds of good quality. On equal cross sections, shear strengths are equivalent to those obtained with resistance spot welds. The capital outlay required for gas tungsten-arc spot welding equipment is considerably less than that required for resistance spot welding equipment. This is particularly advantageous when short production runs are contemplated.

Gas Tungsten-Arc Welding of Tubing

Because of the wide variety of industrial and engineering uses of stainless steel tubing, tube welding has widespread application both in the manufacture of tubes and in the assembly of tubular components. Manual and automatic gas tungsten-arc processes are well suited to the welding of stainless steel tubing, especially when tube wall thickness does not exceed about ¼ in.

For wall thicknesses greater than ¼ in., gas tungsten-arc welding may be used to make the root pass and one or two subsequent passes; but, to reduce cost, the bulk of the weld metal is more likely to be deposited using a process that has a higher deposition rate, such as gas metal-arc welding.

Circumferential Welding. Several stainless steels, including types 304L, 321, 347 and AM-350, are widely used in high-reliability hydraulic systems, such as those installed in aircraft. Choice of tube fittings and connections for these systems is often difficult because of the exacting requirements imposed. Mechanical threaded connections have limited ability to seal and to maintain maximum reliability consistently. Welded joints may be unsatisfactory or incapable of meeting all requirements, depending on joint design and welding procedure. One specification requires that the weld penetration be 100%, that the strength of the weld at the

service temperature be equal to that of the tubing, and that the weld be capable of meeting all performance requirements, including repeated flexure at 35,000-psi stress levels.

Five designs of welded tube fittings for hydraulic systems are shown in Fig. 14. The straight butt weld (Fig. 14a) is seldom used for thin-wall hydraulic tubing, because fixturing is generally needed for control of alignment and because the tubing is unsupported in the annealed heat-affected zones adjacent to the weld. The "wedding band" design (Fig. 14b) constitutes a slight improvement over the butt weld; the band is completely fused during welding, but the heat-affected zones still are unsupported.

The two designs most widely used are the sleeve butt weld (Fig. 14c) and the sleeve double weld (Fig. 14d). In these designs, a loose tubular sleeve supports the ends of the tubes and also serves to provide weld metal. Either a single or a double weld can be used to complete the joint. With a single weld (Fig. 14c), the tube ends are butted together inside the sleeve (a root opening of 0.030 in. max can be tolerated), and the weld penetrates both the sleeve and tube to fuse the butt joint. Because the sleeve covers the butt joint, it is not possible visually to ensure that the weld will be deposited precisely over the butted ends; accordingly, reliance must be placed on the use of appropriate guide markings or of gaging fixtures.

The use of a double weld on a tubular sleeve fitting (Fig. 14d), or of an expanded-tube lap weld (Fig. 14e), eliminates the need to butt the tube ends and makes location of the weld less critical. Nevertheless, it is still necessary to ensure that each weld joins the sleeve to the tube and that neither weld is made at the extreme end of a tube. These two designs place the weld in shear, and it is essential that the width of the weld be carefully controlled. Radiographic or ultrasonic inspection of the double-weld design (Fig. 14d) is difficult because of interference of the welds and tube ends.

The tubular sleeve designs, with either a single or a double weld, and the expanded-tube design support the tube in the heat-affected zones to the extent that the ultimate burst-pressure capability of the joint exceeds that of the system tubing. However, because of clearances, neither the tubular sleeve nor the expanded-tube design provides a snug fit to withstand vibration or flexing. Calculations indicate that the deflection required to take up the clearance exceeds the flex-endurance limit of the tube material.

This weakness can be largely overcome by swaging tubing and sleeve together. Other advantages of the swaged-on fitting over the loose-sleeve design are: (*a*) no clearance between sleeve and tube to entrap contaminants or corrodents, (*b*) no entrapment of air between sleeve and tube to cause contamination during welding, and (*c*) no need to purchase controlled-tolerance tubing or to size the ends of tubes before welding. A patented modification of the swaged-on design is discussed in the next example.

Example 256. Swaged-Sleeve Joint for On-Site Automatic Welding of Tubes for Aircraft Hydraulic Systems (Fig. 15)

Swaged-on 17-4 PH stainless steel sleeves with a mortise-and-tenon design, as shown in Fig. 15, were used in joining AM-350 stainless steel tubes for use in aircraft hydraulic systems. Swaging was performed on bench-type fixtures (to ensure precise positioning for swaging) before the tubes were installed in the aircraft. After swaging, the tube sections were installed in place and the mating ends positioned for welding; the interfitting axial projections on the sleeves provided exact radial location of the two ends to be joined. The assembly was then welded by the automatic gas tungsten-arc process without the use of filler metal. After welding, the coupling was a unitary structure, with the welded sleeve supporting the tube on both sides of the weld. The resulting joint provided the required resistance to vibration and flexing.

(a) For all three welds, joint preparation consisted of either machining or drawfiling the joint edge, followed by cleaning with silicon carbide abrasive and wiping with a solvent. (b) Water-cooled type. (c) Size given is diameter. (d) Power supply for all three welds was a 300-amp transformer-rectifier.

Fig. 13. Cross sections of three sheet-to-sheet butt joints, showing holding setups for single-pass automatic gas tungsten-arc welding to aircraft quality, under conditions given in table (Examples 253 to 255)

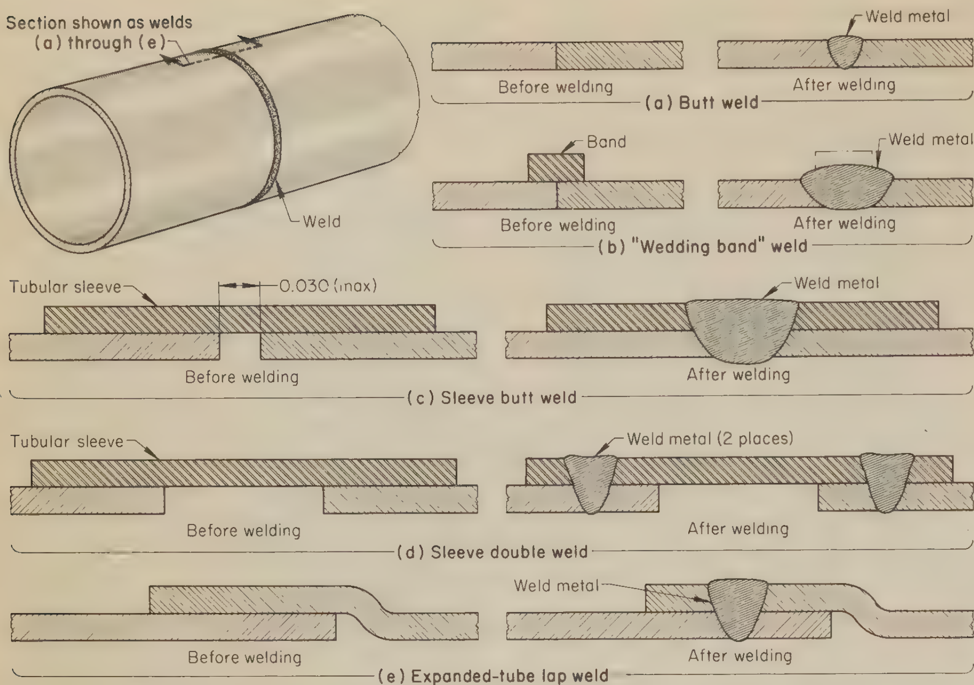

Fig. 14. Five designs of welded tube fittings for aircraft hydraulic systems

Equipment for welding consisted of a self-propelled orbital welding head with a split-ring clamping device designed to fit tightly over the sleeves, and a segmented gear (driven by a high-torque motor) from which the electrode was suspended; the gear served to rotate the electrode around the coupling joint. The orbital welding head was also equipped to supply shielding gas around the joint during welding. The power supply, a 300-amp transformer-rectifier, had built-in sequence controls for complete programing of the welding cycle.

Before welding, the inside of the tube was purged with argon, and a flow of argon was also maintained for backing. The welding head was clamped in position around the sleeve, the programer was set, and welding started. The programer automatically controlled the entire welding operation, including argon preflow, arc initiation (by high frequency), welding speed, current control, and arc termination. Welding conditions are given in the table accompanying Fig. 15.

Complete joint penetration was achieved, and the welds were easily subjected to radiographic and ultrasonic examination. Mechanical tests showed that the swaged-sleeve design outperformed other types of tubular sleeve design in resistance to high pressure and severe vibration.

Longitudinal Welding. The automatic gas tungsten-arc process is used for making longitudinal seam welds in structural tubing formed from thin stainless steel sheet. Welding can be done with or without filler metal. To obtain a high production rate, as in the application described in the following example, requires accurate forming of the tube section, close tolerances on fixturing and torch travel, and an efficient heat sink.

Example 257. High-Speed Seam Welding of Tubular Furniture Legs (Fig. 16)

Rectangular tubes, 6¹⁄₃₂ in. long, were formed from 0.024-in.-thick type 430 stainless steel sheet and seam welded for use as furniture legs (Fig. 16). To obtain high production rates, an automatic welding procedure, using the gas tungsten-arc process, was developed to weld the seam in a single pass without filler metal, at a speed of 60 in. per minute.

The operating sequence consisted in manually slipping the preformed tube over a copper backing die, clamping the tube in position, initiating the welding sequence, and, after welding, ejecting the part from the backing die automatically. Precise mechanical alignment throughout the welding operation was essential to ensure that maximum deviation of the arc from the seam did not exceed ±0.010 in. Forming of the tube also required a high degree of precision, because the fixture used during welding was designed only to hold the part, not to help form it.

The copper backing die served as a heat sink and as a support for fixturing; it was also provided with starting and ending tabs to avoid unstable arc initiation and decay. When the preformed leg had been properly positioned on the backing, a clamping fixture tightened automatically to hold the seam in close alignment.

A sequence timer incorporated with the power supply was preset for argon preflow, current-upslope control, and torch travel. The welding sequence was initiated by pushbutton, and by the time the electrode had traversed the starting tab, arc stability was established. Welding was done in the flat position. At the end of the welding cycle, a limit switch tripped the circuit, ending the operation with sequential current downslope, argon postflow, and travel stop. Argon backing was not used, because the appearance of the inside surface of the weld was not important to the application. Because type 430 steel is ferromagnetic, the nozzle of the electrode holder was equipped with a magnetic ring to prevent arc blow. Welding conditions for the application are given in the table accompanying Fig. 16. Approximately 100 of the tubular furniture legs were welded per hour.

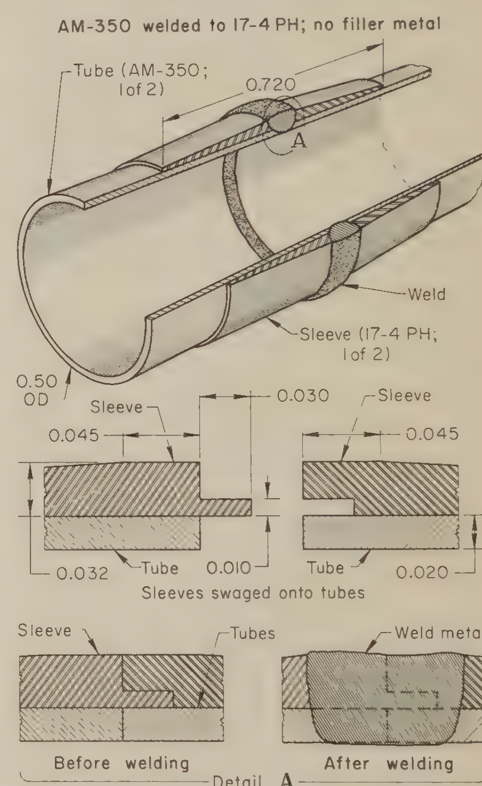
Welding of Tubes to Tube Sheet. Gas tungsten-arc welding is used in joining many types of assemblies that embody stainless steel tubular components. A typical application is the joining of tubes to tube sheets used in high-pressure heat exchangers. Various joint designs and weld configurations, and manual and automatic procedures for producing these critical welds, have been developed. (See Example 246, page 256, which describes an application in which redesign of the joint between tube and tube sheet resulted in improved weld quality and strength.)

Much of this type of assembly welding is done manually, especially on small installations, although automatic equipment has been developed for high production. Manual welding requires accurate control over torch movement, because the tubes used for these weldments have thin walls and usually are of small diameter.

The simplest joint design consists of a tube inserted in a straight drilled and reamed tube hole having no special weld-groove preparation and requiring no filler-metal addition, as described in the following example.

Example 258. Manual Seal Welding of Tubes to Tube Sheet, Without Filler Metal (Fig. 17)

Heat exchangers for use with corrosive gases contained 110 tubes (¾-in. OD, 0.049-in. wall) that were seal welded in a 1⅛-in.-thick tube sheet, as shown in Fig. 17. The tubes and tube sheet were made of



Process	Automatic gas tungsten-arc welding

(Example 256)

type 316L stainless steel and were designed for a maximum working tube pressure of 300 psi at 800 F. The tube-to-tube-sheet joints were welded by the manual gas tungsten-arc process in accordance with the requirements of the ASME code for unfired pressure vessels.

Before welding, the tubes and tube sheet were deburred and cleaned with carbon tetrachloride, using suitable precautions. No special edge preparation was required. The tubes were inserted in the 0.757-in.-diam holes in the tube sheet so that the ends of the tubes were flush with the tube-sheet face. The tubes were lightly expanded for a depth of 1 in. to hold them in place (see Fig. 17), and each was welded in a single pass without filler metal. Welding conditions for the operation are given in the table with Fig. 17.

After welding, tubes were re-expanded for a distance of ¾ in., starting ¼ in. below the welded joint. After assembly in the heat-exchanger shell, the tube bundle was subjected to a 600-psi hydrostatic test. Rejections because of tube-weld leakage averaged less than 0.01%.

Gas Tungsten-Arc Welding of Thin Sections

The welding of thin sections of stainless steel requires the use of low arc currents. The gas tungsten-arc process, widely used for joining thin sections, is generally satisfactory for welding at currents down to about 10 amp. Below this level, considerably more skill is required when welding manually, because a small change in torch standoff and arc length produces a change in arc voltage and results in a fairly large change in current. Therefore, to prevent significant fluctuation in arc current, automatic welding may be mandatory.

The welding of stainless steel in foil thicknesses can be simplified by converting a butt joint into some type of edge joint. Such a joint is easier to weld because it permits the widest latitude in fixturing tolerance and in welding conditions. The following example describes the application of automatic gas tungsten-arc welding to produce a leakproof joint between a diaphragm and backplate fitted to close dimensional tolerances.

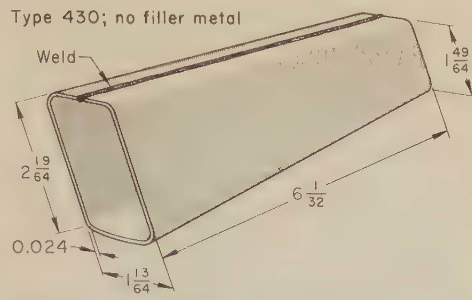
Example 259. Automatic Welding of a 0.002-In.-Thick 17-7 PH Diaphragm to a Type 316L Backplate, To Produce Leakproof Joints (Fig. 18)

The 0.7500-in.-diam diaphragm-and-backplate weldment shown in Fig. 18 was part of a pressure-control system used in ammonia refrigeration. Specifications required the joint between the edge of the 0.002-in.-thick diaphragm (17-7 PH) and the 0.010-in.-thick peripheral lip of the backplate (type 316L) to be leakproof at an air pressure of 650 psi under water. Attempts to join the components by epoxy bonding with a pressure ring and by brazing with silver alloy filler metal resulted in high rejection rates because of leakage; a successful joining procedure was developed, using automatic gas tungsten-arc welding under the conditions given in the table with Fig. 18.

The success of this procedure depended on matching the joint edges of the diaphragm and backplate within a tolerance of ±0.0002 in. on the diameter after assembly (see "Before welding" in detail A in Fig. 18). This was accomplished by carefully machining the baseplate and by forming the diaphragm in a die to close dimensional tolerances. The assembled components, with joint faces precisely aligned, were clamped between special holding fixtures attached to the headstock and tailstock of a small bench lathe. Accurate alignment of the parts was ensured during welding, to avoid arc deflection, and care was taken to prevent fluctuations in the power supply.

The welded assemblies were installed on the pressure-control system and tested for leakage at an air pressure of 650 psi, and a final halogen leak test was performed on a sampling basis, using a mixture of Freon and air at a pressure of 300 psi and a halogen leak-detector probe.

Thin-wall flexible stainless steel hose designed for pressure service must be equipped with reliable joints attaching nozzles or pipes. Depending on the severity of service, brazed joints and even mechanical joints may prove satisfactory, but in more critical applications, where the strength and corrosion resistance of the joint must be equivalent to those of the stainless steel hose, welded joints are usually more reliable. Control of heat input in welding the thin walls of the flexible hose is often difficult. In the welding of type 321 flexible hose to low-carbon steel pipe described in the next example, heat control was achieved by skillful use of manual gas tungsten-arc welding.



Process	Automatic gas tungsten-arc welding

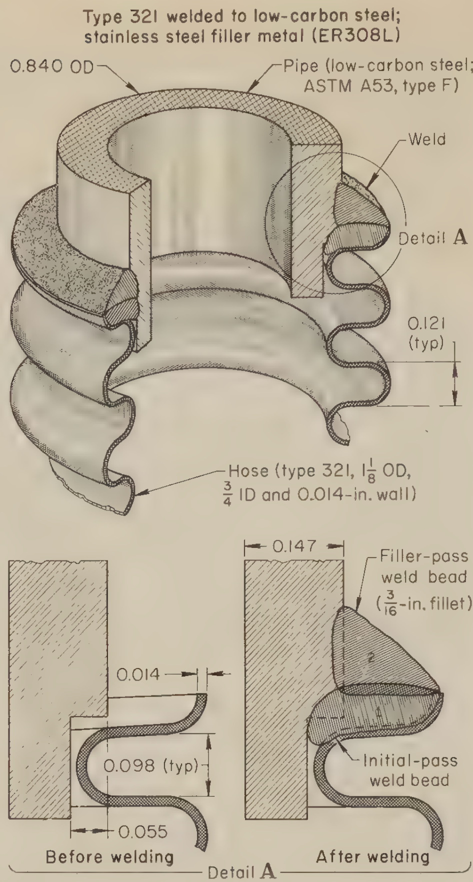
Example 260. Welding 0.014-In.-Wall Type 321 Flexible Hose to Low-Carbon Steel Pipe (Fig. 19)

The 0.014-in.-wall type 321 stainless steel flexible hose shown in Fig. 19 was used to carry ammonia coolant through oil filter-coolers for refrigerant compressors. The helically convoluted hose was bent in the shape of a coil, approximately 65 in. long, and the two ends of the hose were joined to recessed ends of ½-in. schedule 80 (0.840-in. OD) low-carbon steel (ASTM A53, type F) pipes at inlet and outlet terminals. The joints were designed to withstand a pressure of 150 psig in the temperature range of −20 to 200 F and were required to conform to the requirements of the ASME code for unfired pressure vessels.

In developing a welding procedure for the hose-and-pipe joints, silver brazing was tried initially, but was rejected because the ammonia reacted with the brazing filler metal; moreover, the strength of the joint was too low. Oxyacetylene welding, using a nickel filler metal, produced acceptable joints, but the filler metal was expensive and difficult to obtain, and the process resulted in excessive heating of the thin hose wall. Best results were obtained by manual gas tungsten-arc welding with ER308L filler metal, using a special technique to avoid burn-through.

Before welding, the ends of the hose and pipe were cleaned with emery cloth or stainless steel wool. The hose was cut and fitted to the end of the pipe as shown at lower left in Fig. 19, and the assembly was clamped together. To avoid burn-through of the thin hose wall, the joint was welded in two passes — an initial pass and a filler pass (for fillet-weld reinforcement). In the first pass, which was made at a low amperage (see table with Fig. 19 for welding conditions), weld metal was deposited on the flare of the hose wall and partly filled the groove between the hose and pipe (see view at lower right in Fig. 19). The second pass was made at a higher amperage to penetrate the first bead slightly, with the arc directed into the low-carbon steel pipe, to avoid excessive heating of the tube.

After welding, the joints were wire brushed to remove scale, and were pressure tested under water using nitrogen at 225 psig. About 95% of the joints were leakproof in the pressure test.



Process	Manual gas tungsten-arc welding
Joint type	Lap
Weld type	Groove and fillet
Power supply	300-amp transformer-rectifier
Electrode holder	130 amp, air cooled
Electrode	1/16-in.-diam EWTh-2

Weld time	3 min per pass (approx)
Production rate (avg)	10 joints per hour

Fig. 19. Assembly of a thin-wall type 321 flexible hose and low-carbon steel pipe that was welded in a special two-pass sequence to avoid burn-through (Example 260)

Thin-Skin Missile Bodies. Some of the tubular body segments used in missile applications are made of stainless steel sheet that is only 0.028 in. thick; these cylindrical segments require both longitudinal and circumferential welds for assembly. Weld-quality requirements are unusually high and dimensional tolerances are stringent; this necessitates special care in shearing, cleaning, fit-up and welding, as described in the following example.

Example 261. Welding of Segments of Thin-Skin Missile Bodies (Fig. 20)

Cylindrical missile bodies were assembled by joining prefabricated segments of varying length. Each segment consisted of an outer skin, made up of longitudinally welded cylinders, and internal support frames, which were joined to abutting cylinders by circumferential welds that also joined the cylinders. A typical segment, 40 in. long, is shown at upper left in Fig. 20.

The outer-skin cylinders were roll formed from 0.028-in.-thick type 301 stainless steel blanks, sheared accurately to a width of 28.236 in. +0.002, −0.000 in.; length was also closely controlled.
